Appendix A. Data Figures: Neurodevelopmental or Cognitive Effects and Outcomes

Figures

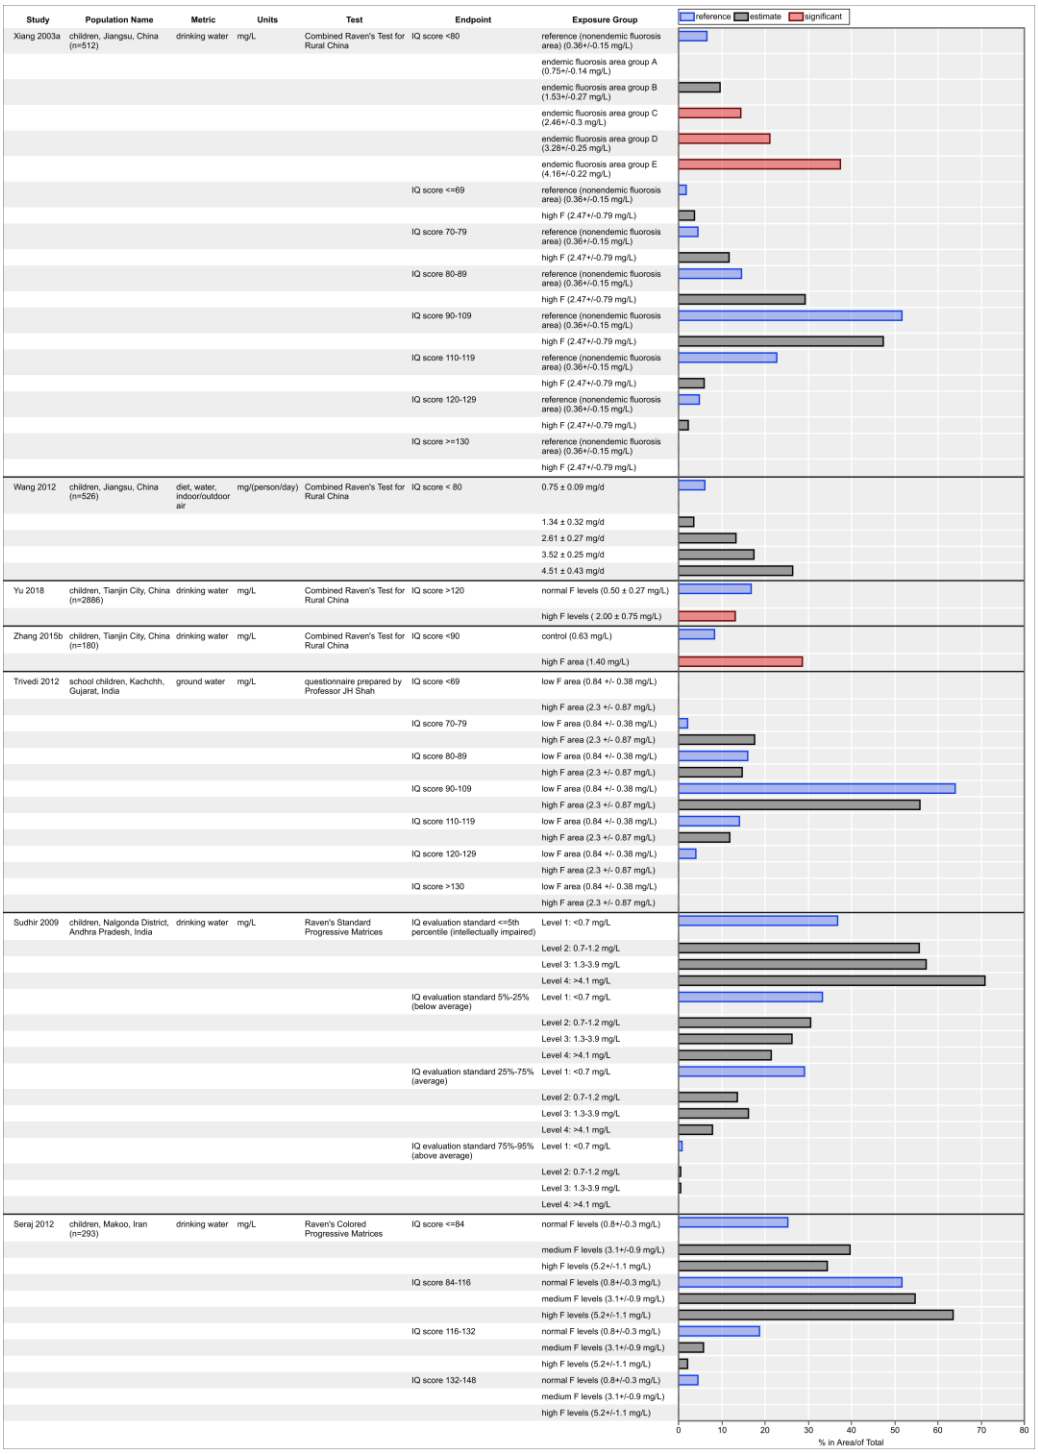

Figure A-1. Distribution of IQ in Children by Fluoride Exposure (Low Risk-of-bias Studies; Presented as % in Area or % of Total Group)

Reference group indicated by blue bars; other bars represent response estimates with red indicating statistical significance compared with the reference group.
An interactive version of Figure A-1 and additional study details in HAWC here. "F" represents fluoride. For IQ distribution results by drinking water fluoride level provided in Xiang et al. (2003a), Trivedi et al. (2012), Sudhir et al. (2009), and Seraj et al. (2012) and rate of low IQ scores by fluoride intake provided in Wang et al. (2012), statistical significance was not evaluated.

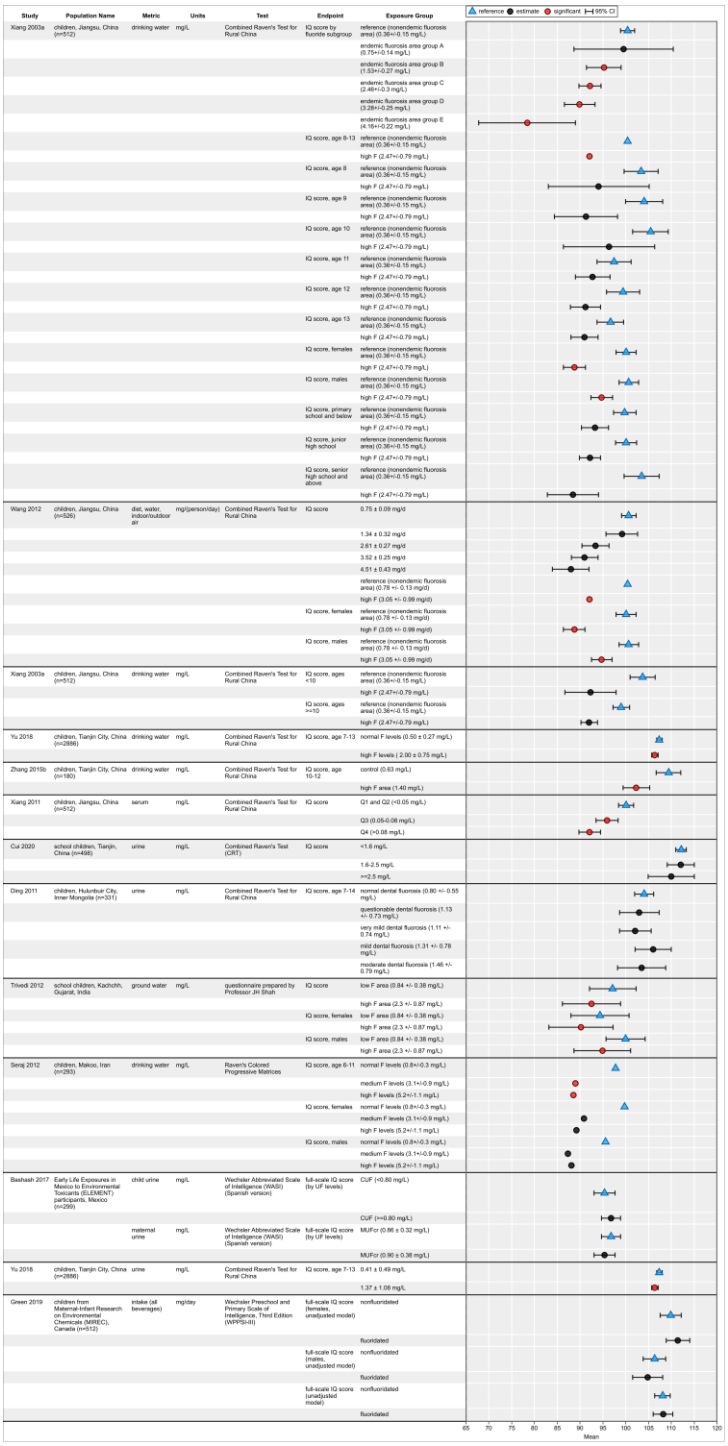

Figure A-2. Mean IQ in Children by Fluoride Exposure (Low Risk-of-bias Studies)

Reference group indicated by blue triangles; circles represent response estimates with red indicating statistical significance. An interactive version of Figure A-2 and additional study details in HAWC here. "F" represents fluoride. Three additional publications based on subsample of the larger Yu et al. (2018) cohort were identified (Zhao et al. 2019; Zhao et al. 2020; Zhou et al. 2019); however, results from these studies are not presented here. The main study by Yu et al. (2018) is considered a better representation of the IQ results. For all studies, SDs are available and can be viewed in HAWC by clicking the data points within the plot area; however, 95% CIs could not be calculated for Seraj et al. (2012) because Ns are not available for exposure groups.

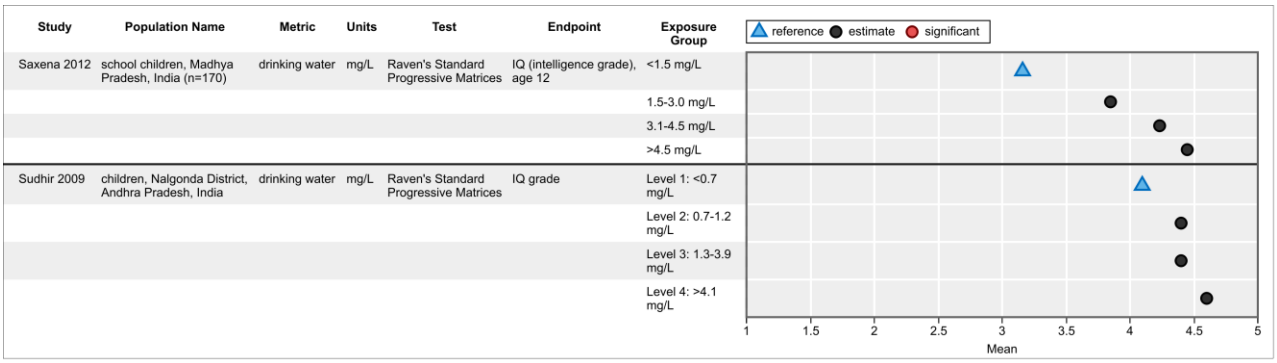

Figure A-3. Intelligence Grade in Children by Fluoride Exposure (Low Risk-of-bias Studies; Presented as Mean)

Reference group indicated by blue triangles; circles represent response estimates with red indicating statistical significance. An interactive version of Figure A-3 and additional study details in HAWC here. For Saxena et al. (2012), children's intelligence was measured using Raven's Standard Progressive Matrices. Children's scores were converted to percentile, and specific grades were allotted based on the percentiles. Grades ranged from intellectually superior (Grade I) to intellectually impaired (Grade V). Results for Soto-Barreras et al. (2019) are not presented here. Outcomes in the study were presented as levels of fluoride exposure associated with each intelligence grade. Results reported were not significant.

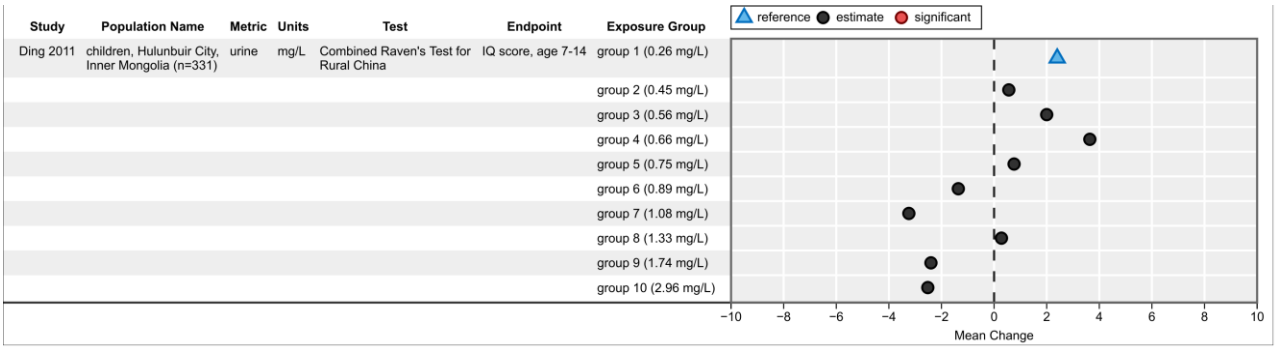

Figure A-4. Mean Change in IQ in Children by Fluoride Exposure (Low Risk-of-bias Studies)

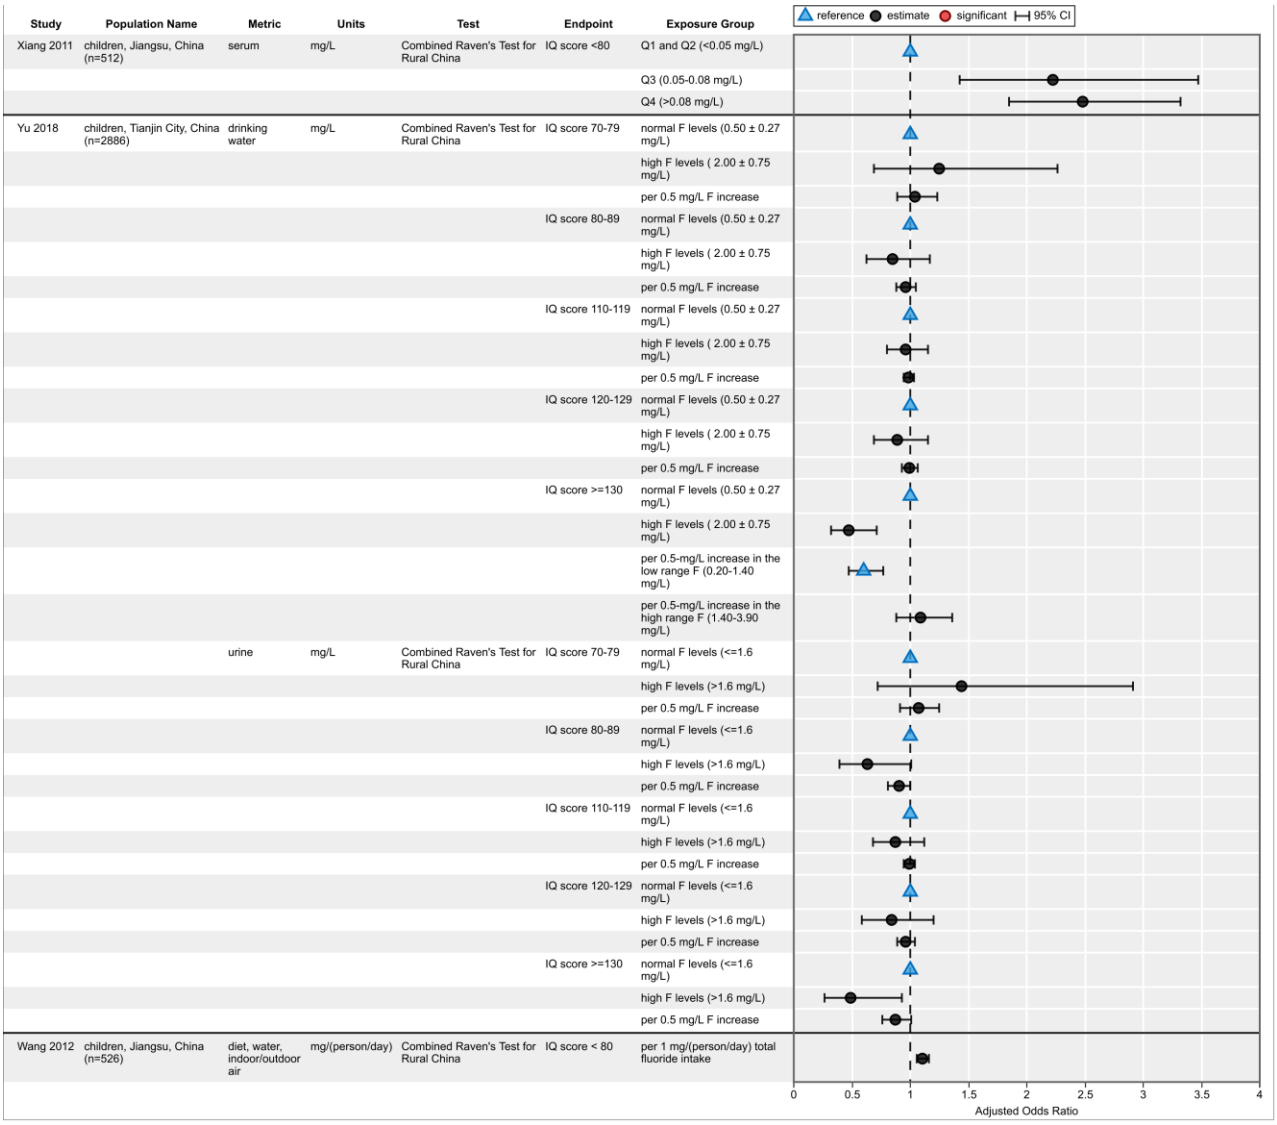
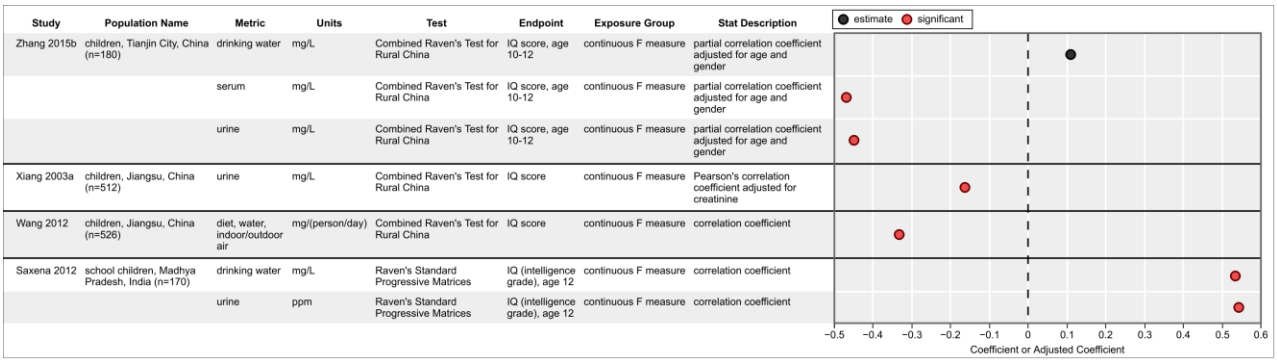
Reference group indicated by blue triangles; circles represent response estimates with red indicating statistical significance. An interactive version of Figure A-4 and additional study details in HAWC here. For Ding et al. (2011), SDs are available and can be viewed in HAWC by clicking the data points within the plot area; however, 95% CIs could not be calculated because Ns for each exposure group are not available.



Study	Population Name	Metric	Units	Test	Endpoint	Exposure Group
Xiang 2011	children, Jiangsu, China (n=512)	serum	mg/L	Combined Raven's Test for Rural China	IQ score <80	Q1 and Q2 (<0.05 mg/L)
						Q3 (0.05-0.08 mg/L)
						Q4 (>0.08 mg/L)
Yu 2018	children, Tianjin City, China (n=2886)	drinking water	mg/L	Combined Raven's Test for Rural China	IQ score 70-79	normal F levels (0.50 ± 0.27 mg/L)
						high F levels (2.00 ± 0.75 mg/L)
						per 0.5 mg/L F increase
					IQ score 80-89	normal F levels (0.50 ± 0.27 mg/L)
						high F levels (2.00 ± 0.75 mg/L)
						per 0.5 mg/L F increase
					IQ score 110-119	normal F levels (0.50 ± 0.27 mg/L)
						high F levels (2.00 ± 0.75 mg/L)
						per 0.5 mg/L F increase
					IQ score 120-129	normal F levels (0.50 ± 0.27 mg/L)
						high F levels (2.00 ± 0.75 mg/L)
						per 0.5 mg/L F increase
					IQ score >=130	normal F levels (0.50 ± 0.27 mg/L)
						high F levels (2.00 ± 0.75 mg/L)
						per 0.5-mg/L increase in the low range F (0.20-1.40 mg/L)
						per 0.5-mg/L increase in the high range F (1.40-3.90 mg/L)
		urine	mg/L	Combined Raven's Test for Rural China	IQ score 70-79	normal F levels (<=1.6 mg/L)
						high F levels (>1.6 mg/L)
						per 0.5 mg/L F increase
					IQ score 80-89	normal F levels (<=1.6 mg/L)
						high F levels (>1.6 mg/L)
						per 0.5 mg/L F increase
					IQ score 110-119	normal F levels (<=1.6 mg/L)
						high F levels (>1.6 mg/L)
						per 0.5 mg/L F increase
					IQ score 120-129	normal F levels (<=1.6 mg/L)
						high F levels (>1.6 mg/L)
						per 0.5 mg/L F increase
					IQ score >=130	normal F levels (<=1.6 mg/L)
						high F levels (>1.6 mg/L)
						per 0.5 mg/L F increase
Wang 2012	children, Jiangsu, China (n=526)	diet, water, indoor/outdoor air	mg/(person/day)	Combined Raven's Test for Rural China	IQ score < 80	per 1 mg/(person/day) total fluoride intake

Figure A-5. Associations between Fluoride Exposure and IQ Scores in Children (Low Risk-of-bias Studies; Presented as Adjusted OR)

Reference group indicated by blue triangles; circles represent response estimates with red indicating statistical significance. Cutoffs for the dichotomous outcome are listed in the Endpoint column.
An interactive version of Figure A-5 and additional study details in HAWC here. For Xiang et al. (2011), there was a significant linear trend across different levels of serum fluoride for IQ score <80 ($p < 0.001$). For Yu et al. (2018), significance levels by IQ score were not reported.



Study	Population Name	Metric	Units	Test	Endpoint	Exposure Group	Stat Description
Zhang 2015b	children, Tianjin City, China (n=180)	drinking water	mg/L	Combined Raven's Test for Rural China	IQ score, age 10-12	continuous F measure	partial correlation coefficient adjusted for age and gender
		serum	mg/L	Combined Raven's Test for Rural China	IQ score, age 10-12	continuous F measure	partial correlation coefficient adjusted for age and gender
		urine	mg/L	Combined Raven's Test for Rural China	IQ score, age 10-12	continuous F measure	partial correlation coefficient adjusted for age and gender
Xiang 2003a	children, Jiangsu, China (n=512)	urine	mg/L	Combined Raven's Test for Rural China	IQ score	continuous F measure	Pearson's correlation coefficient adjusted for creatinine
Wang 2012	children, Jiangsu, China (n=526)	diet, water, indoor/outdoor air	mg/(person/day)	Combined Raven's Test for Rural China	IQ score	continuous F measure	correlation coefficient
Saxena 2012	school children, Madhya Pradesh, India (n=170)	drinking water	mg/L	Raven's Standard Progressive Matrices	IQ (intelligence grade), age 12	continuous F measure	correlation coefficient
		urine	ppm	Raven's Standard Progressive Matrices	IQ (intelligence grade), age 12	continuous F measure	correlation coefficient

Figure A-6. Correlations between Fluoride Exposure and IQ Score in Children (Low Risk-of-bias Studies; Presented as Correlation Coefficient)

Circles represent response estimates with red indicating statistical significance.
An interactive version of Figure A-6 and additional study details in HAWC here. "F" represents fluoride. For Saxena et al. (2012), a significant relationship between water fluoride level and intelligence grade was observed. Increasing intelligence grades reflected increasing levels of impairment (reduced intelligence) in children.

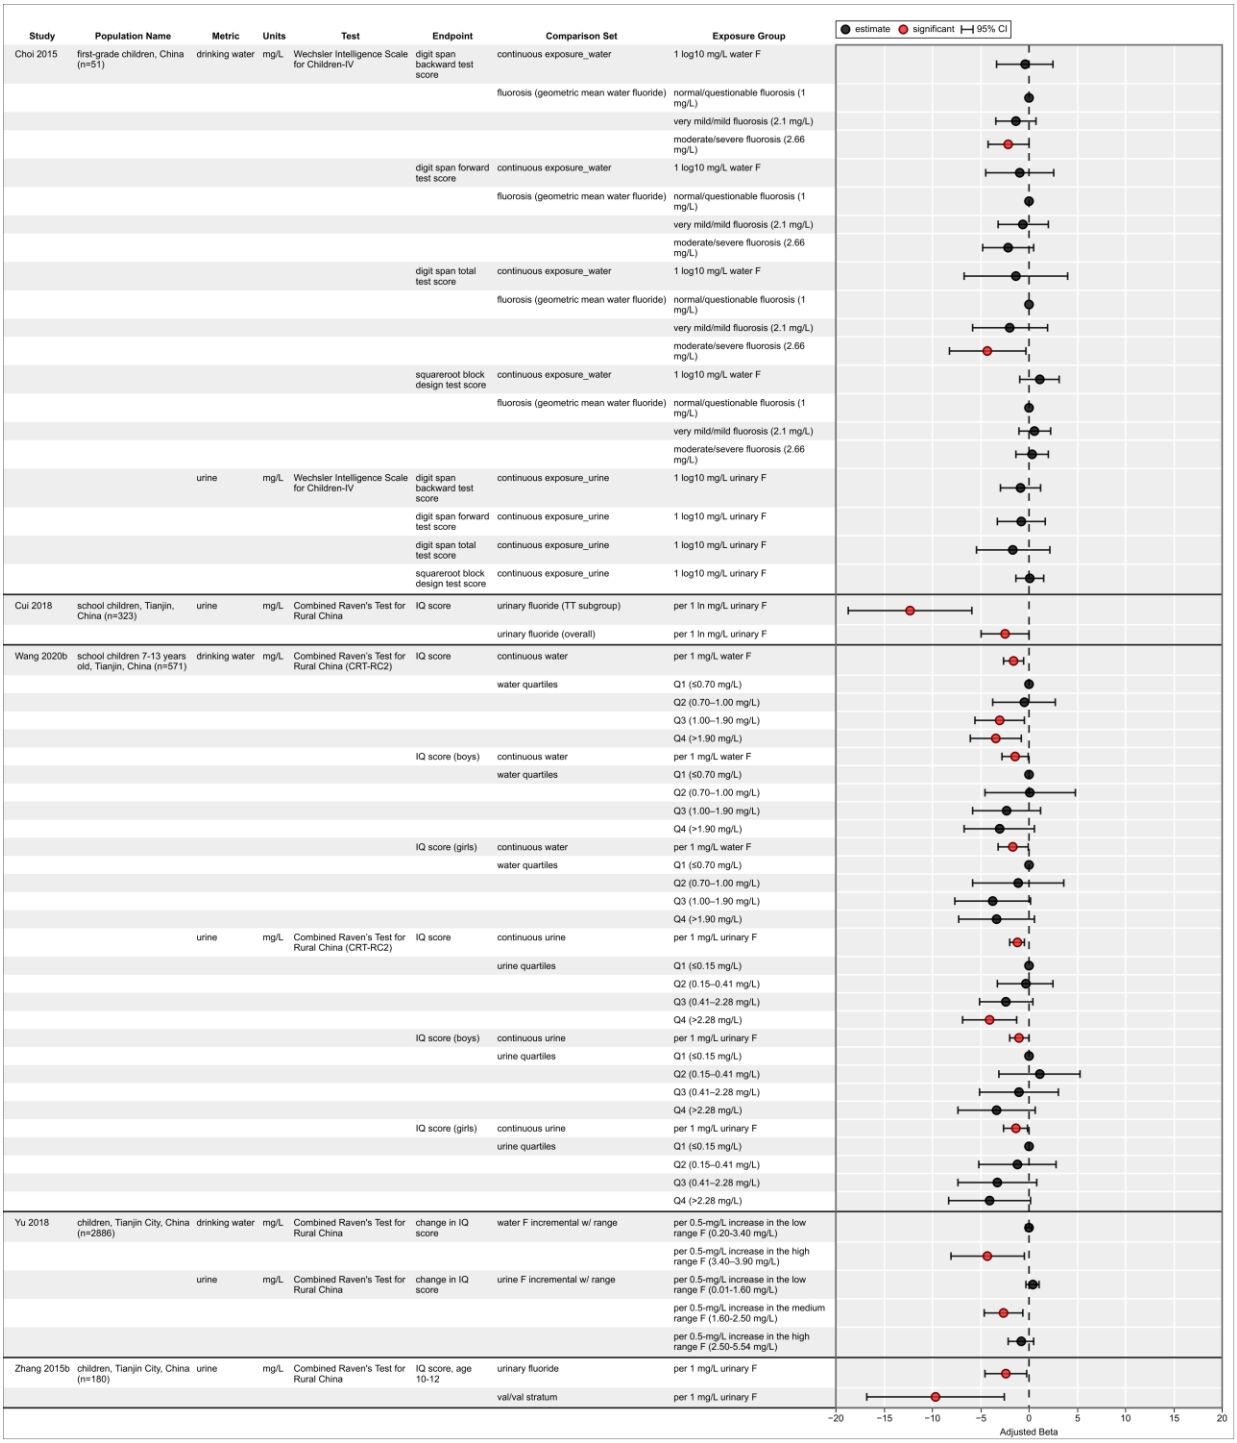


Figure A-7. Associations between Fluoride Exposure and IQ Score in Children (Low Risk-of-bias Studies; Presented as Adjusted Beta)—China

Circles represent response estimates with red indicating statistical significance.
An interactive version of Figure A-7 and additional study details in HAWC here. "F" represents fluoride. For Yu et al. (2018), authors note an obvious decrease in the IQ score at water fluoride exposure levels between 3.40 mg/L and 3.90 mg/L and a similar adverse effect on IQ scores at urinary fluoride exposure levels from 1.60 mg/L to 2.50 mg/L, and so the changes in IQ score are indicated as significant; however, significance levels for change in IQ score were not reported.

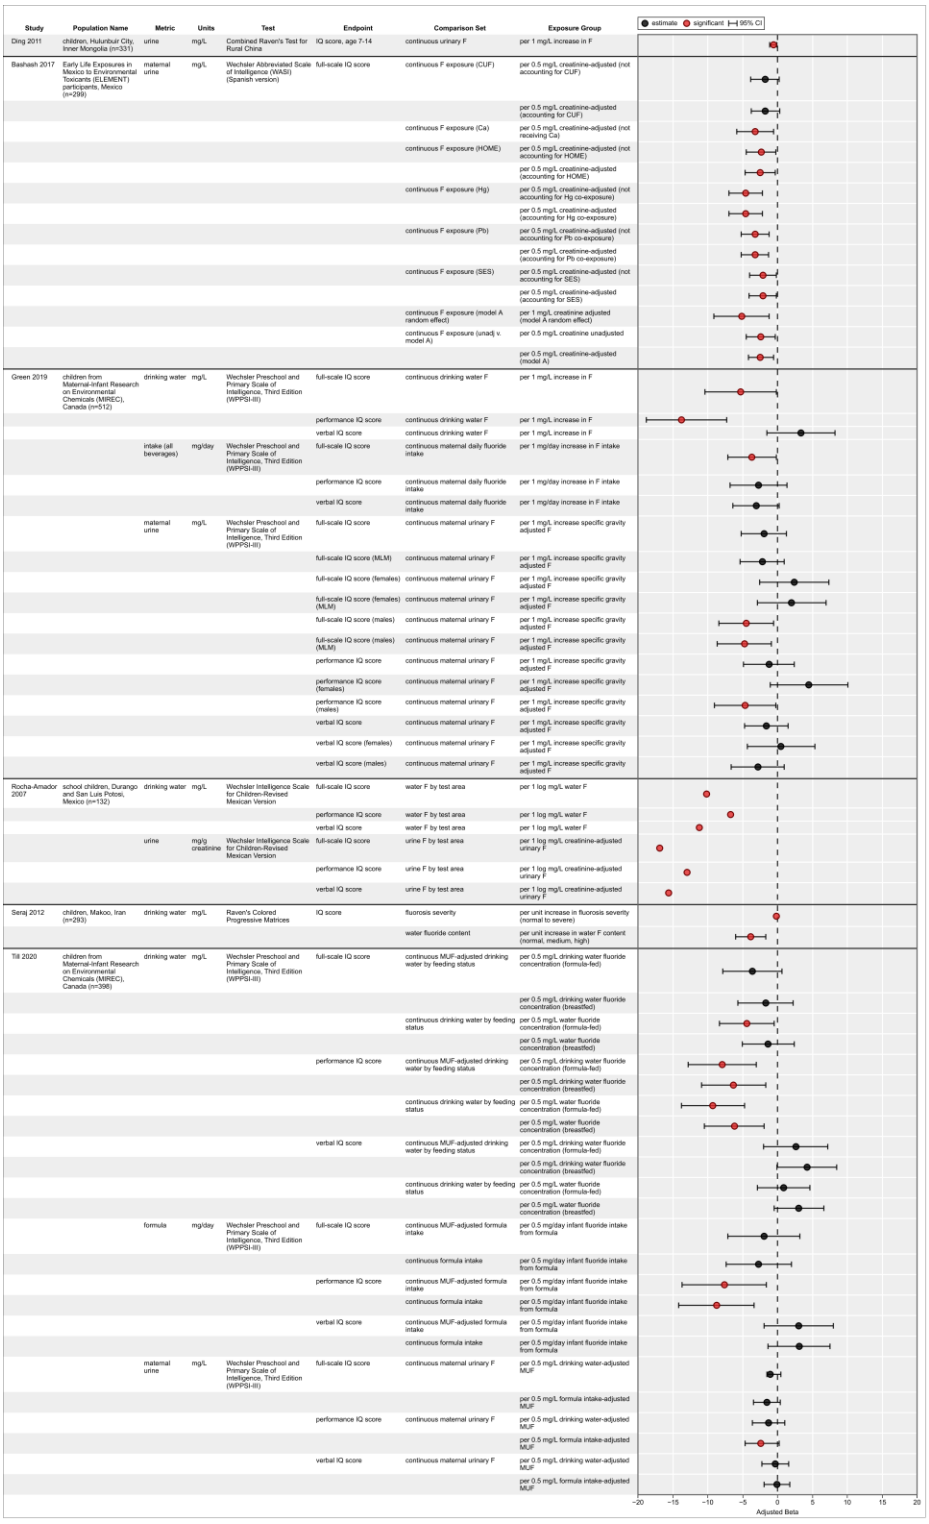

Figure A-8. Associations between Fluoride Exposure and IQ Score in Children (Low Risk-of-bias Studies; Presented as Adjusted Beta)—Areas Other Than China

Circles represent response estimates with red indicating statistical significance.
An interactive version of Figure A-8 and additional study details in HAWC here. "F" represents fluoride.

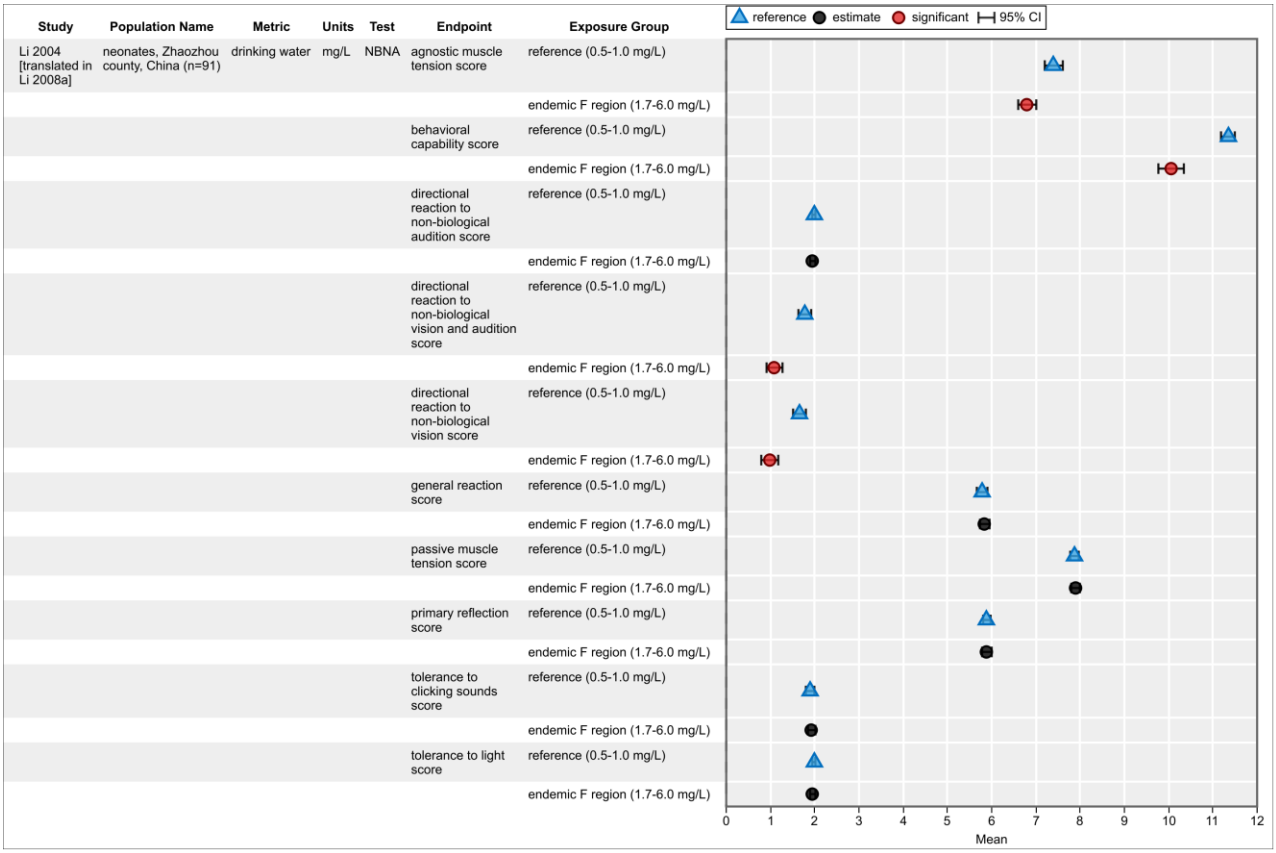

Figure A-9. Mean Motor/Sensory Scores in Children by Fluoride Exposure (Low Risk-of-bias Studies)

Reference group indicated by blue triangles; circles represent response estimates with red indicating statistical significance.
An interactive version of Figure A-9 and additional study details in HAWC here. "F" represents fluoride. 95% CIs are small and are within figure symbols and may be difficult to see. Values for SDs and 95% CIs can be viewed in HAWC by clicking the data points within the plot area. Total neonatal behavioral neurological assessment (NBNA) score was also significantly reduced in the endemic F region versus reference region (not shown).

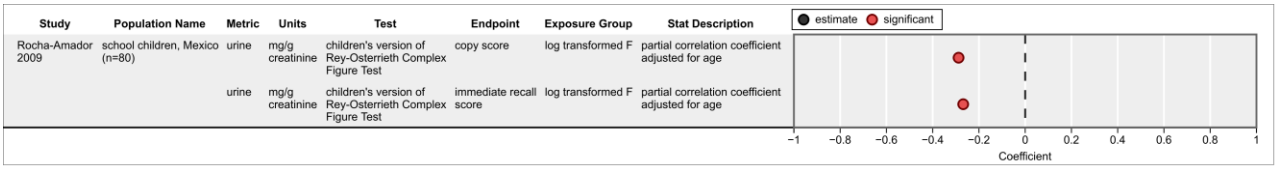

Figure A-10. Correlations between Fluoride Exposure and Other Cognitive Effects in Children (Low Risk-of-bias Studies; Presented as Correlation Coefficient)

Circles represent response estimates with red indicating statistical significance.
An interactive version of Figure A-10 and additional study details in HAWC here. "F" represents fluoride.

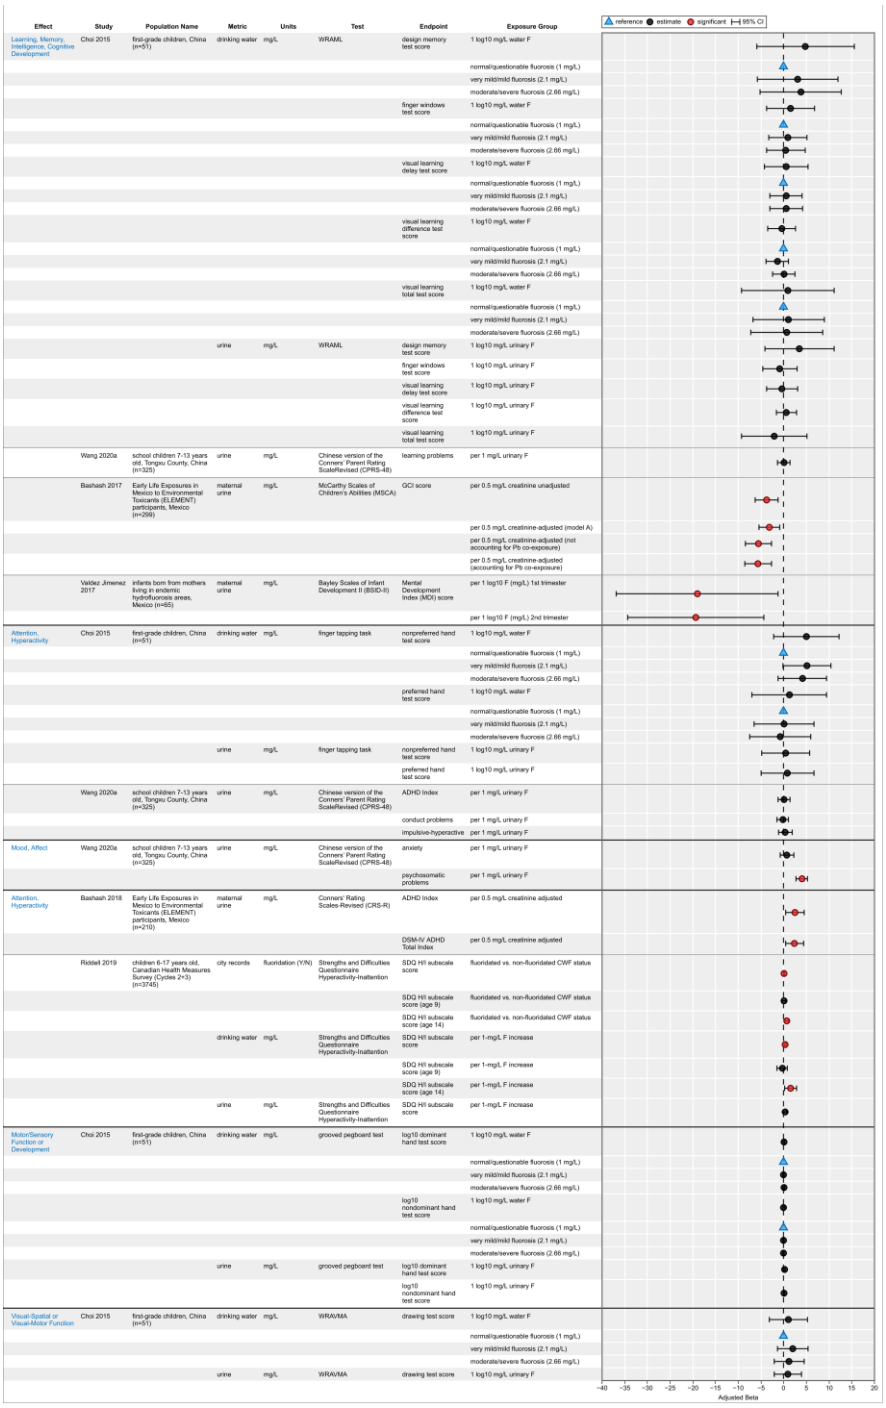

Figure A-11. Associations between Fluoride Exposure and Other Neurodevelopmental Effects in Children (Low Risk-of-bias Studies; Presented as Adjusted Beta)

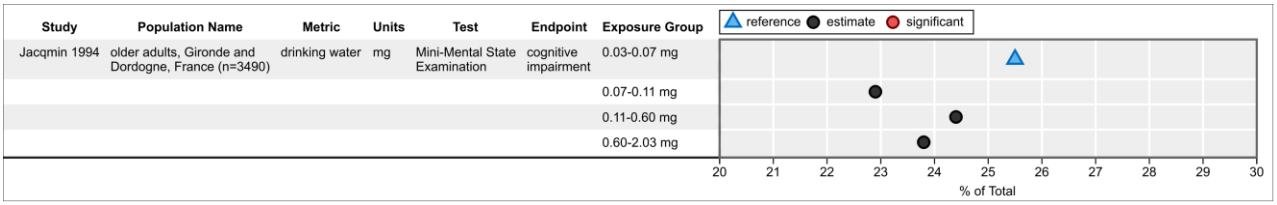
Reference group indicated by blue triangles; circles represent response estimates with red indicating statistical significance. An interactive version of Figure A-11 and additional study details in HAWC here. "F" represents fluoride. Bashash et al. (2018) observed significant associations between maternal urinary fluoride and ADHD-like symptoms related to inattention (an increase in 0.5 mg/L of maternal urinary fluoride was associated with a 2.84-point increase in the DSM-IV Inattention Index and a 2.54-point increase in Cognitive Problems and Inattention Index). These two scales contributed to the global ADHD Index and the DSM-IV ADHD Total Index shown here.

Effect	Study	Population Name	Metric	Units	Test	Endpoint	Comparison Set	Exposure Group
Learning, Memory, Intelligence, Cognitive Development	Wang 2020a	school children 7-13 years old, Tongxu County, China (n=325)	urine	mg/L	Chinese version of the Conners' Parent Rating ScaleRevised (CPRS-48)	learning problems	continuous urinary F	per 1 mg/L urinary F
	Barberio 2017b	children 3-12 years old, Canadian Health Measures Survey (Cycle 2) (n=1120)	urine	umol/L		learning disability	Cycle 2 urine	per 1-umol urinary F
							Cycle 2 SG-adjusted urine	per 1-umol urinary F
				umol/mmol creatinine		learning disability	Cycle 2 creatinine-adjusted urine	per 1-umol urinary F
		children 3-12 years old, Canadian Health Measures Survey (Cycle 3) (n=1101)	drinking water	mg/L		learning disability	Cycle 3 drinking water	per 1 mg/L water F
			urine	umol/L		learning disability	Cycle 3 urine	per 1-umol urinary F
							Cycle 3 SG-adjusted urine	per 1-umol urinary F
				umol/mmol creatinine		learning disability	Cycle 3 creatinine-adjusted urine	per 1-umol urinary F
		children 3-12 years old, Canadian Health Measures Survey (Cycles 2+3) (n=2221)	urine	umol/L		learning disability	pooled urine	per 1-umol urinary F
							pooled SG-adjusted urine	per 1-umol urinary F
				umol/mmol creatinine		learning disability	pooled creatinine-adjusted urine	per 1-umol urinary F
Attention, Hyperactivity	Wang 2020a	school children 7-13 years old, Tongxu County, China (n=325)	urine	mg/L	Chinese version of the Conners' Parent Rating ScaleRevised (CPRS-48)	ADHD Index	continuous urinary F	per 1 mg/L urinary F
						conduct problems	continuous urinary F	per 1 mg/L urinary F
						impulsive-hyperactive	continuous urinary F	per 1 mg/L urinary F
	Barberio 2017b	children 3-12 years old, Canadian Health Measures Survey (Cycle 2) (n=1120)	urine	umol/L		ADHD	Cycle 2 urine	per 1-umol urinary F
							Cycle 2 SG-adjusted urine	per 1-umol urinary F
				umol/mmol creatinine		ADHD	Cycle 2 creatinine-adjusted urine	per 1-umol urinary F
	Riddell 2019	children 6-17 years old, Canadian Health Measures Survey (Cycles 2+3) (n=3745)	city records	fluoridation (Y/N)		ADHD	Cycle 2/3 CWF	fluoridated vs. non-fluoridated CWF status
						ADHD (age 9)	Cycle 2/3 CWF	fluoridated vs. non-fluoridated CWF status
						ADHD (age 14)	Cycle 2/3 CWF	fluoridated vs. non-fluoridated CWF status
			drinking water	mg/L		ADHD	Cycle 3 drinking water	per 1-mg/L F increase
			urine	mg/L		ADHD	Cycle 2/3 SG-adjusted urine	per 1-mg/L F increase
Mood, Affect	Wang 2020a	school children 7-13 years old, Tongxu County, China (n=325)	urine	mg/L	Chinese version of the Conners' Parent Rating ScaleRevised (CPRS-48)	anxiety	continuous urinary F	per 1 mg/L urinary F
						psychosomatic problems	continuous urinary F	per 1 mg/L urinary F

Figure A-12. Associations between Fluoride Exposure and Other Neurodevelopmental Effects in Children (Low Risk-of-bias Studies; Presented as Adjusted OR)

Circles represent response estimates with red indicating statistical significance.
An interactive version of Figure A-12 and additional study details in HAWC here. "F" represents fluoride. Drinking water results for Barberio et al. (2017b) have a large confidence interval and are not completely visible in the figure. 95% CIs are 0.068–11.33 and can be viewed in HAWC by clicking the OR within the plot area.



Study	Population Name	Metric	Units	Test	Endpoint	Exposure Group
Jacqmin 1994	older adults, Gironde and Dordogne, France (n=3490)	drinking water	mg	Mini-Mental State Examination	cognitive impairment	0.03-0.07 mg
						0.07-0.11 mg
						0.11-0.60 mg
						0.60-2.03 mg

Figure A-13. Cognitive Impairment in Adults by Fluoride Exposure (Low Risk-of-bias Studies; Presented as % of Total Group)

Reference group indicated by blue triangles; circles represent response estimates with red indicating statistical significance.
An interactive version of Figure A-13 and additional study details in HAWC here. Results from Li et al. (2016) suggested that fluoride exposure may be a risk factor for cognitive impairment in elderly subjects; however, results from the study were not conducive to presentation in this visualization.

Appendix B. Literature Search and Document Review Details

Table of Contents

Tables

B.1. Introduction

NTP initially published a systematic review of the experimental animal literature in 2016 that was subsequently expanded to include human epidemiological studies, mechanistic studies, and newer experimental animal literature. Table B-1 provides a timeline of key activities contributing to the 2022 NTP monograph including the multiple literature searches, draft monographs, and document review activities that have occurred since 2016.

Table B-2 is a summary of the specific search terms used for the PubMed database. In order to ensure inclusion of relevant papers, the strategy for this search was broad for the consideration of neurodevelopmental or cognitive endpoints and comprehensive for fluoride as an exposure or treatment. The specific search strategies for other databases are available in the protocol (https://ntp.niehs.nih.gov/go/785076).

Table B-1. Literature Search and Document Review Timeline

Date	Action
July 2016	Published 2016 NTP monograph of the systematic literature review on the effects of fluoride on learning and memory in animals only
June 2017	Published protocol for a new NTP monograph on systematic review on effects of fluoride on neurodevelopment and cognition from evidence in human, experimental animal, and mechanistic data
April 2019	Completed final literature search for 2019 draft NTP monograph on human, experimental animal, and mechanistic data (i.e., updated through April 2019)
May 2019	Published 2019 revised protocol for 2019 draft NTP monograph
September 2019	Sent 2019 draft NTP monograph for review by NASEM committee
February 2020	Received NASEM committee's review report of 2019 draft NTP monograph; began the following key changes in response to NASEM report: • Expanded literature search to non-English-language databases • Conducted meta-analysis on children's IQ and fluoride exposure • Revised protocol for monograph to include additional information.
May 2020	Completed final literature search for 2020 draft NTP monograph on human experimental animal and mechanistic data (i.e., updated through May 2020 and expanded to include non-English-language databases)
September 2020	Published 2020 revised protocol for 2020 draft NTP monograph
September 2020	Sent 2020 draft NTP monograph for second review by NASEM committee
February 2021	Received NASEM committee's review report of revised 2020 draft NTP monograph; made the following key changes in response to NASEM report: • Removed hazard step and hazard conclusions • Removed meta-analysis to publish separately.
December 2021	Sent 2021 draft NTP monograph on the state of the science for external peer review
April 2022	Published final 2022 NTP monograph on the state of the science

Appendix C. Detailed Literature Search Results and List of Included Studies

Table of Contents

C.1. Detailed Literature Search Results

C.1.1. Literature Search Results Counts and Title and Abstract Screening

The electronic database searches retrieved 25,450 unique references in total (20,883 references during the initial search conducted in December 2016, 3,657 references during the literature search updates [including the final updated search conducted for the primary epidemiological studies on May 1, 2020], and 910 references from the supplemental Chinese database searches); 11 additional references were identified by technical advisors or from reviewing reference lists in published reviews and included studies. As a result of title and abstract screening, 1,036 references were moved to full-text review, and 24,425 references were excluded (11,402 by manual screening for not satisfying the PECO criteria and 13,023 based on the SWIFT-Active Screener algorithm).

C.1.2. Full-text Review

Among the 1,036 references that underwent full-text review, 489 were excluded at that stage with reasons for exclusion documented; 333 references were excluded for not satisfying the PECO criteria; and 156 references from the May 2020 searches (main literature search update and supplemental Chinese database searches) were excluded for not including information that would materially advance the human, animal in vivo, or mechanistic findings (see the Main Literature Search section for a description of the methodology). These screening results are outlined in a study selection diagram that reports numbers of studies excluded for each reason at the full-text review stage (see Figure 2) [using reporting practices outlined in Moher et al. (2009)]. After full-text review, 547 studies were considered relevant with primary neurodevelopmental or cognitive outcomes, secondary neurobehavioral outcomes, and/or outcomes related to thyroid function. A few studies assessed data for more than one evidence stream (human, non-human mammal, and/or in vitro), and several human and animal studies assessed more than one type of outcome (e.g., primary and secondary outcomes). The number of included studies is summarized below:

- 167 human studies (84 primary only; 13 secondary only; 5 primary and secondary; 8 primary and thyroid; 2 secondary and thyroid; and 55 thyroid only);
- 339 non-human mammal studies (7 primary only; 186 secondary only; 67 primary and secondary; 6 primary, secondary, and thyroid; 4 secondary and thyroid; and 69 thyroid only); and,
- 60 in vitro/mechanistic studies (48 neurological and 12 thyroid).

One publication contained human, experimental non-human mammal, and in vitro data. Three publications contained both human and experimental non-human mammal data. Fourteen publications contained data relevant to both experimental non-human mammal studies and in vitro studies.

C.2. List of Included Studies

C.2.1. Studies in Humans

As described in Figure 2, 167 human studies were included; however, full data extraction was conducted only on studies with neurological outcomes or thyroid hormone data. Data extraction was completed using HAWC. Data were extracted from a subset of included studies in humans (n = 124) and are available in HAWC based on outcome. The following lists of references are organized as studies that are available in HAWC followed by studies that are not available in HAWC. Specifically, data for primary neurodevelopmental or cognitive outcomes (learning, memory, and intelligence) and secondary neurobehavioral outcomes (anxiety, aggression, motor activity, or biochemical changes), as well as thyroid hormone level data, were extracted from included human studies and are available in HAWC. Data for included studies identified through the 2020 literature search update were extracted only for primary neurodevelopmental or cognitive outcomes; a subset of these studies (n = 7) also included secondary neurobehavioral outcomes and/or thyroid hormone level data that were not extracted because those data would not materially advance the human or mechanistic findings. Included human studies that evaluated only other thyroid-related effects such as goiters or thyroid size (n = 43) were not extracted and are not available in HAWC. The list below presents the 167 human studies that were included in the review. An overview of the screening results is outlined in the study selection diagram (Figure 2) that reports numbers of included studies as well as numbers of studies excluded for each reason at the full-text review stage.

C.2.2. Studies in Non-human Animals

As described in Figure 2, 339 non-human mammal studies were included; however, full data extraction was conducted only on studies with primary neurological outcomes and/or secondary functional neurological outcomes (e.g., motor activity). Data extraction was completed using HAWC. Data were extracted from a subset of included studies in animals (n = 123) and are available in HAWC based on outcome. The following lists of references are organized as studies that are available in HAWC followed by studies that are not available in HAWC. Specifically, all primary outcomes and functional neurological secondary outcomes (e.g., motor activity) were extracted from animal studies and are available in HAWC, including studies from the NTP (2016) assessment. Studies are also available in HAWC that evaluated mechanistic effects related to oral fluoride exposure at or below 20 ppm fluoride drinking water equivalents for categories of mechanistic endpoints with the largest amount of available data (i.e., biochemistry of the brain or neurons, neurotransmission, oxidative stress, and histopathology [n = 70]); however, these mechanistic data were generally not extracted. Several animal studies assessed primary neurological outcomes and/or functional neurological secondary outcomes and mechanistic effects in the four mechanistic categories listed above (n = 56). In total, 140 animal studies are available in HAWC (70 with primary neurological outcomes and/or secondary functional neurological outcomes without relevant mechanistic data; 15 with relevant mechanistic data only; and 55 with primary and/or secondary functional neurological outcomes with relevant mechanistic data). Studies that evaluated other mechanistic endpoints, as well as studies that assessed only mechanistic effects at fluoride levels above 20 ppm fluoride drinking water equivalents, are not available in HAWC (n = 199). The list below presents the 339 non-human animal studies that were included in the review. An overview of the screening results is outlined in the study selection diagram (Figure 2) that reports numbers of included studies as well as numbers of studies excluded for each reason at the full-text review stage.

C.2.3. In Vitro Experimental Studies

As described in Figure 2, 60 in vitro experimental studies were included; however, data extraction was not conducted on in vitro studies. Therefore, in vitro experimental studies are not available in HAWC with the exception of in vitro studies that also reported in vivo non-human animal data that met the relevant criteria for being made available in HAWC. The following lists of references are organized as studies that are available in HAWC (n = 6) followed by studies that are not available in HAWC (n = 54).

C.2.3.1. Studies Available in HAWC

Appendix E. Details for Low Risk-of-bias Studies

Table of Contents

E.1. IQ Studies

E.1.1. Bashash et al. (2017)

E.1.1.1. Study Details

- ***Study design:*** Prospective cohort
- ***Population:*** Early Life Exposures in Mexico to Environmental Toxicants (ELEMENT) participants (pregnant mothers and their children aged 4 or 6–12 years).
- ***Study area:*** Mexico City, Mexico
- ***Sample size:*** 299 mother-child pairs, of whom 211 had data for the IQ analyses.
- ***Data relevant to the review:*** Adjusted and unadjusted associations between IQ scores and maternal or child's urinary fluoride concentrations.
- ***Reported association with fluoride exposure:*** Yes: Significant association between maternal urinary fluoride and IQ score (adjusted β = −2.50 per 0.5 mg/L increase; 95% CI: −4.12, −0.59). No significant associations with children's urinary fluoride.

E.1.1.2. Risk of Bias

- **Author contacts:**
  - Authors were contacted for additional information on whether clustering was addressed. The authors provided results from additional models with cohort as a random effect.
- ***Population selection:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Study participants were selected from two different cohorts from three hospitals in Mexico City that serve low-to-moderate income populations. One cohort was from an observational study of prenatal lead exposure and neurodevelopment outcomes, and the other was from a randomized trial of the effect of calcium on maternal blood lead levels. The authors state that participants had no history of psychiatric disorders, high-risk pregnancies, gestational diabetes, illegal drug use, or continuous prescription drugs, but no information on smoking habits was considered. Study populations appear to be similar, but there may be some differences because subjects were selected from two different cohorts that were recruited from slightly different time periods.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the exposure groups were similar despite the subjects coming from different original study populations wherein different methods were used for recruitment.
- ***Confounding:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Data were collected via questionnaire on maternal age, education, marital status at first prenatal visit, birth order, birth weight, gestational age at delivery, maternal smoking, maternal IQ, and HOME scores. All models were adjusted for gestational age at birth, sex, birth weight, birth order, age at testing,

maternal marital status, smoking history, age at delivery, maternal IQ, education, and cohort, with additional testing for children's urinary fluoride, mercury, lead, and calcium. Sensitivity analyses additionally adjusted for HOME score. Important covariates not considered included BMI, iodine deficiency, arsenic, and maternal mental health and nutrition. Arsenic is assumed not to be a potential co-exposure in this population because the study authors did not discuss it as an issue, but did consider other co-exposures. Arsenic is included in the water quality control program in Mexico City and is not considered a concern in this population.

- *Potentially important study-specific covariates:* All key covariates were addressed.
  - *Direction/magnitude of effect size:* Not applicable.
- *Basis for rating:* Probably low risk of bias based on direct evidence that key covariates, including other potential co-exposures, were addressed and indirect evidence that the methods used to collect the information were valid and reliable and that arsenic is not likely to be an issue in this study population.

- ***Attrition:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Although there was a large amount of attrition, the study authors clearly describe all reasons for attrition and also provide characteristics to compare those participants included to those excluded. There were some slight differences between those included and those excluded, but there is nothing to indicate that the attrition would potentially bias the results.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that exclusion of subjects from analyses was adequately addressed, and reasons were documented when subjects were removed from the study or excluded from analyses.
- ***Exposure:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Urinary fluoride concentrations were determined in spot urine samples (2nd morning void) collected from mothers (during at least one trimester) and children ages 6–12 years. Fluoride content was measured using ion-selective electrode-based assays. QC methods were described including between laboratory correlations. All samples were measured in duplicate. Extreme outliers were excluded. Urinary dilution was addressed by using creatinine-adjusted levels.
    - *Direction/magnitude of effect size:* Not applicable.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that exposure was consistently assessed using well-established methods that directly measured exposure.
- ***Outcome:***
  - *Rating:* Definitely low risk of bias (++)

- *Summary:* Outcome was assessed using the McCarthy Scales of Children's Abilities (MSCA) in 4-year-old children (translated into Spanish) and the Wechsler Abbreviated Scale of Intelligence (WASI) in 6–12-year-olds. The WASI is a well-established test, and the validity of both tests is well documented by the authors. Inter-examiner reliability was evaluated and reported with a correlation of 0.99 (++ for methods). The study report stated that psychologists were blind to the children's fluoride exposure (++ for blinding). Overall rating for methods and blinding = ++.
- *Basis for rating:* Definitely low risk of bias based on direct evidence that the outcome was assessed using instruments that were valid and reliable in the study population, and that the outcome assessor was blind to participants' fluoride exposure.

- ***Selective Reporting:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* All outcomes outlined in the abstract, introduction, and methods are reported in sufficient detail.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that all measured outcomes were reported.
- ***Other potential threats:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:*
    - *Statistical analyses:* Statistical analyses used were appropriate for the study. Statistical tests of bivariate associations (using Chi-square tests for categorical variables and analysis of variance [ANOVA]) were used to compare the means of the outcomes or exposure within groups based on the distribution of each covariate. Generalized additive models (GAMs) were used to estimate the adjusted association between fluoride exposure and measures of children's intelligence. Residual diagnostics were used to examine model assumptions and identify any potentially influential observations. Results are reported as adjusted effects and 95% CIs. In sensitivity analyses, regression models accounted for clustering at the cohort level by using cohort as a fixed effect in the models. Although using cohort as a random effect would be more appropriate, using individual-level exposure data and accounting for numerous important covariates in the models likely captured the cohort effect. Additional models with cohort as a random effect were also subsequently made available via personal communication with the study authors and showed similar results to the main model.
    - *Other potential concerns:* None identified.
  - *Basis for rating:* Definitely low risk if bias is based on direct evidence that the statistical analyses were appropriate and there were no other potential threats of risk of bias identified.
- ***Basis for classification as low risk-of-bias study overall:*** Definitely or probably low risk-of-bias ratings in confounding, exposure, and outcome. Study strengths include

individual exposure measurements, blinding of outcome assessor to participants' fluoride exposure, and the prospective cohort study design.

E.1.2. Choi et al. (2015)

E.1.2.1. Study Details

- ***Study design:*** Cross-sectional
- ***Population:*** First-grade children (ages 6–8 years)
- ***Study area:*** Mianning County in southern Sichuan, China
- ***Sample size:*** 51 first-grade children
- ***Data relevant to the review:*** Associations between IQ (digit span for auditory span and working memory and block design for visual organization and reasoning components of WISC-IV only) with continuous urine or drinking water fluoride levels. Study also had information based on dental fluorosis score.
- ***Reported association with fluoride exposure:*** Yes: Compared to the normal/questionable dental fluorosis, the moderate/severe dental fluorosis group was associated with significantly lower total (adjusted β = −4.28; 95% CI: −8.22, −0.33) and backward (adjusted β = −2.13; 95% CI: −4.24, −0.02) digit span scores. Linear associations between total digit span and log-transformed fluoride in urine (adjusted β = −1.67; 95% CI: −5.46, 2.12) and in drinking water (adjusted β = −1.39; 95% CI: −6.76, 3.98) were observed but not significant. Other outcomes not significantly associated with fluoride exposure.

E.1.2.2. Risk of Bias

- **Author contacts:**
  - Authors were not contacted for additional information because it was not necessary.
- ***Population selection:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Subjects were selected during the same time frame using the same methods. Fifty-one first-grade children residing in Mianning County in southern Sichuan, China were included in this pilot study. It is not specified whether the 51 children represented all the first-grade children from this area or whether some refused to participate. Children who did not speak Chinese, were not students at the Primary School of Sunshui Village in Mianning County, or those with chronic or acute disease that might affect neurobehavioral function tests were excluded. Demographic characteristics are presented in Table 1 of the study, which indicates that subjects were similar. Important covariates are adjusted for in the statistical analyses.
  - *Basis for Rating:* Definitely low risk of bias based on direct evidence that the exposure groups were similar and were recruited within the same time frame using the same methods with no evidence of differences in participation/response rates.

- ***Confounding:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* The parents or guardians completed a questionnaire on demographic and personal characteristics of the children (sex, age at testing, parity, illnesses before age 3, and past medical history) and caretakers (age, parity, education and occupational histories, residential history, and household income). A 20-µL capillary blood sample was collected at the school by a Mianning County Center for Disease Control (CDC) health practitioner and tested for possible iron deficiency, which could have been used as a covariate of neurodevelopmental performance. Important covariates that were not assessed include maternal BMI, parental mental health, maternal smoking status, maternal reproductive factors, parental IQ, and HOME score. However, the study authors noted that confounding bias appeared to be limited due to the minimal diversity in the social characteristics of the subjects. The study authors indicated that CDC records documented that levels of other contaminants, including arsenic and lead, were very low in the area. Iodine differences were not specifically addressed, but there is no indication from the information provided that this might have been a concern.
  - *Potentially important study-specific covariates:* All key covariates were considered in this study.
    - *Direction/magnitude of effect size:* Not applicable.
  - *Basis for rating:* Probably low risk of bias because there is direct evidence that the key covariates were considered and indirect evidence that co-exposure to arsenic was likely not an issue in this area and that methods used for collecting the information were valid and reliable.
- ***Attrition:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* The majority of results were reported for the 51 children stated to be included in the pilot study. In Table 5 of the study, the N for each dental fluorosis category totals only 43, but the text indicates 8 children did not have a Dean Index because permanent teeth had not erupted.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that exclusion of subjects from analyses was adequately addressed, and reasons were documented when subjects were removed from the study or excluded from analyses.
- ***Exposure:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* The study used three different measurements of fluoride exposure: well water fluoride concentrations from the residence during pregnancy and onwards, fluoride concentrations from children's first morning urine samples, and degree of children's dental fluorosis. Fluoride concentrations in community well water were measured and recorded by Mianning County CDC; specific analytic methods were not reported, but it is likely that standard methods were used because the

analyses were conducted by the CDC and were likely the same as those used to measure the fluoride in urine. Migration of subjects was noted to be limited. Well water fluoride concentrations of the mother's residence during pregnancy and onward were used to characterize a child's lifetime exposure. To provide a measure of the accumulated body burden, each child was given a 330-mL (11.2-oz) bottle of Robust© distilled water (free from fluoride and other contaminants) to drink the night before the clinical examinations, after emptying the bladder and before bedtime. The first urine sample the following morning was collected at home, and the fluoride concentration was determined on a 5-mL sample using an ion-specific electrode at the Mianning CDC. There is no indication that urinary fluoride levels accounted for dilution, nor was it clear that the method of administering water to the children and collection methods sufficiently controlled for differences in dilution. One of the investigators, a dentist, performed a blinded dental examination on each child's permanent teeth to rate the degree of dental fluorosis using the Dean Index. The Dean Index is a commonly used index in epidemiological studies and remains the gold standard in the dentistry armamentarium. The Index has the following classifications: normal, questionable, very mild, mild, moderate, and severe. Quality control (QC) procedures are not reported but were likely appropriate.

        - *Direction/magnitude of effect size:* Current levels were used to assess lifetime exposure. This is likely to be a non-differential exposure misclassification, and direction of bias is unknown. Because subject migration appears to be limited, it is likely that the current fluoride levels are adequate reflections of past exposure. Dental fluorosis would be an indicator that exposure occurred in the past, and there was a fair correlation between degree of dental fluorosis and current urine and water fluoride levels, with both increasing with increasing levels of dental fluorosis.
    - *Basis for rating:* Probably low risk of bias based on indirect evidence that exposure was consistently assessed using well-established methods that directly measure exposure.

- ***Outcome:***
    - *Rating:* Probably low risk of bias (+)
    - *Summary:* The study authors adopted culture-independent tests considered feasible for children aged 6 to 8 years. The Wide Range Assessment of Memory and Learning (WRAML) was used for the assessment of memory and learning. Three subtests were also used. The Finger Windows subtest assesses sequential visual memory. The Design Memory subtest assesses the ability to reproduce designs from memory following a brief exposure. The Visual Learning subtest assesses the ability to learn the locations of pictured objects over repeated exposures. The Wechsler Intelligence Scale for Children-Revised (WISC-IV) includes digit span for auditory span and working memory and block design for visual organization and reasoning. The grooved pegboard test assesses manual dexterity. The tests used have been validated on a Western population. Although there is no information provided to indicate that the tests were validated on the study population, the study authors indicated that the tests were culture-

independent (+ for methods). Blinding of the outcome assessors to participants' fluoride exposure, or steps to minimize potential bias were not reported. However, it is unlikely that the assessors had knowledge of the individual exposure as children all came from the same area, and water and urine levels were tested at the CDC. (+ for blinding). Overall = +.

- *Basis for rating:* Probably low risk of bias based on indirect evidence that all outcomes were assessed using instruments that were valid and reliable in the study population, and that the outcome assessors were blind to participants' fluoride exposure.

- ***Selective Reporting:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* All outcomes outlined in the abstract, introduction, and methods are reported in sufficient detail.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that all measured outcomes were reported.
- ***Other potential threats:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:*
    - *Statistical analyses:* Statistical analyses are appropriate. Multiple regression models evaluate the associations between exposure indicators and test scores after adjusting for covariates. Specific regression models are not described or refenced, just stated to be "standard regression analysis with confounder adjustment." The distributions of fluoride concentrations in urine and water are skewed and log10-transformed to approximate a Gaussian distribution (test not specified). Results are reported as adjusted effects and 95% CIs. There is no evidence that residual diagnostics were used to examine model assumptions; however, the impact on the effect estimates is expected to be minimal.
    - *Other potential concerns:* It should be noted that this study was a pilot study and, therefore, had a relatively small sample size (i.e., 51 children).
  - *Basis for rating:* Probably low risk if bias based on indirect evidence that the statistical analyses were appropriate and there were no other potential threats of risk of bias identified.
- ***Basis for classification as low risk-of-bias study overall:*** Probably low risk-of-bias ratings in the confounding, exposure, and outcome domains. Study strengths include individual fluoride measurements with blinding at outcome assessment likely. All key covariates and many other important covariates were considered in the study design or analysis.

E.1.3. Cui et al. (2018)

E.1.3.1. Study Details

- ***Study design:*** Cross-sectional

- ***Population:*** School children aged 7–12 years from four schools in two districts in China with different fluoride levels
- ***Study area:*** Jinghai and Dagang in Tianjin City, China
- ***Sample size:*** 323 school children
- ***Data relevant to the review:*** IQ scores by urine fluoride levels.
- ***Reported association with fluoride exposure:*** Yes: Significant association between IQ score and log-transformed urinary fluoride (adjusted β = −2.47; 95% CI: −4.93, −0.01).

E.1.3.2. Risk of Bias

- **Author contacts:**
  - Authors were contacted in June 2019 to obtain additional information for risk-of-bias evaluation.
- ***Population selection:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Four schools were selected from the same district in China. The schools were selected based on levels of fluoride in the local drinking water and the degree of school cooperation. No details were provided on the number of schools in given areas or the difficulty in getting school cooperation. It was noted that the residents in the four areas had similar living habits, economic situations, and educational standards. Although authors do not provide the specific data to support this, fluoride levels and IQ scores were provided by different subject characteristics. The areas were classified as historically endemic fluorosis and non-fluorosis. Cluster sampling was used to select the grades in each school according to previously set child ages, and classroom was randomly selected with all students within a selected classroom included. Reasons for exclusion do not appear to be related to exposure or outcome.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the exposure groups were similar and recruited within the same time frame using the same methods, with no evidence of differences in participation/response rates.
- ***Confounding:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* The measurements of all covariates were obtained by structured questionnaires that were completed by children with the help of their parents. Covariates that were assessed include: sex, age, child's ethnicity, child's BMI, birth (normal vs. abnormal), mother's age at delivery, mother's education, income per family member, mother's smoking/alcohol during pregnancy, family member smoking, environmental noise, iodine region (non-endemic vs. iodine-excess-endemic area), factory within 30 m of residence, iodine salt, diet supplements, seafood/pickled food/tea consumption, surface water consumption, physical activity, stress, anger, anxiety/depression, trauma, having a cold 5 times a year, thyroid disease in relatives, mental retardation in relatives, and cancer in relatives. Covariates not considered include parity, maternal and paternal IQ, and quantity

and quality of caregiving environment (e.g., HOME score). The authors report that there were no other environmentally toxic substances that might have affected intelligence, such as high arsenic or iodine deficiency according to the Tianjin Centers for Disease Prevention and Control.

- *Potentially important study-specific covariates:* All key covariates were considered in this study.
  - *Direction/magnitude of effect size:* Not applicable.
- *Basis for rating:* Probably low risk of bias because there is indirect evidence that the key covariates were considered, methods for collecting the information were valid and reliable, and co-exposure to arsenic was likely not an issue in this area.

- ***Attrition:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Of the 400 children enrolled, 35 were excluded because they did not have informed consent signed by a guardian or they moved out of the area. Forty-two children were excluded because they did not have a DRD2 genotyping measurement. It is unclear whether these children were from the same schools or whether they were evenly distributed throughout the study area. It is also unclear whether the excluded subjects were similar to those included in the study. In the study, some analyses had fewer than the 323 subjects, but this seems reasonable given the subgroups that were being evaluated.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that exclusion of subjects from analyses was adequately addressed, and reasons were documented when subjects were removed from the study or excluded from analyses.
- ***Exposure:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Although children were selected based on area fluoride levels, fluoride in the urine was used in the analysis. Urine was collected from each child during the morning of enrollment and analyzed within a week. Fluoride levels were measured using an ion-selective electrode according to the China standard. A brief description of the method was provided, but no QC methods were reported. The study authors did not account for urinary dilution in the spot samples.
    - *Direction/magnitude of effect size:* Not accounting for dilution could cause some exposure misclassification. The direction and magnitude would depend on where the differences occurred.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that exposure was consistently assessed using acceptable methods that provide individual levels of exposure.
- ***Outcome:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* IQ was measured by professionals using the Combined Raven's Test–The Rural in China method, which is the appropriate test for the study population

(++ for methods). Blinding or other methods to reduce bias were not reported. Although it was unlikely that the outcome assessor would have knowledge of the child's urine fluoride levels, there was potential that they would know whether the child was from an endemic or non-endemic area if the IQ tests were conducted at the child's school, and there was no information provided on how the IQ tests were administered. Correspondence with the study author noted the cross-sectional nature of the study with outcome and exposure assessed at the same time, making the outcome assessors blind to the exposure status of participants. However, there was still potential for knowledge of the area (+ for blinding).

  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the outcome was assessed using instruments that were valid and reliable in the study population, and that the outcome assessors were blind to participants' fluoride exposure.

- ***Selective Reporting:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* All outcomes in the abstract, introduction, and methods are reported in sufficient detail.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that all measured outcomes were reported.
- ***Other potential threats:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:*
    - *Statistical analyses:* Statistical analyses were appropriate. Multiple linear regression models were applied to evaluate the relationship between urine fluoride levels and IQ scores, accounting for numerous important covariates. The urinary fluoride levels were log-transformed due to a skewed distribution. Residual diagnostics were used to examine model assumptions. Model robustness was tested through bootstrap, sensitivity analysis after excluding potential outliers, and cross-validation techniques. Results are reported as adjusted effects and 95% CIs. The analysis did not account for clustering at the school level or at the grade level (students were from four schools in grades selected via a clustered sampling method). There is no evidence that the sampling strategy was otherwise accounted for via sampling weights. The impact of these factors on the effect estimates is expected to be minimal given the use of individual-level data and adjustment for several important covariates.
      - *Other potential concerns:* None identified.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the statistical analyses were appropriate, and there were no other potential threats of risk of bias identified.
- ***Basis for classification as low risk-of-bias study overall:*** Probably low risk-of-bias ratings in confounding, exposure, and outcome. Study strengths include individual exposure measurements but is limited by the cross-sectional study design and lack of

accounting for urine dilution. All key covariates were considered in the study design or analysis.

E.1.4. Cui et al. (2020)

E.1.4.1. Study Details

- ***Study design:*** Cross-sectional
- ***Population:*** School children aged 7–12 years
- ***Study area:*** Tianjin City, China (one randomly selected school from each district based on iodine levels in the water), presumably was an expansion of the Cui et al. (2018) study
- ***Sample size:*** 498 school children
- ***Data relevant to the review:*** IQ scores by urine fluoride levels.
- ***Reported association with fluoride exposure:*** Yes: A 2-point decrease in IQ was observed in the highest urinary fluoride group compared to the lowest urinary fluoride group (i.e., 110.00 in ≥2.5-mg/L group versus 112.16 in <1.6-mg/L group); however, the results did not achieve statistical significance based on a one-way ANOVA comparing the three different urinary fluoride categories only.

E.1.4.2. Risk of Bias

- **Author contacts:**
  - Authors were not contacted for the 2020 publication. Authors were contacted in June 2019 for additional information on the Cui et al. (2018) publication. Information obtained from that correspondence may have been used for additional information in the 2020 publication.
- ***Population selection:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Subjects were recruited from 2014 to 2018. One school was selected from each district where water concentrations of water iodine were <10, 10–100, 100–150, 150–300 and >300 µg/L. In each school, classes were randomly sampled for the appropriate age group of 7–12 years old. A table of subject characteristics was provided by IQ. A total of 620 children were recruited, and 122 children who did not have complete information or enough blood sample were excluded. Reasons for exclusion do not appear to be related to exposure or outcome. The characteristics of the 498 included children are presented.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the exposure groups were similar and were recruited within the same time frame using the same methods, with no evidence of differences in participation/response rates.
- ***Confounding:***
  - *Rating:* Probably high risk of bias (−)

- *Summary:* It was noted by the study authors that there were no other environmental poisons except water fluoride. Other studies also conducted in this area of China noted specifically that arsenic was not a concern. Iodine was addressed as that was one of the main points of the study. Twenty-one factors (provided in Table 1 of the study) were selected as covariates, and a homemade questionnaire of unspecified validity was used for obtaining the information. It was noted that child age, stress, and anger were significantly associated with IQ although it is unclear whether these varied by fluoride level. However, Cui et al. (2018) indicate that stress and anger were not significantly associated with fluoride, and it was assumed that results would be similar for this study even though more children were included.
- *Potentially important study-specific covariates:* Age (children 7–12 years old)
  - *Direction/magnitude of effect size:* Age is a key covariate for IQ, even in the narrow age range evaluated in this study. The direction of the association may depend on the number of children in each age group within the different urinary fluoride categories; however, these data were not provided. In general, there were fewer subjects ≤9 years of age (i.e., 111) compared to >9 years of age (i.e., 387) with a significantly higher IQ in the ≤9-year-old age group. Therefore, if exposure were higher in the older subjects, this could likely bias the association away from the null.
- *Basis for rating:* Probably high risk of bias because there is indirect evidence that age was not addressed as a key covariate and it may be related to both IQ and exposure.

- ***Attrition:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Of the 620 children recruited, 122 (20%) were excluded due to incomplete information or inadequate blood sample. No information was provided to indicate whether there were similarities or differences in the children included versus the children excluded, but exclusion is unlikely to be related to either outcome or exposure.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that exclusion of subjects from analyses was adequately addressed, and reasons were documented when subjects were removed from the study or excluded from analyses.
- ***Exposure:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Children's morning urine was collected with a clean polyethylene tube, and fluoride was measured using a fluoride ion-selective electrode following Chinese standard WS/T 89-2015. A brief description was provided, but no QC methods were reported. The study authors do not account for urinary dilution in the spot samples.

        - *Direction/magnitude of effect size:* Not accounting for dilution could cause some exposure misclassification. The direction and magnitude would depend on where the differences occurred.
    - *Basis for rating:* Probably low risk of bias based on indirect evidence that exposure was consistently assessed using acceptable methods that provide individual levels of exposure.
- ***Outcome:***
    - *Rating:* Probably low risk of bias (+)
    - *Summary:* IQ was measured using the Combined Raven's Test, which is an appropriate test for the study population (++ for methods). Blinding was not mentioned; however, the outcome assessors would not likely have had knowledge of the child's urinary fluoride. Subjects appear to have been recruited based on iodine levels; therefore, it is unlikely that there would have been any knowledge of potential fluoride exposure. Correspondence with the study authors for the Cui et al. (2018) study also indicated that the outcome assessors would have been blind.
    - *Basis for rating:* Probably low risk of bias based on indirect evidence that the outcome was assessed using instruments that were valid and reliable in the study population, and that the outcome assessors were blind to participants' fluoride exposure.
- ***Selective Reporting:***
    - *Rating:* Definitely low risk of bias (++)
    - *Summary:* All outcomes in the abstract, introduction, and methods are reported in sufficient detail.
    - *Basis for rating:* Definitely low risk of bias based on direct evidence that all measured outcomes were reported.
- ***Other potential threats:***
    - *Rating:* Probably low risk of bias (+)
    - *Summary:*
        - *Statistical analyses:* One-way ANOVA was used to make comparisons between mean IQ by urinary fluoride levels. Consideration of heterogeneity of variances was not reported. There is no adjustment for covariates or for clustering of children at the school level. There is no evidence that the sampling strategy was otherwise accounted for (i.e., via sampling weights). The impact of these factors on the effect estimates is expected to be minimal given the use of individual-level data. The primary focus of the study was to evaluate associations between IQ and thyroid hormone or dopamine levels (not between IQ and fluoride levels). It should also be noted that more advanced analyses used for thyroid hormone- and dopamine-IQ associations still lacked adjustment for school and accounting for clustering of children from the same school.
        - *Other potential concerns:* None identified.

  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the statistical analyses were appropriate, and there were no other potential threats of risk of bias identified.
- ***Basis for classification as low risk-of-bias study overall:*** Probably low risk-of-bias ratings in exposure and outcome. Study strengths include individual exposure measurements, but the study is limited by the cross-sectional study design, lack of accounting for urine dilution, and lack of addressing age as a key covariate.

E.1.5. Ding et al. (2011)

E.1.5.1. Study Details

- ***Study design:*** Cross-sectional
- ***Population:*** Elementary school children aged 7–14 years old
- ***Study area:*** Hulunbuir City, Inner Mongolia, China
- ***Sample size:*** 331 school children
- ***Data relevant to the review:*** IQ mean difference based on 10 categories of urine fluoride.
- ***Reported association with fluoride exposure:*** Yes: Significant association between urinary fluoride and IQ score (each 1-mg/L increase in urinary fluoride was associated with a decrease in IQ score of 0.59 points; 95% CI: −1.09, −0.08).

E.1.5.2. Risk of Bias

- **Author contacts:**
  - Authors were not contacted for additional information because it was not necessary.
- ***Population selection:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* The study randomly selected 340 7–14-year-olds from four nearby elementary schools in Hulunbuir. Authors stated that the four elementary schools appeared to be very similar in teaching quality. The study authors noted that they followed the principles of matching social and natural factors like economic situation, educational standards, and geological environments as much as possible; however, how this was done is unclear and no table of study subject characteristics by group was provided.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the exposure groups were similar and were recruited within the same time frame using the same methods, with no evidence of differences in participation/response rates.
- ***Confounding:***
  - *Rating:* Probably high risk of bias (−)
  - *Summary:* It was noted that none of the four sites had other potential neurotoxins, including arsenic, in their drinking water. Details were not provided, except for a

reference supporting the statement. In addition, iodine deficiency was noted as not being issue in any of the four areas. Age was the only key covariate adjusted for in the regression model. Although dental fluorosis severity by % female was reported, not enough data were provided to determine whether sex should have been considered in the regression model. The study authors note that future studies will include covariates such as parents' educational attainment, mother's age at delivery, and household income.

- *Potentially important study-specific covariates:* Sex
  - *Direction/magnitude of effect size:* There is not enough information to determine whether there was an effect from sex. There were some differences in dental fluorosis level by sex, but it is unclear how this might impact the results or whether the distribution of sex differed by age.
- *Basis for rating:* Probably high risk of bias based on indirect evidence that there were differences in sex that were not considered in the study design or analyses.

- ***Attrition:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Data were relatively complete (i.e., <5% loss). Of the 340 subjects selected for inclusion, 5 were excluded because they lived in the area for less than a year with an additional 4 not consenting to participate.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that exclusion of subjects from analysis was adequately addressed, and reasons were documented when subjects were removed from the study or excluded from analyses.
- ***Exposure:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Spot urine samples were collected and measured using China CDC standards. All samples were analyzed twice using a fluoride ion-selective electrode. Recovery rates were specified as 95%–105% with an LOD of 0.05 mg/L. Water samples were collected from small-scale central water supply systems and tube wells with handy pumps and were processed using standard methods, similar to the urine samples. Quality assurance validation was reported. A blind professional examiner evaluated the children for dental fluorosis using Dean's Index. All urine and water samples were above the LOD. Urine levels were the primary exposure measure used in the analysis. The study authors did not account for urinary dilution in the spot samples. The mean urine fluoride concentration was correlated with the dental fluorosis levels.
    - *Direction/magnitude of effect size:* Spot urine samples that did not account for dilution could have exposure misclassification. The misclassification is likely non-differential, and the potential direction of bias is unknown.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that exposure was consistently assessed using well-established methods that directly measure exposure.

- ***Outcome:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* IQ was determined using the Combined Raven's Test–The Rural in China (CRT-RC3) (++ for methods). Although blinding was not reported, it is unlikely that the IQ assessors had knowledge of the children's urine levels or even of the water levels from the four sites, as these were sent to a separate lab for testing (+ for blinding). Overall rating for methods and blinding = +.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the outcome was assessed using instruments that were valid and reliable in the study population, and that the outcome assessors were blind to participants' fluoride exposure.
- ***Selective Reporting:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* All outcomes outlined in the abstract, introduction, and methods are reported in sufficient detail.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that all measured outcomes were reported.
- ***Other potential threats:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:*
    - *Statistical analyses:* Statistical analyses were reasonable (ANOVA and multiple linear regression), but consideration of homogeneity of variance was not reported. The NASEM committee's review (NASEM 2021) pointed out a potential concern regarding the lack of accounting for clustering at the school level because children were selected from four elementary schools. However, as outlined in the ***Selection*** domain, the authors stated that they followed the principles of matching social and natural factors like economic situation, educational standards, and geological environments to the extent possible and that the four elementary schools appeared to be very similar in teaching quality. There is no evidence that the sampling strategy was otherwise accounted for (i.e., via sampling weights). The impact of these factors on the effect estimates is expected to be minimal given the use of individual-level data and adjustment for age as a key covariate.
    - *Other potential concerns:* None identified.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the statistical analyses were appropriate and that there were no other potential threats of risk of bias.
- ***Basis for classification as low risk-of-bias study overall:*** Probably low risk-of-bias ratings in exposure and outcome. Study strengths include individual exposure measurements, but the study is limited by the cross-sectional study design, lack of accounting for urine dilution, and lack of consideration of sex as a key covariate.

E.1.6. Green et al. (2019)

E.1.6.1. Study Details

- ***Study design:*** Prospective cohort
- ***Population:*** Maternal-Infant Research on Environmental Chemicals (MIREC) participants (pregnant mothers and their children aged 3–4 years)
- ***Study area:*** 10 cities, Canada
- ***Sample size:*** 512 mother-child pairs (238 from non-fluoridated areas, 162 from fluoridated areas; 264 females, 248 males)
- ***Data relevant to the review:*** Adjusted linear regression models evaluating associations between IQ in both sexes together and separately, with maternal urinary fluoride across all three trimesters or with estimated maternal fluoride intake.
- ***Reported association with fluoride exposure:*** Yes: Significantly lower full-scale IQ per 1-mg/L increase in maternal urinary fluoride in boys (adjusted $\beta = -4.49$) but not girls (adjusted $\beta = 2.40$) and not in both sexes combined (adjusted $\beta = -1.95$); significantly lower full-scale IQ per 1-mg increase in maternal intake in both sexes combined (adjusted $\beta = -3.66$ [no sex interaction]); significantly lower full-scale IQ per 1-mg/L increase in drinking water fluoride in both sexes combined (adjusted $\beta = -5.29$ [no sex interaction]).

E.1.6.2. Risk of Bias

- **Author contacts:**
  - Authors were contacted in June 2019 for additional information for the risk-of-bias evaluation.
- ***Population selection:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Pregnant women were recruited from the same population during the same time frame and using the same methods as the MIREC program. Methods were reported in detail.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that the exposed groups were similar and were recruited with the same methods during the same time frame.
- ***Confounding:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* The study considered several possible covariates, including maternal age, pre-pregnancy BMI, marriage status, birth country, race, maternal education, employment, income, HOME score, smoking during pregnancy, secondhand smoke in the home, alcohol consumption during pregnancy, parity, sex, age at testing, gestational age, birth weight, time of void, and time since last void. The study also conducted secondary analyses to test for lead, mercury, arsenic, and PFOA. There is no indication of any other potential co-exposures in this study population. Iodine deficiency or excess could not be assessed but is not expected

to differentially occur. The study was not able to assess parental IQ or mental health disorders. Methods used to obtain the information included questionnaires and laboratory tests.

- *Potentially important study-specific covariates:* All key covariates were addressed.
  - *Direction/magnitude of effect size:* Not applicable.
- *Basis for rating:* Probably low risk of bias based on indirect evidence that the methods used to collect the information were valid and reliable and direct evidence that key covariates, including potential co-exposures, were addressed.

- ***Attrition:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Of the 610 recruited children, 601 (98.5%) completed testing. Of the 601 mother-child pairs, 512 (85.2%) had all three maternal urine samples and complete covariate data, and 400 (66.6%) had data available to estimate fluoride intake.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that exclusion of subjects from analyses was adequately addressed, and reasons were documented when subjects were removed from the study or excluded from analyses.
- ***Exposure:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Spot urine samples from all three trimesters of pregnancy were evaluated using appropriate methods, and results were adjusted for creatinine and specific gravity. Fluoride intake was estimated based on fluoride water levels, and information on consumption of tap water and other water-based beverages (e.g., tea, coffee) was obtained via questionnaire.
    - *Direction/magnitude of effect size:* There is not any specific direction or magnitude of bias expected. Urinary fluoride levels are reflective of a recent exposure. Having measurements from all three trimesters of pregnancy provides a better representation of actual exposure than a single measurement, although the potential for missed high exposure is possible. However, the possibility of the occurrence of missed high exposure would be similar in all females and would be non-differential. For the fluoride intake, exposure was based on the fluoride levels in the water at the residence. If women worked outside the home and the majority of intake occurred from areas outside the home (and were different from levels in the home), there is potential to bias toward the null.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that exposure was consistently assessed using well-established methods that directly measured exposure.
- ***Outcome:***
  - *Rating:* Probably low risk of bias (+)

  - *Summary:* The Wechsler Preschool and Primary Scale of Intelligence was normalized for ages 2.5–<4.0 and sex using the U.S population-based norms. Blinding was not reported, but it is unlikely that the outcome assessors had knowledge of the maternal fluoride level or were aware of whether the city had fluoridated water.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the outcome was assessed using instruments that were valid and reliable in the study population, and that the outcome assessors were blind to participants' fluoride exposure.
- ***Selective Reporting:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* All outcomes were reported.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that all measured outcomes were reported.
- ***Other potential threats:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:*
    - *Statistical analyses:* Multivariate linear regression analyses were used to evaluate the associations between maternal urinary fluoride and fluoride intake and children's IQ scores. Regression diagnostics were used to test assumptions for linearity, normality, and homogeneity. There were no potential influential observations (based on Cook's distance). Sensitivity analyses showed that the effects of maternal urinary fluoride (MUF), fluoride intake, and water fluoride were robust to the exclusion of two very low IQ scores in males (<70). City was accounted for as a covariate in the regression models published. Additional models with city as a random effect were also subsequently made publicly available and showed similar results to the main model.
    - *Other potential concerns:* None identified.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that the statistical analyses were appropriate and there were no other potential threats of risk of bias identified.
- ***Basis for classification as low risk-of-bias study overall:*** Probably low risk-of-bias ratings in confounding, exposure, and outcome. Study strengths include individual exposure measurements, prospective cohort design, and the consideration of key covariates.

E.1.7. Rocha-Amador et al. (2007)

E.1.7.1. Study Details

- ***Study design:*** Cross-sectional
- ***Population:*** Children aged 6–10 years

- ***Study area:*** Moctezuma (low fluoride, low arsenic) and Salitral (high fluoride, high arsenic) of San Luis Potosí State and 5 de Febrero (high fluoride, high arsenic) of Durango State, Mexico
- ***Sample size:*** 132 children
- ***Data relevant to the review:*** Associations between full-scale IQ, performance IQ, verbal IQ, and child's urine or water fluoride levels.
- ***Reported association with fluoride exposure:*** Yes: Significant associations between log-transformed fluoride and IQ scores (full-scale IQ adjusted βs of −10.2 [water] and −16.9 [urine]; CIs not reported); arsenic also present, but the effect from arsenic was smaller (full-scale IQ adjusted βs of −6.15 [water] and −5.72 [urine]; CIs not reported).

E.1.7.2. Risk of Bias

- **Author contacts:**
  - Authors were not contacted for additional information because it was not necessary.
- ***Population selection:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* All children in 1st through 3rd grades in three rural areas in Mexico (n = 480) were screened for study eligibility, including age, time at residence, and address. Authors report that the three selected communities were similar in population and general demographic characteristics. Children who had lived in the area since birth and were 6–10 years old were eligible to participate (n = 308). Of the 308 children, 155 were randomly selected and the response rate was 85%, but participation was not reported by area. It was noted, however, that no significant differences in age, sex, or time of residence were observed between participants and non-participants. Time frame for selection was not mentioned but appears to be similar. Sociodemographic characteristics of subjects was provided in Table 1 of the study. There was a significant difference in SES and transferrin saturation, but these were considered in the analysis.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the populations were similar, and differences were noted and addressed in the analysis.
- ***Confounding:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* The study design or analysis accounted for age, sex, SES, transferrin saturation, weight, height, blood lead levels, and mother's education. Arsenic levels were highly correlated with fluoride levels; however, arsenic and fluoride were evaluated alone, and arsenic was found to have less of an effect on IQ than fluoride. This provides evidence that arsenic had been addressed as a co-exposure and cannot explain the association between fluoride exposure and decreased IQ. Smoking was not addressed and methods for measuring many of the covariates were not reported.

- *Potentially important study-specific covariates:* Arsenic
  - *Direction/magnitude of effect size:* The presence of arsenic in this study, which also demonstrated an association, would likely bias the association away from the null. Although arsenic may contribute to some of the magnitude of the observed effect of fluoride (the exact impact of arsenic on the magnitude cannot be assessed), the presence of arsenic does not fully explain the observed association between fluoride exposure and IQ. The presence of arsenic may affect the magnitude of the association between fluoride and IQ, but it has no impact on the direction of the association.
- *Basis for rating:* Probably low risk of bias based on indirect evidence that the methods used to collect the information were valid and reliable and direct evidence that key covariates were addressed.

- ***Attrition:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Of 155 children randomly selected for study participation, 85% responded to enroll. According to the authors, there were no significant differences in age, sex, or time of residence between responders and non-responders. However, no data were provided to support this, and no breakdown of responders/non-responders by region was provided. Data were provided for the 132 children agreeing to participate.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that exclusion of subjects from analyses was adequately addressed, and reasons were documented when subjects were removed from the study or excluded from analyses.
- ***Exposure:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Urine samples were collected on the same day as psychological evaluations and were analyzed for fluoride according to NIOSH Method 8308 (Fluoride in Urine). For QC, a reference standard was also used (NIST SRM 2671a). Urine samples were also analyzed for arsenic by using the Atomic Absorption Spectrophotometer with hydride system and a reference standard for QC. Levels were adjusted for urinary creatinine levels to account for dilution in the spot samples. Tap water samples were collected from each child's home on the day of biological monitoring. Fluoride was measured with a sensitive, specific ion electrode. Detailed methods are provided including internal quality controls. It was noted that in the high fluoride group, it was common to drink bottled water low in fluoride and to use the tap water only for cooking; therefore, urine was considered the most appropriate measure of exposure. Only children who had lived at the same residence since birth were included.
    - *Direction/magnitude of effect size:* Not applicable.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that exposure was consistently assessed using well-established methods that directly measured exposure.

- ***Outcome:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Neuropsychological profiles were assessed through the WISC-RM (revised for Mexico). This is a well-established test appropriately adjusted for the study population. However, no additional validation was provided (+ for methods). The study report stated that the test assessors were masked to both arsenic and fluoride water levels (++ for blinding). Overall rating for methods and blinding = +.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the outcome was assessed using instruments that were valid and reliable in the study population, and that the outcome assessors were blind to participants' fluoride exposure.
- ***Selective Reporting:***
  - *Rating:* Probably high risk of bias (−)
  - *Summary:* It was reported that an interaction between fluoride and arsenic was measured, but it was noted only in the discussion that the study design precluded testing statistical interaction between fluoride and arsenic. This provides indirect evidence of selective reporting.
  - *Basis for rating:* Probably high risk of bias based on indirect evidence that there was selective reporting.
- ***Other potential threats:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:*
    - *Statistical analyses:* Statistical analyses used were appropriate for the study. Multivariate linear analyses were used to evaluate the associations between fluoride in water and urine and children's IQ scores. Exposures were natural log-transformed, but the rationale was not provided. Regression diagnostics were not used to test model assumptions for linearity, normality, and homogeneity. The analyses did not account for clustering at the community level. The three selected communities were similar in population and general demographic characteristics. Although the analysis used individual-level exposures rather than area-level exposures, if the exposure levels within a certain area were highly correlated (which might be expected), then the results might still be biased. However, the overall impact on the effect estimates is expected to be minimal given the use of individual-level data and adjustment for multiple important covariates.
    - *Other potential concerns:* None identified.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the statistical analyses were appropriate and there were no other potential threats of risk of bias identified.
- ***Basis for classification as low risk-of-bias study overall:*** Definitely or probably low risk-of-bias ratings in confounding, exposure, and outcome. Study strengths include

individual exposure measurements and blinding of outcome assessors to participants' fluoride exposure, but it is limited by the cross-sectional study design and the inability to completely rule out the influence of arsenic in the results.

E.1.8. Saxena et al. (2012)

E.1.8.1. Study Details

- ***Study design:*** Cross-sectional
- ***Population:*** Children aged 12 years
- ***Study area:*** Madhya Pradesh, India
- ***Sample size:*** 170 children
- ***Data relevant to the review:*** Mean IQ grade (not standard scores; higher IQ grades are associated with lower intelligence) by water fluoride quartiles, continuous water fluoride, or continuous urinary fluoride.
- ***Reported association with fluoride exposure:*** Yes: Significant correlations between IQ score and water (r = 0.534) and urinary (r = 0.542) fluoride levels. Significant increase in mean IQ grade (i.e., increase in proportion of children with intellectual impairment) with increasing urinary fluoride in adjusted analyses.

E.1.8.2. Risk of Bias

- **Author contacts:**
  - Authors were contacted in August of 2017 to obtain additional information for risk-of-bias evaluation.
- ***Population selection:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* There was indirect evidence that subjects were similar and were recruited using the same methods during the same time frame. The study participants were selected from a stratified cluster of geographic areas based on fluoride concentration in groundwater. According to the authors, the selected villages were similar in population and demographic characteristics. Data are provided to show the breakdown in SES, parental education, height/age, and weight/height, and no significant differences were noted. Participation was stated to be voluntary, but participation rates were not provided. It is unclear whether the 170 subjects were selected with 100% participation or whether the 170 subjects were all who were asked to participate, but it appears that all subjects participated. Timing of the recruitment was not provided but is assumed to occur during the same time frame.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that subjects were similar and recruited using the same methods during the same time frame.
- ***Confounding:***
  - *Rating:* Probably low risk of bias (+)

- *Summary:* There was indirect evidence that key covariates, including potential co-exposures, were addressed using reasonable methods. A questionnaire, completed with the assistance of parents, was used to collect information on child characteristics (age, sex, height, weight), residential history, medical history (including illness affecting the nervous system and head trauma), educational level of the head of the family (in years), and SES of the family. The SES was recorded according to the Pareek and Trivedi classification. The nutritional status of the children was calculated using Waterlow's classification, which defines two groups for malnutrition using height-for-age ratio (chronic condition) and weight for height ratio (acute condition). Within both groups, it categorizes the malnutrition as normal, mildly impaired, moderately impaired, or severely impaired. Urinary lead and arsenic were analyzed using the atomic absorption spectrophotometer. Urinary iodine was measured using the Dunn method. Authors do not report which covariates were included in the multivariate regression models; however, there was no difference in reported demographic characteristics. All subjects were the same age, and there was no difference in iodine, lead, or arsenic between the groups. Mean urinary arsenic levels increased with increasing fluoride even though there was no significant difference by group.
- *Potentially important study-specific covariates:* All key covariates were considered in this study.
  - *Direction/magnitude of effect size:* Not applicable.
- *Basis for rating:* Probably low risk of bias based on indirect evidence that the methods used to collect the information were valid and reliable and that key covariates, including potential co-exposures, were addressed.

- ***Attrition:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Results were provided for all 170 children stated to be included in the study.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence of no attrition.
- ***Exposure:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* A sample of 200 mL of drinking water was collected at each child's home. The fluoride levels were analyzed by a fluoride ion-selective electrode. Each subject was also asked to collect a sample of his/her first morning urine. The fluoride content in the urine was determined using a fluoride ion-selective electrode. QA/QC and LOD were not reported, and urinary dilution was not assessed. Although only current levels were measured, children who had changed their water source since birth were excluded.
    - *Direction/magnitude of effect size:* Spot urine samples that did not account for dilution could have exposure misclassification. The misclassification is likely non-differential and not likely to bias in any specific direction. Children who had changed water source since birth were excluded, but it was not

specifically noted that the fluoride in the water source was stable over the years.

- *Basis for rating:* Probably low risk of bias based on indirect evidence that exposure was consistently assessed using well-established methods that directly measured exposure.

- ***Outcome:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Intelligence was assessed using Raven's Standard Progressive Matrices and categorized into five grade levels. Although it was not noted that the test was validated to the study population, the test is visual and would be applicable to most populations (+ for methods). There is no mention of blinding by test administrators or evaluators, and the exposure groups come from different geographic areas. It was also not reported who measured the levels of fluoride from the home or urine samples. Correspondence with the study authors indicated that the outcome assessors were blind to the children's fluoride status (++ for blinding). Overall rating for methods and blinding = +.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the outcome was assessed using instruments that were valid and reliable in the study population, and that the outcome assessors were blind to participants' fluoride exposure.
- ***Selective Reporting:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* All outcomes outlined in the abstract, introduction, and methods are reported in sufficient detail.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that all measured outcomes were reported.
- ***Other potential threats:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:*
    - *Statistical analyses:* One-way analysis of variance (ANOVA), simple linear regression, and multiple linear regression were used to compare mean intelligence grades by water fluoride levels and to assess the association between grades and urinary fluoride. Consideration of heterogeneity of variance (for ANOVA) was not reported. Regression diagnostics were not used to test model assumptions for linearity, normality, and homogeneity. Given the ordinal nature of the intelligence grade variable (score from 1 to 5), ordinal logistic regression would have been a more appropriate method. There was no adjustment for area-level clustering in multivariate analyses (although subjects were selected via stratified cluster sampling from two areas). Although the analysis used individual-level exposures rather than area-level exposures, if the exposure levels within a certain area were highly correlated (which might be expected), then the results might still be biased. However, the

overall impact on the effect estimates is expected to be minimal given the use of individual-level data and adjustment for important covariates.

- *Other potential concerns:* None identified.

- *Basis for rating:* Probably low risk of bias based on indirect evidence that the statistical analyses were appropriate, and there were no other potential threats of risk of bias identified.

- ***Basis for classification as low risk-of-bias study overall:*** Probably low risk-of-bias ratings in confounding, exposure, and outcome. Study strengths include individual exposure measurements and the consideration of key covariates, but it was limited by the cross-sectional study design and lack of addressing dilution in the urine samples.

E.1.9. Seraj et al. (2012)

E.1.9.1. Study Details

- ***Study design:*** Cross-sectional
- ***Population:*** Children aged 6–11 years
- ***Study area:*** five villages, Makoo, Iran
- ***Sample size:*** 293 children
- ***Data relevant to the review:*** IQ (mean and distribution) assessed by Raven's Colored Progressive Matrices and presented by fluoride area; beta was also provided for water fluoride.
- ***Reported association with fluoride exposure:*** Yes: Significant association between water fluoride and IQ score (adjusted β per 1-mg/L increase in water fluoride = −3.865; CIs not reported); significantly higher IQ score in normal area (97.77 ± 18.91) compared with medium (89.03 ± 12.99) and high (88.58 ± 16.01) areas.

E.1.9.2. Risk of Bias

- **Author contacts:**
  - Authors were not contacted for additional information because it was not necessary.
- ***Population selection:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Subjects were selected from five villages in Makoo. The villages were stated to all be rural with similar general demographic and geographic characteristics and were comparable in terms of SES and parental occupations. Children were 6–11 years old. Age, sex, and education were taken into account in the analysis. No other characteristics were provided or discussed. Participation rates were not reported. There is indirect evidence that the populations were similar, and some possible differences were addressed.

- *Basis for rating:* Probably low risk of bias based on indirect evidence that subjects were similar and recruited using the same methods during the same time frame.

- ***Confounding:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Age, sex, dental fluorosis intensity, and educational levels (child's and parents') were evaluated as important covariates. Other covariates such as smoking were not discussed. Information was obtained from a detailed questionnaire. Lead was measured but found only in low levels in the drinking water throughout the study regions. Iodine in the water was also stated to be measured, and residents were receiving iodine-enriched salt. Arsenic was not addressed, but there is no evidence that arsenic levels would vary across villages in this area. Based on water quality maps, co-exposure to arsenic is likely not a major concern in this area.
  - *Potentially important study-specific covariates:* Arsenic.
    - *Direction/magnitude of effect size:* Conceptually, if there were differential amounts of arsenic in the different villages, co-exposure to arsenic could bias the association, with the direction of the bias dependent on where the arsenic was present; however, arsenic was not expected to be a major concern in this study area based on water quality maps.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the methods used to collect the information were valid and that key covariates, including potential co-exposures, were addressed or were not likely to be an issue in the study area.

- ***Attrition:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Attrition was low if it occurred. It was noted that 293 out of 314 children living in the villages were recruited. It is not clear whether 21 children were excluded based on exclusion criteria or whether they refused to participate; however, this accounts for less than 10% of the population, and results were available for all 293 subjects.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that exclusion of subjects from analyses was minimal, adequately addressed, and reasons were documented when subjects were removed from the study or excluded from analyses.

- ***Exposure:***
  - *Rating:* Probably high risk of bias (−)
  - *Summary:* Exposure was primarily based on area of residence. Fluoride in the groundwater was analyzed by the SPADNS (Sulfophenylazo dihydroxynaphthalene-disulfonate) method, utilizing the 4000 UV-Vis spectrophotometer in the environmental health engineering laboratory of the Public Health School of the Tehran University of Medical Sciences. Specific details were not provided on methods of collection or sample locations or whether

these locations represented the primary sources of drinking water for the subjects. Villages were categorized into normal (0.5–1 ppm), moderate (3.1 ± 0.9 ppm), and high (5.2 ± 1.1 ppm) fluoride based on the mean fluoride content of all seasons presumably for the stated 12-year time period. Subjects were stated to be long-life residents of the village. Dental fluorosis was also measured and increased in severity with fluoride levels; however, all areas had some degree of dental fluorosis. Although authors used an average fluoride level in varying seasons over presumably 12 years, they used a less-established method without reporting reliability or validity, and they did not provide data to indicate that the mean was truly representative of the fluoride levels over time and throughout the village. Although dental fluorosis severity increased with increasing fluoride levels, the data could also indicate potential exposure misclassification.

        - *Direction/magnitude of effect size:* The presence of dental fluorosis in all groups indicates that there may have been different exposures in some children at a younger age. Although there were only about 20 children in the "normal" fluoride group with very mild to mild dental fluorosis, this could bias the results toward the null because those children may have experienced a higher level of fluoride at some point. The other two fluoride groups were exposed to fluoride levels that likely exceeded those in the "normal" fluoride group.
    - *Basis for rating:* Probably high risk of bias based on indirect evidence that exposure was assessed using insensitive methods.

- ***Outcome:***
    - *Rating:* Probably low risk of bias (+)
    - *Summary:* Intelligence was evaluated using Raven's Color Progressive Matrices. This is a well-established method. Although the study authors did not provide data to indicate that the methods were valid in this study population, the test is designed to be culturally diverse (+ for methods). The study report stated that test administrators were blinded to subjects' exposure status (++ for blinding). Overall rating for methods and blinding = +.
    - *Basis for rating:* Probably low risk of bias based on indirect evidence that outcomes were assessed using instruments that were valid and reliable in the study population, and that the outcome assessors were blind to participants' fluoride exposure.
- ***Selective Reporting:***
    - *Rating:* Probably low risk of bias (+)
    - *Summary:* All outcomes outlined in the abstract, introduction, and methods were reported. However, because the study author did not report the method for obtaining the betas in Table 4 of the study, it is not clear whether these were adjusted or unadjusted regression coefficients.
    - *Basis for rating:* Probably low risk of bias based on direct evidence that all the study's measured outcomes were reported, but the results were not sufficiently reported.

- ***Other potential threats:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:*
    - *Statistical analyses:* Statistical methods for comparisons of IQ level by exposure groups were reasonable (ANOVA, post hoc test, and Kruskal-Wallis test), but consideration of heterogeneity of variance was not reported. Clustering at the village levels was not accounted for in multivariate analyses, which used area-level water fluoride levels. Because the exposure levels within a certain area are highly correlated (which might be expected), the results are likely to be biased. There was adjustment for some individual-level important covariates, and the children were from five rural areas with similar general demographic and geographic characteristics and were comparable in terms of SES and parental occupations. These factors are expected to mitigate some of the impact of lack of accounting for clustering, and the overall impact on the effect estimates is expected to be minimal.
    - *Other potential concerns:* None identified.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the statistical analyses were appropriate and there were no other potential threats of risk of bias identified.
- ***Basis for classification as low risk-of-bias study overall:*** Probably low risk-of-bias ratings in confounding and outcome. Study strengths include addressing potential key covariates, but it was limited by the cross-sectional study design and the group-level exposure data.

E.1.10. Soto-Barreras et al. (2019)

E.1.10.1. Study Details

- ***Study design:*** Cross-sectional
- ***Population:*** Children aged 9–10 years
- ***Study area:*** Chihuahua, Mexico
- ***Sample size:*** 161 children
- ***Data relevant to the review:*** Water fluoride, urinary fluoride, exposure dose, and dental fluorosis index by IQ grade.
- ***Reported association with fluoride exposure:*** No: Results were not presented to evaluate an association between fluoride exposure and IQ but to compare fluoride levels within IQ grades. For this reason, the results of this study are not comparable to other studies that evaluated IQ scores by fluoride exposure levels. No significant differences in measured fluoride levels across IQ grades were observed.

E.1.10.2. Risk of Bias

- **Author contacts:**
  - Authors were not contacted for additional information because it was not necessary.

- ***Population selection:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Subjects were selected using a multistage cluster sampling. During the first stage, 13 public elementary schools were randomly selected from a pool of 73 using a cluster sample design. Secondly, only fourth-grade students were included. Authors stated that they wanted to keep the same grade level, but there were no specific details as to why fourth graders were selected as opposed to any other grade. Lastly, only children whose parents or guardians attended and responded to the survey were included. There is no information provided on how the 13 schools selected may have been similar to or different from the 60 schools not selected. There is no information provided on the number of children in the fourth grade to know participant rates. It was only noted that 245 children were examined, but 161 were included after the exclusion rules were applied. Inclusion and exclusion criteria are presented. Reasons for exclusion do not appear to be related to exposure or outcome. Characteristics of participants and non-participants are not compared; however, characteristics of the 161 included children were provided, and any differences were taken into account in the analysis.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the exposed groups were similar and were recruited using similar methods during the same time frame.
- ***Confounding:***
  - *Rating:* Probably high risk of bias (−)
  - *Summary:* No covariates were considered when evaluating associations between fluoride exposure and intelligence; covariates were considered only when evaluating associations between fluoride levels and dental caries. According to Table 4 of the study, there was no significant association between IQ grade and age, sex, parental education, or SES status. No other information was reported or considered. There is no information on potential co-exposures. According to water quality maps, the arsenic prediction indicates a greater than 50% probability of exceeding the WHO guidelines for arsenic of 10 µg/L in areas of Chihuahua, Mexico.
  - *Potentially important study-specific covariates:* Arsenic.
    - *Direction/magnitude of effect size:* The impact on the direction and magnitude of effect size is unknown. There is potential for arsenic to occur in the study area, but it is not known how it relates to fluoride exposure. If they occur together in the water, it would likely bias the association away from the null; however, if they occur in different areas, there is potential to bias the association toward the null.
  - *Basis for rating:* Probably high risk of bias based on indirect evidence that there is potential for exposure to arsenic that was not sufficiently addressed.
- ***Attrition:***
  - *Rating:* Definitely low risk of bias (++)

- *Summary:* A total of 161 of 245 children were included in the study. Exclusion criteria are presented and are unrelated to outcome or exposure. For the 161 children, there are no missing outcome data.
- *Basis for rating:* Definitely low risk of bias based on direct evidence that exclusion of subjects from analyses was adequately addressed, and reasons were documented when subjects were removed from the study or excluded from analyses.

- ***Exposure:***
  - *Rating:* Probably low risk of bias (+); Probably high risk of bias (−)
  - *Summary:* **Urinary Fluoride (probably low risk of bias):** First morning void urine samples were collected based on NIOSH methods. Water samples were also stated to be collected, but it does not appear that methods followed any particular standard, and there is no indication that subjects were provided with collection containers. Analysis was based on a calibration curve using fluoride ion-selective electrode. QC methods were mentioned. Based on results, there were values below detection limits, but LODs or % below LOD were not reported.

    Daily fluoride exposure (probably high risk of bias): Daily fluoride exposure was based on the water fluoride level, drinking water consumption (based on parental report of how many glasses of water consumed), and body weight.

    - *Direction/magnitude of effect size:* Spot urine samples that did not account for dilution could have exposure misclassification. The misclassification is likely non-differential and is not likely to bias in any specific direction. Daily exposure was based partially on parental report of water consumption. The direction and magnitude of effect is unknown.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that exposure was consistently assessed using well-established methods that directly measured exposure. The daily fluoride exposure is probably high risk of bias because there is indirect evidence that the exposure was assessed using methods of unknown validity.

- ***Outcome:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Intellectual ability was evaluated using Raven's Colored Progressive Matrices by an independent examiner. Some details were provided, but it was not stated that the tests were assessed blind; however, there is no indication that subjects were from high fluoride areas, and the assessor would not have knowledge of the urine or water fluoride levels. Results for children were converted into a percentile according to age (details not provided), and overall scores were assigned an intellectual grade of I to V as described in the report.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the outcome was assessed using instruments that were valid and reliable in the study population, and that the outcome assessor was blind to participants' fluoride exposure.

- ***Selective Reporting:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* All outcomes outlined in the abstract, introduction, and methods were reported in sufficient detail.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that all measured outcomes were reported.
- ***Other potential threats:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:*
    - *Statistical analyses:* The Kolmogorov-Smirnov test was used to determine variable distribution. The Kruskal-Wallis test was used to compare exposure levels between IQ grades with Dunn's post hoc test. Multivariate logistic regression was used to estimate the association between presence of dental caries and various risk factors. Fluoride levels in drinking water and urine and fluoride exposure dose were compared across intellectual grades. Children were from 13 schools selected via stratified cluster sample design. There was no adjustment for clustering at the school level or for the sampling design. Although the analysis used individual-level exposures rather than area-level exposures, if the exposure levels within a certain school were highly correlated (which might be expected), then the results might still be biased. The large number of clusters (13 schools) makes clustering less of a concern, and the impact on the effect estimates is expected to be minimal.
    - *Other potential concerns:* None identified.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the statistical analyses were appropriate and there were no other potential threats of risk of bias identified.
- ***Basis for classification as low risk-of-bias study overall:*** Probably low risk-of-bias ratings in exposure and outcome. Study strengths include individual exposure measurements and blinding of outcome assessor to participants' fluoride exposure, but it is limited by the cross-sectional study design, lack of accounting for urine dilution, and lack of consideration for potential exposures to arsenic in the study area. Although the study is considered to have low potential for bias overall, the focus of the study was to evaluate the relationship between fluoride exposure and lower rates of dental caries. In terms of evaluating an association between fluoride exposure and IQ scores, the study is limited by the way the data were reported.

E.1.11. Sudhir et al. (2009)

E.1.11.1. Study Details

- ***Study design:*** Cross-sectional
- ***Population:*** Children aged 13–15 years
- ***Study area:*** Nalgonda district (Andhra Pradesh), India

- ***Sample size:*** 1,000 children
- ***Data relevant to the review:*** Mean IQ grade (not standard scores) or IQ distribution by water fluoride strata (<0.7, 0.7–1.2, 1.3–4.0, and >4.0 ppm).
- ***Reported association with fluoride exposure:*** Yes: Significant increase in mean and distributions of IQ grades (i.e., increase in proportion of children with intellectual impairment) with increasing drinking water fluoride levels.

E.1.11.2. Risk of Bias

- **Author contacts:**
  - Authors were contacted in September of 2017 for additional information related to risk-of-bias evaluation, but no response was received.
- ***Population selection:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Children were selected from the same general population during the same time frame and were then broken down into nearly equal exposure groups. A cross-sectional study was conducted among 13–15-year-old school children of Nalgonda district, Andhra Pradesh, between August and October 2006. Data were collected from the school children who were lifelong residents of Nalgonda district, Andhra Pradesh, and who consumed drinking water from the same source during the first 10 years of life. A stratified random sampling technique was used. The entire geographical area of Nalgonda district was divided into four strata based on different levels of naturally occurring fluoride in the drinking water supply. Children were randomly selected from schools in the different strata. It was noted that the 1,000 selected children were equally divided among all four strata; however, each group did not have 250 children (rather, each had 243–267). Participation rates were not reported. Exclusion criteria included children who had a history of brain disease and head injuries, children whose intelligence had been affected by congenital or acquired disease, children who had migrated or were not permanent residents, children with orthodontic brackets, and children with severe extrinsic stains on their teeth. Age and sex data are presented in Table 1 of the study, but this information is not presented by the different fluoride groups.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that subjects were similar and were recruited using the same methods during the same time frame.
- ***Confounding:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Data were collected using a self-administered questionnaire and clinical examination. The questionnaire requested information on demographic data (appears to cover age and sex), permanent residential address, staple food consumed, liquids routinely consumed, and aids used for oral hygiene maintenance (fluoridated or non-fluoridated). SES was measured using the Kakkar socioeconomic status scale (KSESS) with eight closed-ended questions

related to parental education, family income, father's occupation, and other factors. All children were asked to fill out the form, and the answers obtained were scored using Kakkar socioeconomic status scoring keys. Based on this scoring, children were divided into three groups: lower class, middle class, or upper class. Age, sex, and SES were not found to be significantly associated with IQ. Other covariates, including smoking, were not addressed. Co-exposures such as arsenic and lead were not addressed; however, there is no indication that lead is a co-exposure in this population, and arsenic is not likely a major concern in this area based on water quality maps.

- *Potentially important study-specific covariates:* Key covariates age, sex, and measures of SES were similar between exposure groups; however, arsenic was not considered. Arsenic often occurs in the drinking water along with fluoride in some Indian populations; however, based on water quality maps, this does not appear to be an issue in the Nalgonda district of Andhra Pradesh. Iodine deficiencies are not mentioned.
  - *Direction/magnitude of effect size:* Conceptually, the presence of arsenic would potentially bias the association away from the null if present with fluoride. Deficiencies in iodine would likely bias the association away from the null if present in areas of high fluoride but toward the null if present in areas of non-high fluoride. Neither of these were considered issues in this study for reasons noted above.
- *Basis for rating:* Probably low risk of bias based on indirect evidence that the key covariates were considered, co-exposure to arsenic was likely not an issue in this area, and methods used for collecting the information were valid and reliable.

- ***Attrition:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Results were available for the 1,000 children selected to participate.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence of no attrition.
- ***Exposure:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Children were placed into one of four strata based on the level of fluoride in drinking water. Collection of water samples was done in the districts. The placement into strata was based on fluoride levels obtained from documented records of the District Rural Water Works Department. Once the children were assigned to strata, it was confirmed that the fluoride level of their drinking water was within the strata assigned. This was done using the methodology followed in the National Oral Health Survey and Fluoride Mapping 2002–2003. During the initial visits to the schools, the children were interviewed regarding their history of residence and source of drinking water from birth to 10 years. The first child meeting the criteria was given a bottle for water collection, and the next child was given a bottle for collection only if the water source was different from that of a previous child. Children were asked to collect a water sample from the source that

was used in the initial 10 years of their life (and that sample was collected the next day). It was not reported whether all bottles were returned. The water samples collected were subjected to water fluoride analysis using an ion-specific electrode, Orion 720A fluoride meter at District Water Works, Nalgonda to confirm the fluoride levels in the water before commencement of clinical examination. LOD and QA/QC details were not reported.

        - *Direction/magnitude of effect size:* There is some potential for exposure misclassification based on recall of the children on the source of water used in their first 10 years of life. The misclassification is likely non-differential and not likely to bias in any specific direction. Children who had changed water since birth were excluded, but it was not specifically noted that the fluoride in the water source was stable over the years.
    - *Basis for rating:* Probably low risk of bias based on indirect evidence that exposure was consistently assessed using well-established methods that directly measured exposure.

- ***Outcome:***
    - *Rating:* Probably high risk of bias (NR)
    - *Summary:* Raven's standard progressive matrices (1992 edition) was used to assess IQ. Raven's test is a standard test; although there is no information provided to indicate that the methods were reliable and valid in this study population, the test was created to be culturally fair (+ for methods). Blinding or other methods to reduce potential bias were not reported (NR for blinding). No response was received to an email request for clarification in September 2017. Overall rating for methods and blinding = NR.
    - *Basis for rating:* Probably high risk of bias based on indirect evidence that the outcome assessors were not blind to participants' fluoride exposure and could bias the results.
- ***Selective Reporting:***
    - *Rating:* Definitely low risk of bias (++)
    - *Summary:* All outcomes outlined in the abstract, introduction, and methods are reported in sufficient detail.
    - *Basis for rating:* Definitely low risk of bias based on direct evidence that all measured outcomes were reported.
- ***Other potential threats:***
    - *Rating:* Probably low risk of bias (+)
    - *Summary:*
        - *Statistical analyses:* Chi-square test and Spearman rank correlation were used to assess the association between four different fluoride levels and IQ grades. Area-level exposures were used. Clustering of children within the four areas was not accounted for in the analysis; however, because multiple villages were included in each fluoride exposure level, clustering was less of a concern and the impact on the effect estimates was expected to be minimal.

    - *Other potential concerns:* None identified.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the statistical analyses were appropriate and there were no other potential threats of risk of bias identified.
- ***Basis for classification as low risk-of-bias study overall:*** Probably low risk-of-bias ratings in confounding and exposure. Study strengths include verification of exposure measurements and consideration of key covariates, but it was limited by the cross-sectional study design and lack of information on blinding during outcome assessment.

E.1.12. Till et al. (2020)

E.1.12.1. Study Details

- ***Study design:*** Prospective cohort
- ***Population:*** MIREC participants (pregnant mothers and their children aged 3–4 years)
- ***Study area:*** 10 cities, Canada
- ***Sample size:*** 398 mother-child pairs (247 from non-fluoridated areas, 151 from fluoridated areas; 200 breastfed as infants, 198 formula-fed as infants)
- ***Data relevant to the review:*** Adjusted linear regression models evaluating associations between IQ and water fluoride concentration (with or without adjusting for maternal urine) in formula-fed or breastfed infants or fluoride intake from formula.
- ***Reported association with fluoride exposure:*** Yes: Significantly lower performance IQ with water fluoride per 0.5-mg/L increase by breastfeeding status (adjusted βs = −9.26 formula-fed, −6.19 breastfed) and fluoride intake from formula (adjusted β = −8.76); significantly lower full-scale IQ with water fluoride per 0.5-mg/L increase in formula-fed children (adjusted β = −4.40); no significant changes in full-scale IQ for water fluoride in breastfed children or fluoride intake from formula-fed children; no significant changes in verbal IQ scores with fluoride exposure.

E.1.12.2. Risk of Bias

- **Author contacts:**
  - Authors were not contacted for additional information because it was not necessary.
- ***Population selection:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Pregnant women were recruited between 2008 and 2011 by the MIREC program from 10 cities across Canada. Inclusion and exclusion criteria were provided. Additional details were stated to be available in Arbuckle et al. (2013). A total of 610 children were recruited to participate in the developmental follow-up with 601 children completing all testing. The demographic characteristics of women included in the current analyses (n = 398) were not

substantially different from the original MIREC cohort (n = 1,945) or the subset without complete water fluoride and covariate data (n = 203). A table of characteristics of the study population was provided. Approximately half of the children lived in non-fluoridated cities and half lived in fluoridated cities.

- *Basis for rating:* Definitely low risk of bias based on direct evidence that the exposed groups were similar and were recruited with the same methods during the same time frame.

- ***Confounding:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Covariates were selected a priori that have been associated with fluoride, breast feeding, and children's intellectual ability. Final covariates included sex and age at testing, maternal education, maternal race, secondhand smoke in the home, and HOME score. City was considered but excluded from the models. Covariates that were not assessed include parental mental health, iodine deficiency/excess, parental IQ, and co-exposure to arsenic and lead. Co-exposure to arsenic is less likely an issue in this Canadian population because it receives water mainly from municipal water supplies that monitor for lead and arsenic, and the lack of information is not considered to appreciably bias the results. In addition, a previous study on this population (Green et al. 2019) conducted sensitivity analyses on co-exposures to lead and arsenic. Results from these sensitivity analyses support the conclusion that co-exposures to lead and arsenic are not likely a major concern in this study population.
  - *Potentially important study-specific covariates:* All key covariates were considered in this study.
    - *Direction/magnitude of effect:* Not applicable.
  - *Basis for rating:* Probably low risk of bias based on direct evidence that key covariates were considered and indirect evidence that the methods used to collect the information were valid and reliable and co-exposures were not an issue.

- ***Attrition:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Of 610 children, 601 (98.5%) in the MIREC developmental study who were ages 3–4 years completed the neurodevelopment testing. Of the 601 children who completed the neurodevelopmental testing, 591 (99%) completed the infant feeding questionnaire and 398 (67.3%) reported drinking tap water. It was noted that the demographic characteristics were not substantially different from the original MIREC cohort or the 203 subjects without complete water fluoride or covariate data.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that exclusion of subjects from analyses was adequately addressed, and reasons were documented when subjects were removed from the study or excluded from analyses.

- ***Exposure:***
  - *Rating:* Probably low risk of bias (+)

  - *Summary:* Information on breastfeeding was obtained via questionnaire at 30–48 months. Fluoride concentration in the drinking water was assessed by daily or monthly reports provided by water treatment plants. Water reports were first linked with mothers' postal codes, and the daily or weekly amounts were averaged over the first 6 months of each child's life. Additional details can be found in Till et al. (2018). Maternal urinary exposure was used to assess fetal fluoride exposure. Procedures can be found in Green et al. (2019).
    - *Direction/magnitude of effect size:* There is not any specific direction or magnitude of bias expected. Urinary fluoride levels are reflective of recent exposure. The possibility of exposure misclassification would be similar in all subjects and would be non-differential. For the fluoride intake from formula, exposure was based on the fluoride levels in the water at the residence and the proportion of time that the infant was not exclusively breastfed. This exposure misclassification would also be non-differential.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that exposure was consistently assessed using well-established methods that directly measured exposure.
- ***Outcome:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Intelligence was tested using the Wechsler Preschool and Primary Scale of Intelligence III, which is considered a gold standard test. It is appropriate for both the study population and age group. It was not reported whether the evaluators were blind to the child's fluoride exposure status during the assessment. Although it is unlikely that the assessors had knowledge of the specific drinking water levels or maternal urine levels, there is potential that the outcome assessors had knowledge of the city the child lived in and whether the city was fluoridated or non-fluoridated. Correspondence with the study authors on the outcome assessment for Green et al. (2019) indicated that it was unlikely that the testers had knowledge of the city's fluoridation. The same is assumed here. Specific measurements included were identified.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the outcome was assessed using instruments that were valid and reliable in the study population, and that the outcome assessors were blind to participants' fluoride exposure.
- ***Selective Reporting:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* All outcomes outlined in the abstract, introduction, and methods were reported in sufficient detail.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that all measured outcomes were reported.
- ***Other potential threats:***
  - *Rating:* Probably low risk of bias (+)

- *Summary:*
  - *Statistical analyses:* Regression diagnostics were used to test assumptions for linearity, normality, and homogeneity. There were two potential influential observations (based on Cook's distance), and sensitivity analyses re-estimated the models without these two variables. Effect modification by breastfeeding status was evaluated. Interestingly, all regression coefficients were divided by 2 to represent change in IQ per 0.5-mg/L change in fluoride. One concern is posed by the lack of accounting for city in the regression models, ideally as a random effect. The authors explored including city as a covariate in the models; however, city was not included either because it was strongly multi-collinear with water fluoride concentration (VIF > 20) (model 1, with water fluoride concentration) or because fluoride intake from formula is a function of water fluoride concentration (assessed at the city level) and was therefore deemed redundant (model 2). However, the models use city-level water fluoride concentrations—and, in sensitivity analyses, adjust for maternal urinary fluoride—which warrants exploration of city as a random effect rather than a fixed effect (as would be the case by having it included as a covariate). Even including individual-level maternal urinary fluoride might not fully account for lack of a city effect, given that the subjects were from six different cities, with half of them fully on fluoridated water. Hence, even individual-level exposures are likely to be correlated at the city level. Based on a previous analysis (Green et al. 2019), it is unlikely that exclusion of city from models (as a fixed or random effect) would significantly impact the effect estimates.
  - *Other potential concerns:* None identified.
- *Basis for rating:* Probably low risk of bias based on indirect evidence that the statistical analyses were appropriate and there were no other potential threats of risk of bias identified.

- ***Basis for classification as low risk-of-bias study overall:*** Probably low risk-of-bias ratings in confounding, exposure, and outcome. Study strengths include individual exposure measurements, prospective cohort design, and consideration of key covariates.

E.1.13. Trivedi et al. (2012)

E.1.13.1. Study Details

- ***Study design:*** Cross-sectional
- ***Population:*** Children aged 12–13 years
- ***Study area:*** Kachchh, Gujarat, India
- ***Sample size:*** 84 children
- ***Data relevant to the review:*** Mean IQ scores and distribution by low and high fluoride villages.

- ***Reported association with fluoride exposure:*** Yes: Significantly lower mean IQ score in the high fluoride villages (92.53 ± 3.13) compared with the low-fluoride villages (97.17 ± 2.54) in boys and girls combined (and by sex).

E.1.13.2. Risk of Bias

- **Author contacts:**
  - Authors were contacted in September of 2017 to obtain additional information for risk-of-bias evaluation.
- ***Population selection:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* There is insufficient information provided on the sampling methods to determine whether the populations were similar. Although it was noted that samples were obtained for groundwater quality from March to May of 2011, there is no indication that the children were selected at the same time or during a similar time frame. Correspondence with the author indicates that children were selected within a week of the water collection based on random selection of a school in the village. Study participants were selected from six different villages of the Mundra region of Gujarat, India. Subjects were grouped into high and low villages based on the level of fluoride in the drinking water of those villages. The number of subjects per village was not reported, but it was noted that there were 50 children in the low-fluoride group and 34 children in the high fluoride group. It is not clear whether the differences in numbers were based on different participation rates or whether there were fewer children in the high fluoride villages. Recruitment methods, including any exclusion criteria and participation rates, were not provided. SES was stated to be low and equal based on questionnaire information, but the results were not provided. It should also be noted that only regular students (having attendance more than 80%) of standard 6th and 7th grades were selected, but it was not noted whether attendance varied by village. Correspondence with the study author indicated that there was an average of 20 students per class with an average of 40 students per village. It appears that keeping the requirement of 80% attendance was a limiting factor that resulted in different numbers of children by area; however, this was applied similarly to both groups.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that subjects were similar and recruited using the same methods during the same time frame.
- ***Confounding:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Children were stated to be students of the 6th and 7th standard grades. Age was not addressed, but the children would all be of similar ages based on the grades included. Results were reported for males and females separately as well as combined. SES and iodine consumption were stated to be analyzed via a questionnaire and were standardized on the basis of the 2011 census of India. Although it was noted in the abstract that the SES was equal (no data provided),

the study report did not mention the iodine results. Although arsenic and lead were not considered, the study authors provided physicochemical analyses for the water samples from the six different villages. While the authors did not specifically analyze lead or arsenic in the water samples, these physicochemical analyses suggest that differential lead or arsenic exposure was unlikely. Moreover, based on water quality maps, arsenic was not expected to be a major concern in this study area. According to the information from the water quality maps and the physiochemical analysis of the water provided, there is indirect evidence that neither arsenic nor lead were a concern in this study population.

- *Potentially important study-specific covariates:* Key covariates age, sex, and measures of SES were similar between exposure groups; however, arsenic was not considered. Arsenic often occurs in the drinking water along with fluoride in some Indian populations; however, based on water quality maps, arsenic does not appear to be an issue in the study area.
  - *Direction/magnitude of effect size:* Conceptually, the presence of arsenic would potentially bias the association away from the null if present with fluoride, or toward the null if present in the reference group; however, for reasons noted above, arsenic is not considered a concern in this study population.
- *Basis for rating:* Probably low risk of bias based on indirect evidence that the methods used to collect the information were valid and reliable, that potential co-exposures were not an issue, and that key covariates were addressed.

- ***Attrition:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Results were provided for 84 children, but the methods do not indicate how many children were initially selected to participate, nor were any exclusion criteria provided. It was noted in the results that 84 children had their groundwater and urine tested, but it was not noted whether analyses were restricted to these children or whether exposures were assessed in all the children who had IQ measurements. Correspondence with the study author indicated that the main reason for exclusion was a <80% attendance rate, with fluoride and IQ measured on all 84 children who met the criteria.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence of no attrition.
- ***Exposure:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Children in villages were grouped based on fluoride levels that were assessed in groundwater (low fluoride villages versus high fluoride villages). The average concentration of these levels was considered to be the levels in the drinking water with confirmation using urinary fluoride levels. The groundwater samples were selected to cover major parts of the taluka and represent overall groundwater quality. Ten samples were obtained from each village. Fluoride was measured in the groundwater using ion exchange chromatography. Although urine

levels were also significantly higher in the high fluoride village, no information was provided on how or when the urinary samples were obtained or how they were measured. However, correspondence with the study author indicated that the groundwater and urine fluoride levels were available for all 84 children, indicating that the urine measures were available for the children that had IQ measures. The urine samples were stated to be collected at the same time the second water sample was collected.

    - *Direction/magnitude of effect size:* Fluoride levels were measured in both the drinking water and urine. Although there is some variability in the measurements, there is no overlap between the two groups, and the urine and drinking water levels in the children support each other. Any potential exposure misclassification would be non-differential, and the impact on the direction and magnitude of the effect size is unknown.

  - *Basis for rating:* Probably low risk of bias based on indirect evidence that exposure was consistently assessed using well-established methods that directly measured exposure.

- ***Outcome:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Outcome methods were only noted to be reported in Trivedi et al. (2007), which was scored as follows: IQ was measured in the children of both areas using a questionnaire prepared by Professor JH Shah, copyrighted by Akash Manomapan Kendra, Ahmedabad, India, and standardized on the Gujarati population with a 97% reliability rate in relation to the Stanford-Binet Intelligence Scale (+ for methods). Blinding or other methods to reduce bias were not reported, but correspondence with the study author indicated that the teachers were blind to the status of fluoride. The teachers administered the tests in the presence of a research fellow. It is not completely clear who scored the tests, but it is assumed the teachers (+ for blinding). Overall rating for methods and blinding = +.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the outcomes were assessed using instruments that were valid and reliable in the study population, and that the outcome assessors were blind to participants' fluoride exposure.
- ***Selective Reporting:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* All outcomes outlined in the abstract, introduction, and methods are reported in sufficient detail.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that all measured outcomes were reported.
- ***Other potential threats:***
  - *Rating:* Probably high risk of bias (−)
  - *Summary:*

        - *Statistical analyses:* Mean IQ scores in low and high fluoride villages were compared using a t-test. Consideration of heterogeneity of variances was not reported. Results are reported as means and standard errors of the means, with p-values for significant differences. Area-level exposures were used. There was no accounting for clustering of children within the villages, and comparative analyses did not account for covariates. Urinary fluoride was not considered in the comparative analyses. The lack of individual exposure levels and the lack of accounting for clustering are likely to bias the standard error of the difference in mean IQ levels between the high- and low-fluoride villages and make the differences appear stronger than they actually are.
    - *Basis for rating:* Probably high risk of bias based on indirect evidence that the statistical analyses did not account for clustering, and this lack of accounting could bias the association. There were no other potential threats of risk of bias identified.
- ***Basis for classification as low risk-of-bias study overall:*** Probably low risk-of-bias ratings in confounding, exposure, and outcome. Study strengths include individual exposure measurements and the addressing of potential key covariates, but the study was limited by the cross-sectional study design. Another limitation was the lack of accounting for clustering, which may bias the standard error of the differences, making the effect appear stronger than it actually is; however, this does not change the nearly 5-point difference in IQ scores between the two villages.

E.1.14. Wang et al. (2012)

E.1.14.1. Study Details

- ***Study design:*** Cross-sectional
- ***Population:*** Children aged 8–13 years [possibly the same study population as Xiang et al. (2003a)]
- ***Study area:*** Wamiao and Xinhuai villages located in Sihong County, Jiangsu Province, China
- ***Sample size:*** 526 school children
- ***Data relevant to the review:*** Mean IQ and % low IQ (<80) by total fluoride intake.
- ***Reported association with fluoride exposure:*** Yes: Significantly lower mean IQ in the endemic versus non-endemic regions, as reported in Xiang et al. (2003a); when the high-exposure group was broken into four exposure groups based on fluoride intake, a dose-dependent decrease in IQ and increase in % with low IQ was observed; significant correlation between total fluoride intake and IQ ($r = -0.332$); for IQ <80, adjusted OR of total fluoride intake per 1 mg/(person/day) was 1.106 (95% CI: 1.052, 1.163).

E.1.14.2. Risk of Bias

- **Author contacts:**
    - Authors were not contacted for additional information because it was not necessary.

- ***Population selection:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* The study appears to have the same study population as Xiang et al. (2003a) and Xiang et al. (2011); however, it does not cite these studies as providing additional information, and the numbers of children differ; therefore, it may be a separate analysis on the same villages. The years of testing were not provided, so it cannot be determined whether study subjects were the same. Two villages, Wamiao and Xinhuai, located 64 km apart in Sihong County, Jiangsu Province, were selected for the study. Wamiao is a village in a region with severe endemic fluorosis, and Xinhuai is a village in a non-endemic fluorosis region. Neither village has fluoride pollution from coal or industrial sources. Villages were stated to be similar in terms of annual per capita income, transportation, education, medical conditions, natural environment, and lifestyle. All primary students ages 8–13 years currently in school in either village were surveyed with exclusions noted. Of 243 children from Wamiao, 236 (97.12%) were included, and of 305 children from Xinhuai, 290 (95.08%) were included. No table of subject characteristics was provided.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the exposure groups were similar and were recruited using the same methods within the same time frame, with direct evidence that there was no difference in participation/response rates.
- ***Confounding:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Logistic regression of low IQ rate and total fluoride intake adjusted for age and sex. Both villages had hand-pumped well water for drinking water, but the authors do not mention whether arsenic was also present in the drinking water. However, a publication by Xiang et al. (2013) in the same study areas indicates that Xinhuai (the low-fluoride area) had significantly higher arsenic levels compared with Wamiao (the endemic fluorosis area), which would bias the association toward the null. Areas were stated to be similar in annual per capita income, transportation, education, medical conditions, natural environment, and lifestyle; however, no details were provided. This study did not address other co-exposures, but other studies on populations in these villages (Xiang et al. 2003a; Xiang et al. 2011) indicate that iodine and lead are not concerns.
  - *Potentially important study-specific covariates:* Arsenic often occurs in the drinking water along with fluoride in some Chinese populations; however, based on information provided in Xiang et al. (2013), arsenic concentrations were higher in the low-fluoride area compared with the high fluoride area. Because there were significant effects on IQ observed in the high fluoride areas, the impact of co-exposure to arsenic is less of a concern. The presence of arsenic in the control village may cause an underestimation of the effect of fluoride, but despite this potential impact, a significant association between fluoride exposure and IQ was reported.

        - *Direction/magnitude of effect size:* Presence of arsenic in this study population would potentially bias the association toward the null.
    - *Basis for rating:* Probably low risk of bias because there is indirect evidence that the key covariates were considered, methods used for collecting the information were valid and reliable, and co-exposures to arsenic and lead and iodine deficiency were not attributing to the association observed in this study. The potential for bias toward the null combined with the reported significant association increases confidence in the observed effect.

- ***Attrition:***
    - *Rating:* Probably low risk of bias (+)
    - *Summary:* Data are reported for all 526 children noted to be included in the study. There is a slight discrepancy in the reported total number of children from the high-fluoride village and the number of participants from the high-fluoride village between this paper (236 participated of 243 total children) and the 2003 and 2011 publications on the same study population (222 of 238). This discrepancy is not explained but is not expected to appreciably bias the results.
    - *Basis for rating:* Probably low risk of bias based on indirect evidence that exclusion of subjects from analyses was adequately addressed, and reasons were documented when subjects were removed from the study or excluded from analyses.

- ***Exposure:***
    - *Rating:* Probably low risk of bias (+); Probably high risk of bias (−)
    - *Summary:* **Water fluoride (+ probably low risk of bias):** Exposure was based on drinking water levels and fluoride intake. Residents in the Wamiao village were divided into five groups based on fluoride levels in the drinking water. Clean, dry polyethylene bottles were used to collect 50 mL of drinking water from each student's household, and fluoride content was measured.

      Total fluoride intake (− probably high risk of bias): Six families from each of the five Wamiao groups were randomly selected as dietary survey households. Intakes of various foods by each person at each meal and intakes of unboiled water, boiled water, and tea were surveyed for four consecutive days. Methods for food collection were described. Five representative households from each village were selected based on geographic location, population distribution, housing structure, and other conditions. Indoor air samples were collected once daily for five consecutive days; outdoor air was sampled at two points once daily for five days. Methods for determining fluoride content in samples were noted to follow specific guidelines. Calculation of total fluoride intake was stated to follow Appendix A of the People's Republic of China Health Industry Standard with some details provided. Although it is assumed the method is valid, it was not detailed how each fluoride determination was made for each subject, and it appears that total fluoride intake was determined based on data from select subjects and not all subjects.

        - *Direction/magnitude of effect size:* There is potential for exposure misclassification based on calculating fluoride intake based on measurements from a few select subjects rather than all subjects. The potential impact on the direction and magnitude of effect size cannot be assessed based on the information provided.
    - *Basis for rating:* Probably low risk of bias based on indirect evidence that exposure was consistently assessed using well-established methods that directly measured exposure. The total fluoride intake is probably high risk of bias because there is indirect evidence that the exposure was assessed using methods of unknown validity.
- ***Outcome:***
    - *Rating:* Definitely low risk of bias (++)
    - *Summary:* The IQ of each child was measured with the Combined Raven's Test for Rural China (CRT-RC) (++ for methods). The test was stated to be administered to the children independently in a school classroom under the supervision of three exam proctors. Testing methods, testing language, and testing conditions were all in strict accordance with the CRT-RC guidebook. Major testing personnel received necessary training by the Psychology Department of East China Normal University. The children undergoing IQ testing and the test scorers were kept double-blind throughout the testing process (++ for blinding). Overall rating = ++.
    - *Basis for rating:* Definitely low risk of bias based on direct evidence that the outcome was assessed using instruments that were valid and reliable in the study population, and that the outcome assessors were blind to participants' fluoride exposure.
- ***Selective Reporting:***
    - *Rating:* Definitely low risk of bias (++)
    - *Summary:* All outcomes outlined in the abstract, introduction, and methods are reported in sufficient detail.
    - *Basis for rating:* Definitely low risk of bias based on direct evidence that all measured outcomes were reported.
- ***Other potential threats:***
    - *Rating:* Probably low risk of bias (+)
    - *Summary:*
        - *Statistical analyses:* Logistic regression analysis was used to determine the odds of having low IQ with increasing fluoride intake. Analyses and methods are not well described. There is no mention of what tests were used for the mean IQ comparison by village; however, statistical software (SPSS) was used, suggesting appropriate tests were applied. Simple linear regression analyses were conducted to evaluate associations between total fluoride intake and children's IQ or low IQ rate. There is no evidence that regression diagnostics were used to test model assumptions for linearity, normality, and homogeneity. Clustering at the village level was not accounted for in the

analyses. The overall impact of these factors on effect estimates is expected to be minimal given the use of individual-level data and adjustment for important covariates.

- *Other potential concerns:* None identified.

- *Basis for rating:* Probably low risk of bias based on indirect evidence that the statistical analyses were appropriate and there were no other potential threats of risk of bias identified.

- ***Basis for classification as low risk-of-bias study overall:*** Definitely or probably low risk-of-bias ratings in confounding, exposure, and outcome. Study strengths include individual exposure measurements with blinding at outcome assessment, but is limited by the cross-sectional study design and lack of individual measurements to calculate fluoride intake. All key covariates were accounted for in the study design or analysis, but there is potential for the presence of arsenic to bias the association toward the null.

E.1.15. Wang et al. (2020b)

E.1.15.1. Study Details

- ***Study design:*** Cross-sectional
- ***Population:*** School children aged 7–13 years
- ***Study area:*** Tianjin City, China [possibly a subset of the children from Yu et al. (2018)]
- ***Sample size:*** 571 school children
- ***Data relevant to the review:*** IQ scores by urine and water fluoride levels.
- ***Reported association with fluoride exposure:*** Yes: Significant associations between IQ score and water fluoride (adjusted $\beta = -1.587$ per 1-mg/L increase) and urinary fluoride (adjusted $\beta = -1.214$ per 1-mg/L increase) in boys and girls combined based on both quartiles and continuous measures. No significant modification effect of sex.

E.1.15.2. Risk of Bias

- **Author contacts:**
  - Authors were not contacted for additional information because it was not necessary.
- ***Population selection:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Subjects were from a cross-sectional study conducted in 2015, but no citation was provided on this cohort [presumably the Yu et al. (2018) cohort]. It was noted that the subjects in that cohort were from districts with historically high or normal fluoride levels. Subjects for this study were selected by using a stratified and multistage random sampling approach. Brief description was provided. The study area consisted of three historically high fluoride areas and four non-endemic areas. A flow diagram was provided for inclusion and exclusion, but this detail was given for all children and not by area. Therefore, it

cannot be determined whether the participation differed by area. However, there was a 93% recruitment rate, and the 13 excluded due to missing data were not likely excluded due to exposure. Detailed characteristics of the study population are provided. Exclusion criteria included: "children who had congenital or acquired diseases affecting intelligence, or a history of cerebral trauma and neurological disorders, or those with a positive screening test history (like hepatitis B virus infection, Treponema palladium infection and Down's syndrome) and adverse exposures (smoking and drinking) during maternal pregnancy, prior diagnosis of thyroid disease, and children who had had missing values of significant factors (2.2%) were also excluded."

- *Basis for rating:* Definitely low risk of bias based on direct evidence that the exposed groups were recruited using similar methods during the same time frame and that any differences between the exposed groups were accounted for in the statistical analyses.

- ***Confounding:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Study authors noted that the study areas were not exposed to other neurotoxins such as lead, arsenic, or mercury nor were they iodine-deficient. Final models included age, sex, child's BMI, maternal and paternal education, household income, and low birth weight. The other covariates that were considered are unclear as the authors only noted that the covariates were selected based on current literature. Reasons for exclusion included history of disease affecting intelligence, history of trauma or neurological disorders, positive screening test history, or exposures such as smoking or drinking during pregnancy. Information was obtained by questionnaire or measurements. Covariates such as parental BMI, behavioral and mental health disorders, IQ, and quantity and quality of the caregiving environment were not considered.
  - *Potentially important study-specific covariates:* All key covariates were considered in this study.
    - *Direction/magnitude of effect size:* Not applicable.
  - *Basis for rating:* Probably low risk of bias because there is direct evidence that the key covariates were considered and indirect evidence that the methods for collecting the information were valid and reliable and that co-exposure to arsenic was not an issue in this area.

- ***Attrition:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* A detailed chart of the recruitment process is presented. The study had a 93% recruitment rate, and only 2.2% of subjects with missing data for certain covariates were excluded.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that exclusion of subjects from analyses was adequately addressed, and reasons were documented when subjects were removed from the study or excluded from analyses.

- ***Exposure:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Children provided spot urine samples, presumably at the time of examination. Water samples were randomly collected from public water supplies in each village. Fluoride concentrations were analyzed using fluoride ion-selective electrode according to the national standardized method in China. There is no indication of whether the urine samples accounted for dilution.
    - *Direction/magnitude of effect size:* Not accounting for dilution could cause some exposure misclassification. The impact on the direction and magnitude of effect size would depend on where the differences occurred.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that exposure was consistently assessed using acceptable methods that provide individual levels of exposure.
- ***Outcome:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Assessments of IQ scores were conducted by graduate students at the School of Public Health, Tongji Medical College, Huazhong University of Science and Technology. Each team member was assigned a single task, meaning that only one person would have conducted the IQ tests. A Combined Raven's Test for Rural China was used. Therefore, the test was appropriate for the study population (++ for method). It was noted that the examiner was trained and blind to the exposure (++ for blinding). Overall = ++
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that the outcome was assessed using instruments that were valid and reliable in the study population, and that the outcome assessor was blind to participants' fluoride exposure.
- ***Selective Reporting:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* All outcomes in the abstract, introduction, and methods are reported in sufficient detail.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that all measured outcomes were reported.
- ***Other potential threats:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:*
    - *Statistical analyses:* Logistic and multivariate regression models accounting for covariates were used. Results are presented as betas or ORs and 95% CIs. Regression diagnostics were conducted for all models, including examination of multicollinearity, heteroscedasticity, and influential observations. Mediation and interaction analyses were appropriate. There is no evidence that the stratified and multistage random sampling approach for subject selection was accounted for in the analyses by using sampling weights or

accounting for clustering using random effect models; however, selected villages were similar in population and general demographic characteristics. Given the use of individual-level data and adjustment for important covariates, the impact on the regression coefficients is likely to be minimal.

- *Other potential concerns:* None identified.

- *Basis for rating:* Probably low risk of bias based on indirect evidence that the statistical analyses were appropriate and no other potential threats of risk of bias were identified.

- ***Basis for classification as low risk-of-bias study overall:*** Definitely or probably low risk-of-bias ratings in confounding, exposure, and outcome. Study strengths include individual exposure measurements but is limited by the cross-sectional study design and lack of accounting for urine dilution. All key covariates were considered in the study design or analysis.

E.1.16. Xiang et al. (2003a)

E.1.16.1. Study Details

- ***Study design:*** Cross-sectional
- ***Population:*** Children aged 8–13 years
- ***Study area:*** Wamiao and Xinhuai villages located in Sihong County, Jiangsu Province, China
- ***Sample size:*** 512 school children
- ***Data relevant to the review:*** Comparison of IQ (mean and distribution) between Wamiao County (a severe endemic fluorosis area) and Xinhuai County (a non-endemic fluorosis area); additional breakdown of the Wamiao area into five water fluoride exposure groups.
- ***Reported association with fluoride exposure:*** Yes: Significantly lower IQ scores observed with water fluoride levels of 1.53 mg/L or higher. Percentage of subjects with IQ scores below 80 was significantly increased at water fluoride levels of 2.46 mg/L or higher. Significant inverse correlation between IQ and urinary fluoride ($r = -0.164$). Mean IQ scores for children in the non-endemic region (100.41 ± 13.21) were significantly higher than the endemic region (92.02 ± 13.00).

E.1.16.2. Risk of Bias

- **Author contacts:**
  - Authors were not contacted for additional information because it was not necessary.
- ***Population selection:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Two villages, Wamiao and Xinhuai, located 64 km apart in Sihong County, Jiangsu Province, were selected for this study, which was conducted between September and December 2002. Wamiao is located in a severe fluorosis endemic area, and Xinhuai is located in a non-endemic fluorosis area. Neither

village has fluoride pollution from burning coal or other industrial sources. All eligible children in each village were included; children who had been absent from either village for 2 years or longer or who had a history of brain disease or head injury were excluded. In Wamiao, 93% of the children (222 out of 238) were included in the study; in Xinhuai, 95% were included (290 out of 305). The children in Wamiao were divided into five subgroups according to the level of fluoride in their drinking water: <1.0 mg/L (group A), 1.0–1.9 mg/L (group B), 2.0–2.9 mg/L (group C), 3.0–3.9 mg/L (group D), and >3.9 mg/L (group E). Children in Xinhuai (0.18–0.76 mg/L in the drinking water) served as a control group (group F). Demographic characteristics are not presented, and statistical analyses are not adjusted, but mean IQ scores are stratified by age, sex, family income, and parental education.

- *Basis for rating:* Probably low risk of bias based on indirect evidence that the exposure groups were similar and were recruited using the same methods within the same time frame, with direct evidence that there was no difference in participation/response rates.

- ***Confounding:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Although information was stated to be collected on personal characteristics, medical history, education levels of the children and parents, family SES, and lifestyle, only sex, age, family income, and parental education were considered. Potential co-exposures, such as arsenic, were not addressed. A separate publication in 2003 [(Xiang et al. 2003b), letter to the editor] indicated that blood lead levels were not significantly different between the two areas. Although arsenic was not addressed specifically in this publication, Xiang et al. (2013) measured both fluoride and arsenic in the Wamiao and Xinhuai areas. Xinhuai (the low-fluoride area) had significantly higher arsenic levels compared with Wamiao (the endemic fluorosis area). This is likely to bias the association toward the null; however, the study observed a significantly lower IQ score in the endemic fluorosis area. Iodine was tested in a subset of the children and found not to be significantly different between the two groups.
  - *Potentially important study-specific covariates:* Arsenic often occurs in the drinking water along with fluoride in some Chinese populations; however, based on information provided in Xiang et al. (2013), arsenic concentrations were higher in the low-fluoride area compared with the high fluoride area. Because there were significant effects on IQ observed in the high fluoride areas, the impact of co-exposure to arsenic is less of a concern. The presence of arsenic in the control village may cause an underestimation of the effect of fluoride, but despite this potential impact, there was still a significant association between fluoride exposure and IQ.
    - *Direction/magnitude of effect size:* Presence of arsenic in this study population would potentially bias the association toward the null.
  - *Basis for rating:* Probably low risk of bias because there is indirect evidence that the key covariates were taken into account, methods used for collecting the

information were valid and reliable, and co-exposures to arsenic and lead and iodine deficiency were not attributing to the effect observed in this area. The potential for bias toward the null, combined with the reported significant association increases confidence in the observed effect.

- ***Attrition:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Data are complete. IQ results were reported for all 512 children included in the study (222 in the endemic area and 290 in the nonendemic area).
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that there was no attrition.
- ***Exposure:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Exposure was based on drinking water and urinary levels of fluoride. The two study areas were selected to reflect a severe endemic area and a non-endemic area. Drinking water was collected from wells, and early-morning spot urine samples were collected from a randomly selected subsample of children. Both water and urine samples were measured using fluoride ion-selective electrode, but no quality control was discussed. Both absolute and creatinine-adjusted urine results were reported.
    - *Direction/magnitude of effect size:* There is potential for exposure misclassification because only current levels were assessed. Migration of subjects in or out of the area was not assessed, but the study authors noted that if the children had been absent from the village for 2 or more years, they were excluded. Misclassification would likely be non-differential, which could likely bias the association in either direction.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that exposure was consistently assessed using well-established methods that directly measured exposure.
- ***Outcome:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* The IQ of each child was measured with the Combined Raven's Test for Rural China (CRT-RC) (++ for methods). The test was stated to be administered to the children independently in a school classroom, in a double-blind manner, under the supervision of an examiner and two assistants, and in accordance with the directions of the CRT-RC manual regarding test administration conditions, instructions to be given, and test environment (++ for blinding). Overall rating = ++
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that the outcome was assessed using instruments that were valid and reliable in the study population, and that the outcome assessor was blind to participants' fluoride exposure.
- ***Selective Reporting:***

- *Rating:* Definitely low risk of bias (++)
- *Summary:* All outcomes outlined in the abstract, introduction, and methods are reported in sufficient detail.
- *Basis for rating:* Definitely low risk of bias based on direct evidence that all measured outcomes were reported.

- ***Other potential threats:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:*
    - *Statistical analyses:* There is no mention of the tests conducted, but data were stated to be analyzed using SAS, suggesting appropriate tests were applied. Results provided in the tables indicate that t-tests comparing IQ values between the villages (overall and by sex) were conducted, but it was not reported that heterogeneity of variance was assessed. In addition, correlations between IQ and age, family income, and parents' education level were tested with Pearson's correlation. There is no evidence that a test for trend was conducted to evaluate the stated "significant inverse concentration-response relationship between the fluoride level in drinking water and the IQ of children."
    - A potential concern raised by the NASEM (2020) committee's review was the lack of accounting for relationships in exposure between persons from the same village. Given only two villages were included and the analyses consisted of village-level comparisons (no use of individual-level covariate data), it is likely that the standard error of the difference in mean IQ between fluoride in water exposure groups will be biased, making differences appear stronger than they actually are. Without controlling for village effects and given the large differences in fluoride concentrations and IQ levels between villages, the apparent dose-response relationship could be due to a village effect in addition to a fluoride effect. However, a dose-response relationship is apparent within the "exposed" village, diminishing the concern for a village-only effect and likely minimizing the impact on the effect estimates.
    - *Other potential concerns:* None identified.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that statistical analyses were appropriate and that there were no other threats of risk of bias.

- ***Basis for classification as low risk-of-bias study overall:*** Definitely or probably low risk-of-bias ratings in confounding, exposure, and outcome. Study strengths include individual exposure measurements and blinding of outcome assessor to exposure but is limited by the cross-sectional study design and lack of accounting for urine dilution. All key covariates were considered in the study design or analysis, but there is potential for the presence of arsenic to bias the association toward the null.

E.1.17. Xiang et al. (2011)

E.1.17.1. Study Details

- ***Study design:*** Cross-sectional
- ***Population:*** Children aged 8–13 years [same study population as Xiang et al. (2003a)]
- ***Study area:*** Wamiao and Xinhuai villages located in Sihong County, Jiangsu Province, China
- ***Sample size:*** 512 school children
- ***Data relevant to the review:*** Mean IQ scores and odds ratio for having an IQ <80 presented by serum fluoride quartiles.
- ***Reported association with fluoride exposure:*** Yes: Significant linear trend across quartiles of serum fluoride and children's IQ score <80 (adjusted ORs for Q1 and Q2; Q1 and Q3; and Q1 and Q4, respectively: 1; 2.22 [95% CI: 1.42, 3.47]; and 2.48 [95% CI: 1.85, 3.32]); significant effects observed at ≥0.05 mg/L serum fluoride.

E.1.17.2. Risk of Bias

- **Author contacts:**
  - Authors were not contacted for additional information because it was not necessary.
- ***Population selection:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* The study population was the same as that used in the Xiang et al. (2003a) study, but a few more measurements were available and different analyses were conducted. The comparison population was considered the same based on the study populations being recruited from similar populations, using similar methods, during the same time frame. Demographic characteristics were not provided.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the exposure groups were similar and were recruited using the same methods within the same time frame, with direct evidence that there was no difference in participation/response rates.
- ***Confounding:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* As was noted in the 2003 publication (Xiang et al. 2003a), information was collected on personal characteristics, medical history, education levels in the children and parents, family SES, and lifestyle. In the logistic regression model age and sex were adjusted for in the analysis. In the previous report, no significant associations were observed between groups for family income and parents' education (Xiang et al. 2003a). Urinary iodine and blood lead levels were also stated to be measured and were noted not to be significantly different between the groups. Although the iodine levels were reported in the previous publication, the

lead levels were not and neither were the methods. Lead information is reported in a letter to the editor (Xiang et al. 2003b) and was not significantly different between the areas. Although arsenic was not addressed specifically in this publication, Xiang et al. (2013) measured both fluoride and arsenic in the Wamiao and Xinhuai areas. Xinhuai (the low-fluoride area) had significantly higher arsenic levels compared with Wamiao (the endemic fluorosis area). This is likely to bias the association toward the null; however, the study observed a significantly lower IQ score in the endemic fluorosis area and with increasing serum fluoride.

- *Potentially important study-specific covariates:* Arsenic often occurs in the drinking water along with fluoride in some Chinese populations; however, based on information provided in Xiang et al. (2013), arsenic concentrations were higher in the low-fluoride area compared to the high fluoride area. Because there were significant effects on IQ observed in the high fluoride areas, the impact of co-exposure to arsenic is less of a concern. The presence of arsenic in the control village may cause an underestimation of the effect of fluoride, but despite this potential impact, there was still a significant association between fluoride exposure and IQ.
  - *Direction/magnitude of effect size:* Presence of arsenic in this study population would potentially bias the association toward the null.
- *Basis for rating:* Probably low of risk bias because there is indirect evidence that the key covariates were considered, methods used for collecting the information were valid and reliable, and co-exposures to arsenic and lead and iodine deficiency were not attributing to the effects observed in this area. The potential bias toward the null, combined with the reported significant association increases confidence in the observed effect.

- ***Attrition:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Data are reported for all 512 children noted to be included in the study.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that there was no attrition.
- ***Exposure:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Fluoride levels were measured in serum with a fluoride ion-selective electrode. A fasting venous blood sample was used. No details are provided on validation (including correlation with drinking water levels) or QA. Children who did not reside in their village for at least 2 years were excluded. Results were provided in quartiles, but the authors combined the lower two quartiles. After combining the two lower quartiles, the exposure levels ranged from <0.05 mg/L (Q1 + Q2) to >0.08 mg/L (Q4).
    - *Direction/magnitude of effect size:* Serum fluoride may not be the best estimate for exposure. There is potential for exposure misclassification because only current levels were assessed. Migration of subjects in or out of

the area was not assessed, but the study authors noted that if the children had been absent from the village for 2 or more years, they were excluded. Misclassification would likely be non-differential, which could bias results in either direction.

- *Basis for rating:* Probably low risk of bias based on indirect evidence that exposure was consistently assessed using well-established methods that directly measured exposure.

- ***Outcome:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* IQ was assessed as part of the 2003 evaluation. IQ was measured with the Combined Raven's Test for Rural China, which is appropriate for this population (++ for methods). Although this study does not provide details, the original study article from 2003 provides specific details. The study authors indicate in the 2003 publication that the tests were conducted in a double-blind manner, and these are the same results and population (++ for methods). Overall rating = ++
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that the outcome was assessed using instruments that were valid and reliable in the study population, and that the outcome assessor was blind to participants' fluoride exposure.
- ***Selective Reporting:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* All outcomes outlined in the abstract, introduction, and methods are reported in sufficient detail.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that all measured outcomes were reported.
- ***Other potential threats:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:*
    - *Statistical analyses:* Statistical analyses conducted were appropriate for the study. Chi-square tests were used to compare categorical variables, and multiple logistic regression was used to evaluate the association between serum fluoride levels and risk of low IQ. A potential concern raised by the NASEM (2020) peer review was the lack of accounting for relationships in exposure between persons from the same village. Although only two villages were included, in the analyses that consisted of village-level comparisons, it is likely that the standard error of the difference in mean IQ between villages is biased. This is less of a concern for the mean IQ comparisons across quartiles of serum fluoride levels and for the logistic regression analyses of risk of low IQ and individual-level serum fluoride levels. Without controlling for village effects and given the large differences in fluoride concentrations and IQ between villages, the apparent dose-response relationship could be due to a village effect in addition to a fluoride effect. However, the dose-response

relationship is still present within the "exposed" village, diminishing the concern for a village-only effect and likely minimizing the impact on the effect estimates.

- *Other potential concerns:* None identified.

- *Basis for rating:* Probably low risk of bias based on indirect evidence that the statistical analyses were appropriate and there were no other potential threats of risk of bias identified.

- ***Basis for classification as low risk-of-bias study overall:*** Definitely or probably low risk-of-bias ratings in confounding, exposure, and outcome. Study strengths include individual exposure measurements with blinding at outcome assessment but is limited by the cross-sectional study design and use of serum concentrations. All key covariates were considered in the study design or analysis, but there is potential for the presence of arsenic to bias the association toward the null.

E.1.18. Yu et al. (2018)

E.1.18.1. Study Details

- ***Study design:*** Cross-sectional
- ***Population:*** Children aged 7–13 years
- ***Study area:*** Tianjin City, China
- ***Sample size:*** 2,886 school children
- ***Data relevant to the review:*** IQ for normal (≤1 mg/L) versus high (>1 mg/L) water fluoride; betas for IQ score by water and urine fluoride groupings; ORs by IQ category using water and urine fluoride levels.
- ***Reported association with fluoride exposure:*** Yes: Significant difference in mean IQ scores in high water fluoride areas (>1.0 mg/L; 106.4 ± 12.3 IQ) compared to the normal water fluoride areas (≤1.0 mg/L; 107.4 ± 13.0). Distribution of IQ scores was also significantly different (p = 0.003). Every 0.5-mg/L increase in water fluoride (between 3.40 and 3.90 mg/L) was associated with a 4.29 decrease in IQ score (95% CI: −8.09, −0.48).

E.1.18.2. Risk of Bias

- **Author contacts:**
  - Authors were contacted in September 2018 to obtain additional information for the risk-of-bias evaluation.
- ***Population selection:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* School children (2,886), aged 7–13 years, were recruited from the rural areas of Tianjin City, China. After exclusion, 1,636 children were assigned to the "normal-fluoride" exposure group, and 1,250 were assigned to the "high-fluoride" exposure group based on a cut-off water fluoride level of 1.0 mg/L. A multistage random sampling technique, stratified by area, was performed to select representative samples among local children who were permanent residents since

birth. Detailed characteristics of the study population were provided. Exclusion criteria included: 1) children who had congenital or acquired diseases affecting intelligence, 2) children with a history of cerebral trauma and neurological disorders, 3) children with a positive screening test history (like hepatitis B virus infection, Treponema palladium infection and Down's syndrome), and 4) children with adverse exposures (smoking and drinking) during maternal pregnancy. A table of characteristics was provided by fluoride level with differences adjusted in the analysis.

- *Basis for rating:* Definitely low risk of bias based on direct evidence that the exposed groups were recruited using similar methods during the same time frame and that any differences between the exposed groups were considered in the statistical analyses.

- ***Confounding:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Demographic data were collected by trained investigators during a face-to-face interview with the recruited children and their parents. Questionnaires were not stated to be validated. The developmental status of the children was further assessed by calculation of BMI, and all measurements were conducted by nurses based on recommended standard methods. Variables that presented differential distribution between the normal-fluoride and high-fluoride exposure groups were adjusted in the linear regression analysis of IQ data and included age, sex, paternal and maternal education levels, and low birth weight. Children exposed to smoking in utero were excluded from the study. Sensitivity analyses were conducted by modifying covariates adjusted in multivariable models among demographics (age and sex); development (BMI); socioeconomics (maternal education, paternal education, and household income); history of maternal disease during pregnancy (gestational diabetes, malnutrition, and anemia); and delivery conditions (hypoxia, dystocia, premature birth, post-term birth, and low birth weight). None of the study sites selected were in areas endemic for iodine deficiency disorders, nor were other potential neurotoxins like lead, arsenic, and mercury present. Variables such as parental BMI and behavioral and mental health disorders were not addressed.
  - *Potentially important study-specific covariates:* All key covariates were considered in this study.
    - *Direction/magnitude of effect size:* Not applicable.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that methods of obtaining the information were valid and reliable and direct evidence that all key covariates and co-exposures were considered.

- ***Attrition:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* There were 1,636 children assigned to the “normal-fluoride” exposure group based on water fluoride and 1,250 children assigned to the “high-fluoride” exposure group. Exclusion from the original group of 2,886 children was

adequately described. A total of 2,380 children provided urine samples. There is no indication that the data presented excludes any additional children or urine samples, but results do not indicate a sample size for all results.

- *Basis for rating:* Probably low risk of bias based on indirect evidence that exclusion of subjects from analyses was adequately addressed, and reasons were documented when subjects were removed from the study or excluded from analyses.

- ***Exposure:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* According to the annual surveillance data from the CDC, the drinking water sources and water fluoride concentrations in each village had remained at stable levels over the past decade. During the investigation, water samples were collected randomly from the public water supplies in each village. Spot (early-morning) urine samples from every child and water samples from each village were collected in pre-cleaned, labeled polythene tubes and transported to the lab within 24 hours while frozen. Samples were stored at −80°C until analysis. Concentrations of fluoride ions (mg/L) were analyzed using the national standardized ion-selective electrode method in China; the detection limit was 0.01 mg/L. Samples were diluted with an equal volume of total ionic strength adjusted buffer (TISAB) of pH 5–5.5 for optimal analysis. Double-distilled deionized water was used throughout the experiment. There is no reporting of any QC methods.
    - *Direction/magnitude of effect size:* Spot urine samples may lead to non-differential exposure misclassification. The large population size likely dilutes any potential effects of occasional misclassification. Because the drinking water sources of fluoride had been noted to be stable for the past decade and the children were 13 years or younger, there would only be exposure misclassification if there was a lot of migration between areas.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that exposure was consistently assessed using well-established methods that directly measured exposure.

- ***Outcome:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* IQ scores were measured using the second edition of the Combined Raven's Test–The Rural in China (CRT-RC2) for children aged 7–13 years (++ for methods). The test was completed by each participant within 40 minutes, according to the instruction manual. For each test, 40 children were randomly allocated to one classroom to take the test independently under the supervision of four trained professionals. There is no mention of whether the evaluators were blinded to the fluoride group of each child (normal vs. high fluoride) or whether there were steps taken to ensure consistency in scoring across the evaluators. It is also not clear whether the 40 children randomly assigned to the classroom were specific to the village or whether a local center was used. Correspondence with the study authors indicated that the four professionals worked together throughout

the examination without knowledge of the child's fluoride exposure (++ for blinding).

- *Basis for rating:* Definitely low risk of bias based on the direct evidence that the outcome was assessed using instruments that were valid and reliable, and that the outcome assessors were blind to participants' fluoride exposure.

- ***Selective Reporting:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* All outcomes outlined in the abstract, introduction, and methods are reported in sufficient detail.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that all measured outcomes were reported.
- ***Other potential threats:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:*
    - *Statistical analyses:* Statistical analyses used were appropriate for the study. Univariate and multivariable piecewise linear regression models were used to estimate the associations between water fluoride or urinary fluoride levels and IQ scores. Multiple logistic regression analysis was used to evaluate the association between water or urinary fluoride levels and IQ degree using the normal intelligence group as the control. Sensitivity analyses were conducted. There is no evidence that residual diagnostics were used to examine model assumptions or that the complex sampling design (stratified multistage random sampling) was accounted for in the analysis using sampling weights and adjustment for clustering. The impact of these factors on the effect estimates is expected to be minimal given the use of individual-level data and adjustment for numerous important covariates.
    - *Other potential concerns:* None identified.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the statistical analyses were appropriate and there were no other potential threats of risk of bias identified.
- ***Basis for classification as low risk-of-bias study overall:*** Definitely or probably low risk-of-bias ratings in confounding, exposure, and outcome. Study strengths include individual exposure measurements with blinding at outcome assessment but is limited by the cross-sectional study design and lack of accounting for urine dilution. All key covariates, including potential co-exposures, were considered in the study design or analysis.

E.1.19. Zhang et al. (2015b)

E.1.19.1. Study Details

- ***Study design:*** Cross-sectional
- ***Population:*** Children aged 10–12 years

- ***Study area:*** Tianjin City, China
- ***Sample size:*** 180 children
- ***Data relevant to the review:*** IQ by control and high fluoride groups; IQ correlations with water, serum, or urinary fluoride levels; betas for IQ with urinary fluoride levels (by genotypes)
- ***Reported association with fluoride exposure:*** Yes: Significant correlation between IQ score and children's serum fluoride ($r = -0.47$) and urinary fluoride ($r = -0.45$); significant difference in mean IQ score for high-fluoride area (defined as >1 mg/L in drinking water; 102.33 ± 13.46) compared with control area (<1 mg/L; 109.42 ± 13.30).

E.1.19.2. Risk of Bias

- **Author contacts:**
  - Authors were not contacted for additional information because it was not necessary.
- ***Population selection:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Subjects were similar and recruited during the same time frame using the same methods. Authors recruited schoolchildren from a high fluoride area (1.40 mg/L) and a control area (0.63 mg/L) in Tianjin City, China. In accordance with the principles of matching social and natural factors such as educational standard, economic situation, and geological environments as much as possible, two areas with different fluoride concentrations in the groundwater were selected by a stratified cluster random sampling of this region. A total of 180 5th grade children aged 10 to 12 years from two primary schools located 18 km apart in the Jinnan District were recruited—Gegu Second Primary School (from an endemic fluorosis area) and Shuanggang Experimental Primary School (from a non-endemic fluorosis area). The areas are not affected by other drinking water contaminants, such as arsenic or iodine. All subjects were unrelated ethnic Han Chinese and residents in Tianjin with similar physical and mental health status. The authors excluded subjects with known neurological conditions, including pervasive developmental disorders and epilepsy. Descriptive statistics of the study population are presented by exposure group in Table 1 of the study. A number of potential differences were considered in the statistical analyses.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that the exposure groups were similar and recruited using similar methods during the same time frame.
- ***Confounding:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Covariates included in the statistical models were age, sex, educational levels of parents, drinking water fluoride (mg/L), and levels of thyroid hormones (T3, T4, and TSH). Authors report that the study areas were not affected by other contaminants such as arsenic or iodine, and residents were of similar physical and

mental health status. Other important covariates (maternal demographics, smoking, reproductive health) were not considered. Covariate data were obtained from a study questionnaire.

- *Potentially important study-specific covariates:* All key covariates were considered in this study.
  - *Direction/magnitude of effect size:* Not applicable.
- *Basis for rating:* Probably low risk of bias based on indirect evidence that the methods used to collect the information were valid and reliable and direct evidence that key covariates, including potential co-exposures, were considered.

- ***Attrition:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Results are complete for the 180 children selected for the study.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that there was no attrition.
- ***Exposure:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Drinking water samples (10 mL) were collected from the tube wells of each child's household. Three fasting venous blood samples were also collected. Urine samples were collected in the early morning before breakfast. Fluoride content in drinking water (W-F), serum (S-F), and urine (U-F) was measured using an ion analyzer EA940 with a fluoride ion-selective electrode (Shanghai Constant Magnetic Electronic Technology Co, Ltd, China), according to the China standard GB 7484-87. All reference solutions for the fluoride determinations were double-deionized water. Parallel samples were set for determination, and averages were taken. The quantitation limits of this method for W-F, S-F, and U-F were 0.2, 0.012, and 0.5 mg/L, respectively. Recovery rates for this method were in the range of 94.3%–106.4%. The intra- and inter-assay coefficients of variation for fluoride were 2.7% and 6.7%, respectively. Dilution of the urinary fluoride was not addressed.
    - *Direction/magnitude of effect size:* Not applicable.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that the exposure was consistently assessed using well-established methods that directly measured exposure.
- ***Outcome:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* A Combined Raven's Test for Rural China (CRT-RC) was taken to evaluate the IQ of each child (++ for methods). The study report stated that all tests were administered at school by a trained examiner who was masked to participants' drinking water fluoride levels (++ for blinding). Overall rating for methods and blinding = ++.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that the outcome was assessed using instruments that were valid and reliable in the study

population, and that the outcome assessor was blind to participants' fluoride exposure.

- ***Selective Reporting:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* All results outlined in the abstract, introduction, and methods sections were reported in sufficient detail.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that all measured outcomes were reported.
- ***Other potential threats:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:*
    - *Statistical analyses:* Associations between serum and urinary fluoride levels and IQ score were estimated using general linear models and multivariate linear regression by COMT polymorphism. Normality (Kolmogorov-Smirnov test) was evaluated for all continuous variables. There is no evidence that residual diagnostics were used to examine model assumptions or that the complex sampling design (stratified multistage random sampling) was accounted for in the analysis using sampling weights and adjustment for clustering. The impact of these factors on the regression effect estimates is expected to be minimal given the use of individual-level data and adjustment for numerous covariates.
    - *Other potential concerns:* None identified.
  - *Basis for rating:* Probably low risk of bias based on direct evidence that the statistical analyses were appropriate and there were no other potential threats of risk of bias identified.
- ***Basis for classification as low risk-of-bias study overall:*** Definitely or probably low risk-of-bias ratings in confounding, exposure, and outcome. Study strengths include individual exposure measurements, blinding of outcome assessor to participants' fluoride exposure, and consideration of key covariates including potential co-exposures.

E.2. Other Neurodevelopmental Studies

E.2.1. Barberio et al. (2017b)

E.2.1.1. Study Details

- ***Study design:*** Cross-sectional
- ***Population:*** Canadian Health Measures Survey (cycles 2 and 3) participants (children aged 3–12 years)
- ***Study area:*** general population of Canada
- ***Sample size:*** 2,221 children (1,120 from Cycle 2, 1,101 from Cycle 3)

- ***Data relevant to the review:*** Associations between learning disability or ADHD (Cycle 2 only) assessed by parent or child self-report and urinary fluoride.
- ***Reported association with fluoride exposure:*** Yes: Significant increase in adjusted OR for learning disability with unadjusted urinary fluoride per 1-µmol/L increase (1.02; 95% CI: 1.00, 1.03) when Cycles 2 and 3 were combined. No significant associations with creatinine-adjusted or specific gravity-adjusted urinary fluoride. No significant association between urinary fluoride and ADHD.

E.2.1.2. Risk of Bias

- **Author contacts:**
  - Authors were not contacted for additional information because it was not necessary.
- ***Population selection:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* The comparison groups were selected from Cycles 2 and 3 of the Canadian Health Measures Survey. This is a nationally representative sample of residents living in 10 provinces, with clear exclusion criteria provided. Exclusion represented only about 4% of the target population (all Canadian residents 3–79 years old living in 10 provinces). A table of characteristics of the study population is provided.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that the subjects were recruited from the same population using the same methods during the same time frame, and exposure groups were similar.
- ***Confounding:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* The study adjusted for sex, age (3–12 years old), household education, and household income adequacy. Variables to discern fluoride source, including drinking water and dental products, were also considered. Cycle 2 data also included adjustments for: 1) children for whom tap water (vs. bottled or other) was the primary source of drinking water at home or away from home and 2) children who had lived in their current home for 3 or more years. Covariates such as parental behavioral and mental health disorders, smoking, and nutrition were not discussed. The study used data from the Canadian Health Measures Survey, which consists of a nationally representative sample of Canadians. Most Canadians (~89%) receive water from municipal water supplies, which monitor for levels of lead and arsenic. Therefore, co-exposure to lead and arsenic are less likely an issue in this population and the lack of information is not considered to appreciably bias the results.
  - *Potentially important study-specific covariates:* All key covariates were considered in this study.
    - *Direction/magnitude of effect size:* Not applicable.

- *Basis for rating:* Probably low risk of bias based on direct evidence that key covariates were addressed and indirect evidence that the methods used to collect the information were valid and reliable and that co-exposures were not an issue.

- ***Attrition:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Covariate data were missing for less than 5% of all analyses, apart from household income; household income was reported for only 71%–77% of participants and was imputed for the remainder.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that exclusion of subjects from analyses was adequately addressed, and reasons were documented when subjects were removed from the study or excluded from analyses.
- ***Exposure:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Estimates of urinary fluoride (µmol/L) from spot urine were available for a subsample of respondents. Analysis was performed under standardized operating procedures at the Human Toxicology Laboratory of the Institut National de Santé Publique du Québec (accredited under ISO 17025). Fluoride content of urine samples was analyzed using an Orion pH meter with a fluoride ion-selective electrode with limits of detection of 20 µg/L (Cycle 2) and 10 µg/L (Cycle 3). Urinary dilution was addressed by using creatinine-adjusted levels as well as specific gravity-adjusted levels. In Cycle 3 only, estimates of the fluoride concentration of tap water samples collected from randomly selected households were available. The subsample of households selected for tap water sample collection corresponded to the person-level urine fluoride subsample. Analysis of the fluoride concentration of tap water was performed using a basic anion exchange chromatography procedure, with a limit of detection of 0.006 mg/L. QC methods were not addressed.
    - *Direction/magnitude of effect size:* There is not any specific impact on the direction or magnitude of effect size expected. Urinary fluoride levels are reflective of a recent exposure. Having a single concurrent measurement may not be reflective of the exposure associated with the outcome, but if subjects lived in the same area throughout life, the exposure may be an adequate representation. Although there is possible exposure misclassification, it would likely be non-differential.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that exposure was consistently assessed using well-established methods that directly measured exposure.
- ***Outcome:***
  - *Rating:* Probably high risk of bias (−)
  - *Summary:* The primary outcome variable, diagnosis of a learning disability by a health professional, was based on a single item from a household survey asked to all respondents: “Do you have a learning disability?” Answer options were: “yes,”

"no," "don't know," or the participant refused to answer. For Cycle 2, those who indicated having a learning disability were also asked what kind, with the answer options of: "ADD," "ADHD," "dyslexia," or "other." This question was omitted in Cycle 3, and the reason for omission was not described. Parents or guardians answered all questions for children aged 3–11 years, while children 12 years and older answered questions themselves. The self-reporting of a learning disability did not appear to have been confirmed by medical records or a health professional (− for methods based on self-report of diagnosis by a health care professional; also, in Cycle 3, no specific disabilities were described). Blinding was not a concern as spot urine samples were sent to a separate lab, and self-reports would not have knowledge of their urine or tap water exposure level (+ for blinding). Overall rating = −.

- *Basis for rating:* Probably high risk of bias based on indirect evidence that the outcome was measured using an insensitive method in the study population.

- ***Selective Reporting:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* All outcomes outlined in the abstract, introduction, and methods sections were reported in sufficient detail.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that all measured outcomes were reported.
- ***Other potential threats:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:*
    - *Statistical analyses:* Logistic regression analyses, adjusted and unadjusted for covariates, examined the associations between fluoride exposure and diagnosis of learning disability. Analyses were performed for Cycle 2 only (urinary fluoride and type of learning disability diagnosis), Cycle 3 only (urinary fluoride, water fluoride, and learning disability diagnosis), and Cycles 2 and 3 combined. Analyses used survey weights and bootstrapped weights to ensure proper computation of variance estimates. Results are reported as unadjusted and adjusted ORs with 95% CIs.
    - *Other potential concerns:* None identified.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that the statistical analyses were appropriate and there were no other potential threats of risk of bias identified.
- ***Basis for classification as low risk-of-bias study overall:*** Probably low risk-of-bias ratings in confounding and exposure. Study strengths include individual exposure measurements and the consideration of key covariates, but was limited by the cross-sectional study design and insensitive outcome measures.

E.2.2. Bashash et al. (2017)

E.2.2.1. Study Details

- ***Study design:*** Prospective cohort
- ***Population:*** Early Life Exposures in Mexico to Environmental Toxicants (ELEMENT) participants (pregnant mothers and their children aged 4 or 6–12 years).
- ***Study area:*** Mexico City, Mexico
- ***Sample size:*** 299 mother-child pairs, of whom 287 had data for the general cognitive index (GCI).
- ***Data relevant to the review:*** Adjusted and unadjusted associations between GCI and maternal or child's urinary fluoride concentrations.
- ***Reported association with fluoride exposure:*** Yes: Significant association between maternal urinary fluoride and GCI score (adjusted β per 0.5 mg/L increase = −3.15; 95% CI: −5.42, −0.87). No significant associations with children's urinary fluoride.

E.2.2.2. Risk of Bias

- **Author contacts:**
  - Authors were not contacted for additional information because it was not necessary.
- ***Population selection:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Study participants were selected from two different cohorts from three hospitals in Mexico City that serve low-to-moderate income populations. One cohort was from an observational study of prenatal lead exposure and neurodevelopmental outcomes, and the other was from a randomized trial of the effect of calcium on maternal blood lead levels. The authors state that participants had no history of psychiatric disorders, high-risk pregnancies, gestational diabetes, illegal drug use, or continuous prescription drugs, but information on smoking habits was not included. Study populations appear to be similar, but there may be some differences because subjects were selected from two different cohorts that were recruited during slightly different time periods.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the exposure groups were similar despite the subjects coming from different original study populations for whom different methods were used for recruitment.
- ***Confounding:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Data were collected via questionnaire on maternal age, education, marital status at first prenatal visit, birth order, birth weight, gestational age at delivery, maternal smoking, maternal IQ, and HOME scores. All models were adjusted for gestational age at birth, sex, birth weight, birth order, age at testing, maternal marital status, smoking history, maternal age at delivery, maternal IQ, education, and cohort, with additional testing for children's urinary fluoride,

mercury, lead, and calcium. Sensitivity analyses were additionally adjusted for HOME score. Covariates not considered included BMI, iodine deficiency, arsenic, and maternal mental health and nutrition. Arsenic is assumed not to be a potential co-exposure in this population as the study authors did not discuss it as an issue but did discuss other co-exposures. Arsenic is included in the water quality control program in Mexico City and is not considered a concern in this population.

- *Potentially important study-specific covariates:* All key covariates were addressed.
  - *Direction/magnitude of effect size:* Not applicable.
- *Basis for rating:* Probably low risk of bias based on direct evidence that key covariates, including other potential co-exposures, were considered, and indirect evidence that the methods used to collect the information were valid and reliable and that arsenic was not likely to be an issue in this study population.

- ***Attrition:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Although there was a large amount of attrition, the study authors clearly describe all reasons for attrition and also provide characteristics to compare those participants included to those excluded. There were some slight differences between those included and those excluded, but there is nothing to indicate that the attrition would potentially bias the results.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that exclusion of subjects from analyses was adequately addressed, and reasons were documented when subjects were removed from the study or excluded from analyses.
- ***Exposure:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Urinary fluoride concentrations were determined in spot urine samples (2nd morning void) collected from mothers (during at least one trimester) and children ages 6–12 years. Fluoride content was measured using ion-selective electrode-based assays. QC methods were described including between laboratory correlations. All samples were measured in duplicate. Extreme outliers were excluded. Urinary dilution was addressed by using creatinine-adjusted levels.
    - *Direction/magnitude of effect size:* Not applicable.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that exposure was consistently assessed using well-established methods that directly measured exposure.
- ***Outcome:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Outcome was assessed using the McCarthy Scales of Children's Abilities (MSCA) in 4-year-old children (translated into Spanish) and the Wechsler Abbreviated Scale of Intelligence (WASI) in 6–12-year-olds. The

WASI is a well-established test, and the validity of both tests is well documented by the authors. Inter-examiner reliability was evaluated and reported with a correlation of 0.99 (++ for methods). The study report stated that psychologists were blind to the children's fluoride exposure (++ for blinding). Overall rating for methods and blinding = ++.

- *Basis for rating:* Definitely low risk of bias based on direct evidence that the outcome was assessed using instruments that were valid and reliable in the study population, and that the outcome assessor was blind to participants' fluoride exposure.

- ***Selective Reporting:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* All outcomes outlined in the abstract, introduction, and methods are reported in sufficient detail.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that all measured outcomes were reported.
- ***Other potential threats:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:*
    - *Statistical analyses:* Statistical analyses used were appropriate for the study. Statistical tests of bivariate associations (using Chi-square tests for categorical variables and analysis of variance [ANOVA]) were used to compare the means of the outcomes or exposures within groups based on the distribution of each covariate. Generalized additive models (GAMs) were used to estimate the adjusted association between fluoride exposure and measures of children's intelligence. Residual diagnostics were used to examine model assumptions and identify any potentially influential observations. Results are reported as adjusted effects and 95% CIs. In sensitivity analyses, regression models accounted for clustering at the cohort level by using cohort as a fixed effect in the models. Although using cohort as a random effect would be more appropriate, using individual-level exposure data and accounting for numerous covariates in the models likely captured the cohort effect.
    - *Other potential concerns:* None identified.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that the statistical analyses were appropriate and there were no other potential threats of risk of bias identified.
- ***Basis for classification as low risk-of-bias study overall:*** Definitely or probably low risk-of-bias ratings in confounding, exposure, and outcome. Study strengths include individual exposure measurements, blinding of outcome assessor to participants' fluoride exposure, and the prospective cohort study design.

E.2.3. Bashash et al. (2018)

E.2.3.1. Study Details

- ***Study design:*** Prospective cohort
- ***Population:*** ELEMENT participants (pregnant mothers and their children aged 6–12 years)
- ***Study area:*** Mexico City, Mexico
- ***Sample size:*** 210 mother-child pairs
- ***Data relevant to the review:*** Associations between ADHD and other attention/impulsivity scores and maternal urinary fluoride concentrations.
- ***Reported association with fluoride exposure:*** Yes: Significant associations between maternal urinary fluoride (per 0.5-mg/L increase) and Conners' Rating Scales-Revised (CRS-R) scores, including Cognitive Problems and Inattention Index (adjusted $\beta = 2.54$; 95% CI: 0.44, 4.63), DSM-IV Inattention Index (adjusted $\beta = 2.84$; 95% CI: 0.84, 4.84), DSM-IV ADHD Total Index (adjusted $\beta = 2.38$; 95% CI: 0.42, 4.34), and ADHD Index (adjusted $\beta = 2.47$; 95% CI: 0.43, 4.50).

E.2.3.2. Risk of Bias

- **Author contacts:**
  - Authors were not contacted for additional information because it was not necessary.
- ***Population selection:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Participants were a subset of mother-child dyads enrolled in various longitudinal birth cohort studies of the Early Life Exposure in Mexico to Environmental Toxicants (ELEMENT) project. Subjects were included from two of the four cohorts for which maternal urinary samples were available. Participants in cohort 2A were recruited between 1997 and 1999, and participants in cohort 3 were recruited from 2001 to 2003. Inclusion and exclusion criteria were applied consistently across the two cohorts. A table of subject characteristics was provided in the study, and any differences were considered in the analysis. Study populations appear to be similar, but there may be some differences because subjects were selected from two different cohorts: one from an observational study on prenatal lead exposure and the other from a randomized trial on the effects of calcium on blood lead levels. In addition, they were recruited from slightly different time periods.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the exposed groups were similar, and any differences were considered in the analysis.
- ***Confounding:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Questionnaires were used to collect information on maternal age, maternal education, history of smoking, and marital status during the first

pregnancy visit. Child information at birth included birth weight, sex, birth order, and gestational age as calculated by the nurse. Mothers also responded to an SES questionnaire during the visit when the psychometric tests were administered. The Home Observation for Measurement of the Environment (HOME) score was evaluated in a subset of participants. Covariates were selected a priori. Models were adjusted for maternal age at delivery, years of education, marital status, smoking history, gestational age at birth, age at outcome assessment, sex, birth order, SES, cohort, and calcium intervention. Arsenic is included in the water quality control program in Mexico City and is not considered a concern in this population.

- *Potentially important study-specific covariates:* None identified, although this study did not specifically address arsenic or other co-exposures. Bashash et al. (2017) addressed potential co-exposure to lead and mercury but did not address arsenic. Arsenic was potentially addressed as part of the water quality program in Mexico City.
  - *Direction/magnitude of effect size:* Not applicable.
- *Basis for rating:* Probably low risk of bias based on direct evidence that key covariates were addressed, and indirect evidence that the methods used to collect the information were valid and reliable and that arsenic and other potential co-exposures were not likely to be an issue in this study population.

- ***Attrition:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Although there was a large amount of attrition from the original cohorts, it was unlikely related to outcome or exposure, and there were very little missing data from those included in the study. Of the 231 mothers with a minimum of one maternal urine fluoride measurement and matching outcome identified for the project, only 17 were excluded based on incomplete demographic and outcome information.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that exclusion of subjects from analyses was adequately addressed, and reasons were documented when subjects were removed from the study or excluded from analyses.
- ***Exposure:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Mothers provided at least one spot urine sample during pregnancy. As described in Bashash et al. (2017), urinary concentrations were determined on second morning void. Fluoride content was measured using ion-selective electrode-based assay. Bashash et al. (2017) describes QC methods. All samples were measured in duplicate, and extreme outliers were excluded. Urinary dilution was addressed by using creatinine-adjusted levels.
    - *Direction/magnitude of effect:* N/A

  - *Basis for rating:* Definitely low risk of bias based on direct evidence that exposure was consistently assessed using well-established methods that directly measured exposure.
- ***Outcome:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Behaviors associated with ADHD were assessed using the Spanish version of Conners' Rating Scales-Revised, which has been validated for the evaluation of ADHD. Mothers completed the CRS-R at the same follow-up visit in which the child completed the CPT-II tests. All tests were applied under the supervision of an experienced psychologist (++ for methods). Use of only parent reports and not teacher reports was noted by the authors as a study limitation because there is considerable variation between the two sources in terms of identifying ADHD-associated behaviors. Blinding was not reported, but it is unlikely that the mothers were aware of their urinary fluoride levels. Although mothers may have had knowledge that they were receiving fluoride through fluoridated salt or naturally occurring fluoride in their water, they would not have knowledge that this was relevant to the study purpose as the ADHD tests were conducted for the original cohort (as was acknowledged by the study authors in the discussion) (++ for blinding). Overall rating = ++.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that the outcome was assessed using instruments that were valid and reliable in the study population, and that the outcome assessors were blind to participants' fluoride exposure.
- ***Selective Reporting:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* All outcomes outlined in the abstract, introduction, and methods were reported in sufficient detail.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that all measured outcomes were reported.
- ***Other potential threats:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:*
    - *Statistical analyses:* Bivariate analyses included Chi-square tests for categorical variables and ANOVA for continuous outcomes. Appropriate univariate statistics and transformations were performed before bivariate analyses. Residuals from fully adjusted linear regressions were checked and suggested skewness. Gamma regression with an identity link was used to examine the adjusted association between prenatal fluoride and each neurobehavioral outcome (instead of using log transformation). Generalized additive models were used to visually examine potential non-linearity. Sensitivity analyses examined impact of other covariates. Diagnostics tests were used to assess violations of the model assumptions and to identify

remaining influential observations. The Benjamini-Hochberg false discovery rate (FDR) procedure was used to correct for multiple testing.
    - *Other potential concerns:* None identified.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that the statistical analyses were appropriate and there were no other potential threats of risk of bias identified.
- ***Basis for classification as low risk-of-bias study overall:*** Definitely or probably low risk-of-bias ratings in confounding, exposure, and outcome. Study strengths include individual exposure measurements, blinding of outcome assessor to participants' fluoride exposure, and the prospective cohort study design.

E.2.4. Choi et al. (2015)

E.2.4.1. Study Details

- ***Study design:*** Cross-sectional
- ***Population:*** First-grade children (ages 6–8 years)
- ***Study area:*** Mianning County in southern Sichuan, China
- ***Sample size:*** 51 first-grade children
- ***Data relevant to the review:*** Associations between learning, memory, visual motor ability, motor ability, and manual dexterity with continuous urine or drinking water fluoride levels. Study also had information based on dental fluorosis score.
- ***Reported association with fluoride exposure:*** No: None of the outcomes were significantly associated with fluoride exposure.

E.2.4.2. Risk of Bias

- **Author contacts:**
  - Authors were not contacted for additional information because it was not necessary.
- ***Population selection:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Subjects were selected during the same time frame using the same methods. Fifty-one first-grade children residing in Mianning County in southern Sichuan, China were included in this pilot study. It is not specified whether the 51 children represented all first-grade children from this area or whether some refused to participate. Children who did not speak Chinese, were not students at the Primary School of Sunshui Village in Mianning County, or those with chronic or acute disease that might affect neurobehavioral function tests were excluded. Demographic characteristics are presented in Table 1 of the study, which indicates that subjects were similar. Covariates were adjusted for in the statistical analyses.
  - *Basis for Rating:* Definitely low risk of bias based on direct evidence that the exposure groups were similar and were recruited within the same time frame

using the same methods with no evidence of differences in participation/response rates.

- ***Confounding:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* The parents or guardians completed a questionnaire on demographic and personal characteristics of the children (sex, age at testing, parity, illnesses before age 3, and past medical history) and caretakers (age, parity, education and occupational histories, residential history, and household income). A 20-µL capillary blood sample was collected at the school by a Mianning County Center for Disease Control (CDC) health practitioner and tested for possible iron deficiency, which could be used as a covariate of neurodevelopmental performance. Covariates that were not assessed include maternal BMI, parental mental health, maternal smoking status, maternal reproductive factors, parental IQ, and HOME score. However, the study authors noted that confounding bias appeared to be limited due to the minimal diversity in the social characteristics of the subjects. The study authors indicated that CDC records documented that levels of other contaminants, including arsenic and lead, were very low in the area. Iodine differences were not specifically addressed, but there is no indication from the information provided that this might have been a concern.
  - *Potentially important study-specific covariates:* All key covariates were considered in this study.
    - *Direction/magnitude of effect size:* Not applicable.
  - *Basis for rating:* Probably low risk of bias because there is direct evidence that the key covariates were considered and indirect evidence that co-exposure to arsenic was likely not an issue in this area and that methods used for collecting the information were valid and reliable.
- ***Attrition:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* The majority of results were reported for the 51 children stated to be included in the pilot study. In Table 5 of the study, the N for each dental fluorosis category totals only 43, but the text indicates 8 children did not have a Dean Index because permanent teeth had not erupted.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that exclusion of subjects from analyses was adequately addressed, and reasons were documented when subjects were removed from the study or excluded from analyses.
- ***Exposure:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* The study used three different measurements of fluoride exposure: well water fluoride concentrations from the residence during pregnancy and onwards, fluoride concentrations from children's first morning urine samples, and degree of children's dental fluorosis. Fluoride concentrations in community well water were measured and recorded by Mianning County CDC; specific methods were not

reported, but standard methods were likely used because analyses were conducted by the CDC and were likely the same as those used to measure the fluoride in urine. Migration of subjects was noted to be limited. Well water fluoride concentrations of the mother's residence during pregnancy and onward were used to characterize a child's lifetime exposure. To provide a measure of the accumulated body burden, each child was given a 330-mL (11.2-oz) bottle of Robust© distilled water (free from fluoride and other contaminants) to drink the night before the clinical examinations, after emptying the bladder and before bedtime. The first urine sample was collected at home the following morning, and the fluoride concentration was determined on a 5-mL sample using an ion-specific electrode at the Mianning CDC. There is no indication that urinary fluoride levels accounted for dilution, nor was it clear that the method of administering water to the children and collection methods sufficiently controlled for differences in dilution. One of the investigators, a dentist, performed a blinded dental examination on each child's permanent teeth to rate the degree of dental fluorosis using the Dean Index. The Dean Index is commonly used in epidemiological studies and remains the gold standard in the dentistry armamentarium. The Index has the following classifications: normal, questionable, very mild, mild, moderate, and severe. Quality control (QC) procedures are not reported but were likely appropriate.

        - *Direction/magnitude of effect size:* Current levels were used to assess lifetime exposure. This is likely to be a non-differential exposure misclassification, and direction of bias is unknown. Because subject migration appears to be limited, it is likely that the current fluoride levels are adequate reflections of past exposure. Dental fluorosis would be an indicator that exposure occurred in the past, and there was a fair correlation between degree of dental fluorosis and current urine and water fluoride levels, with both increasing with increasing levels of dental fluorosis.
    - *Basis for rating:* Probably low risk of bias based on indirect evidence that exposure was consistently assessed using well-established methods that directly measure exposure.

- ***Outcome:***
    - *Rating:* Probably low risk of bias (+)
    - *Summary:* The study authors adopted culture-independent tests considered feasible for children aged 6 to 8 years. The Wide Range Assessment of Memory and Learning (WRAML) was used for the assessment of memory and learning. Three subtests were also used. The Finger Windows subtest assesses sequential visual memory. The Design Memory subtest assesses the ability to reproduce designs from memory following a brief exposure. The Visual Learning subtest assesses the ability to learn the locations of pictured objects over repeated exposures. The Wechsler Intelligence Scale for Children-Revised (WISC-IV) included digit span for auditory span and working memory and block design for visual organization and reasoning. The grooved pegboard test assesses manual dexterity. The tests used have been validated on a Western population. Although there is no information provided to indicate that the tests were validated on the

study population, the study authors indicated that the tests were culture-independent (+ for methods). Blinding of the outcome assessors or steps to minimize potential bias was not reported. However, it is unlikely that the assessors had knowledge of the individual exposure as children all came from the same area, and water and urine levels were tested at the CDC (+ for blinding). Overall = +.

  - *Basis for rating:* Probably low risk of bias based on indirect evidence that all outcomes were assessed using instruments that were valid and reliable in the study population, and that the outcome assessors were blind to participants' fluoride exposure.

- ***Selective Reporting:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* All outcomes outlined in the abstract, introduction, and methods are reported in sufficient detail.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that all measured outcomes were reported.
- ***Other potential threats:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:*
    - *Statistical analyses:* Statistical analyses were appropriate. Multiple regression models evaluated the associations between exposure indicators and test scores after adjusting for covariates. Specific regression models are not described or referenced, just stated to be "standard regression analysis with confounder adjustment." The distributions of fluoride concentrations in urine and water were skewed and were log10-transformed to approximate a Gaussian distribution (test not specified). Results were reported as adjusted effects and 95% Cis. There was no evidence that residual diagnostics were used to examine model assumptions; however, the impact on the effect estimates is expected to be minimal.
    - *Other potential concerns:* It should be noted that this study was a pilot study and, therefore, had a relatively small sample size (i.e., 51 children).
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the statistical analyses were appropriate and there were no other potential threats of risk of bias identified.
- ***Basis for classification as low risk-of-bias study overall:*** Probably low risk-of-bias ratings in the confounding, exposure, and outcome domains. Study strengths include individual fluoride measurements with blinding at outcome assessment likely. All key covariates and many other covariates were considered in the study design or analysis.

E.2.5. Li et al. (2004) [translated in Li et al. 2008a]

E.2.5.1. Study Details

- ***Study design:*** Cross-sectional

- ***Population:*** Full-term, normal neonates 24–72 hours old from healthy mothers
- ***Study area:*** Zhaozhou County, Heilongiang Province, China
- ***Sample size:*** 91 neonates (46 males and 45 females)
- ***Data relevant to the review:*** Comparison of neurobehavioral capacity between children in the high-fluoride area compared to the control area.
- ***Reported association with fluoride exposure:*** Yes: Significant differences in neurobehavioral assessment total scores between high-fluoride (36.48 ± 1.09) and control (38.28 ± 1.10) groups; significant differences in total neurobehavioral capacity scores as measured by non-biological visual orientation reaction and biological visual and auditory orientation reaction between the two groups (11.34 ± 0.56 in controls compared to 10.05 ± 0.94 in high-fluoride group).

E.2.5.2. Risk of Bias

- **Author contacts:**
  - Authors were not contacted for additional information because it was not necessary.
- ***Population selection:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* There is indirect evidence that the exposure groups were similar. Participants were recruited during the same time frame using the same methods. From 2002 to 2003, 273 neonates were born in a hospital in Zhaozhou County, China. Ninety-one of 273 full-term neonates (46 males, 45 females) were randomly selected. Mothers ranged in age from 20 to 31 years, met multiple health criteria, and had not changed residence during pregnancy. Authors report that the two study groups were located in the same area with similar climate, living habits, economic and nutritional conditions, and cultural backgrounds, but do not provide these data in the manuscript. There is no statistically significant difference in the mode of delivery, birth weight, infant length, or sex. Subjects were separated into exposure groups after random selection.
  - *Basis for Rating:* Probably low risk of bias based on indirect evidence that the exposure groups were similar and were recruited within the same time frame using the same methods with no evidence of differences in participation/response rates.
- ***Confounding:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* No covariates were specifically considered in the analysis. The study authors note similarities in characteristics in the two populations (i.e., living habits, economic and nutritional conditions, and cultural backgrounds) but do not provide these data nor do they indicate which specific characteristics were considered. There were no significant differences in infant sex, birth method, gestational age, or infant weight and length. All tests were conducted when children were 1–3 days old. No potential co-exposures were discussed. Although arsenic is considered a potential issue in China, water quality maps indicate that

there is a 25%–50% probability that the drinking water in that area exceeds the WHO guideline for arsenic of 10 µg/L.

- *Potentially important study-specific covariates:* Key covariates, including age, sex, and measures of socioeconomic status (SES), were similar between exposure groups; however, arsenic was not considered. Arsenic often occurs in the drinking water along with fluoride in some Chinese populations; however, based on water quality maps, arsenic does not appear to be an issue in Zhaozhou County of the Heilongjiang Province. Iodine deficiencies are not mentioned.
  - *Direction/magnitude of effect size:* Conceptually, the presence of arsenic would potentially bias the association away from the null if it were present with fluoride. Deficiencies in iodine would potentially bias the association away from the null if it were present in areas of higher fluoride but toward the null if it were present in areas of lower fluoride. Neither of these are considered a concern in this study for reasons detailed above.
- *Basis for rating:* Probably low risk of bias based on indirect evidence that the key covariates were considered, co-exposure to arsenic was likely not an issue in this area, and methods used for collecting the information were valid and reliable.

- ***Attrition:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Although authors did not discuss why only 91 of the 273 neonates available were randomly selected, results were available for all 91 subjects.
  - *Basis for rating:* Definitely low risk of bias based on results being available for all subjects.
- ***Exposure:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Subjects were split into control and high-fluoride groups based on fluoride levels in their places of residence. Although the levels were provided (1.7–6.0 mg/L for the high-fluoride group compared to 0.5–1.0 mg/L for the control group), it was not reported how or when these levels were measured. Urine was collected when women were hospitalized but before labor began. Urine samples were sent to a specific lab for measurement using fluoride ion-selective electrode. It was noted that this procedure strictly followed the internal controls of the laboratory, indicating quality control. Level of detection (LOD) was not provided. Urinary fluoride levels were significantly higher in the high-fluoride mothers (3.58 ± 1.47 mg/L) compared to the control-group mothers (1.74 ± 0.96 mg/L). There was indirect evidence that exposure was consistently assessed using well-established methods that directly measure exposure. Although results were mainly based on exposure area, they were supported by urine data, making exposure misclassification less of a concern.
    - *Direction/magnitude of effect size:* There is high variability in both water fluoride and urine fluoride in the subjects from the high-exposure area. Although there is no overlap in the water fluoride levels in the exposure areas, there is some overlap in the urine concentrations in the mothers from the two

areas. This may reflect the single measurement and pose no specific bias, or it could indicate that some mothers in the high-fluoride area have lower fluoride exposure, which could bias the association toward the null.

- *Basis for rating:* Probably low risk of bias based on indirect evidence that exposure was consistently assessed using well-established methods that directly measure exposure.

- ***Outcome:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* A standard neonatal behavioral neurological assessment method was carried out by professionals in the pediatric department working in a neonatal section trained specifically for these programs and passing the training exams (+ for methods). The examinations were carried out 1 to 3 days after delivery. Because urine samples were collected on the day of delivery and sent to a separate laboratory, it is likely that the outcome assessors were blind. Although the subjects were separated by fluoride exposure area, it is not likely that the professionals were aware of the exposure as the tests were conducted in the hospital (+ for blinding).
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the outcome was assessed using instruments that were valid and reliable in the study population, and that the outcome assessors were blind to participants' fluoride exposure.
- ***Selective Reporting:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* The study authors reported numerous outcomes in sufficient detail; however, because a list of outcomes tested was not provided, there is no direct evidence that all were reported.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that all the study's measured outcomes were reported.
- ***Other potential threats:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:*
    - *Statistical analyses:* Statistical analyses are described only as a t-test. Consideration of heterogeneity of variance was not reported. Results are reported as mean and standard deviations of neurological scores. Maternal urinary fluoride levels were used only to compare exposures between exposed and control groups. Infants in the control group were from four villages, and those in the exposed group were from five villages within the same district. Infants were randomly selected before they were assigned to exposed or control groups. In the comparisons, there was no accounting for clustering at the village level. It is likely that the standard error of the difference in mean neurobehavioral assessment scores between the high fluoride group and control group will be biased, making differences appear stronger than they actually are. However, the use of multiple villages per exposure group is

likely to mitigate some of the impact of this lack of accounting for clustering, and the overall impact on effect estimates is expected to be minimal.

- *Other potential concerns:* It should be noted that although the study states that subjects were randomly selected, it is unclear why only 91 subjects were included and whether they were randomly selected to obtain equal numbers in the high-fluoride and control groups.

- *Basis for rating:* Probably low risk of bias based on indirect evidence that statistical analyses were appropriate and that there were no other potential threats of risk of bias.

- ***Basis for classification as low risk-of-bias study overall:*** Probably low risk-of-bias ratings in the confounding, exposure, and outcome domains. Study strengths include individual fluoride measurements to support the differences in the two areas. Tests were noted to be conducted at the hospital, providing indirect evidence that blinding was not a concern during the outcome evaluation. Although there was some potential for bias due to the lack of accounting for arsenic or iodine deficiencies, co-exposure to arsenic was likely not a major concern according to groundwater quality maps.

E.2.6. Riddell et al. (2019)

E.2.6.1. Study Details

- ***Study design:*** Cross-sectional
- ***Population:*** Canadian Health Measures Survey (Cycles 2 and 3) participants (children aged 6–17 years)
- ***Study area:*** General population, Canada
- ***Sample size:*** 3,745 children
- ***Data relevant to the review:*** Adjusted odds ratios for ADHD and attention symptoms per 1 unit increase in urinary fluoride by water fluoride in the tap water or community fluoridation status.
- ***Reported association with fluoride exposure:*** Yes: Significantly increased odds of ADHD diagnosis (adjusted OR = 6.10; 95% CI: 1.60, 22.8) or hyperactivity/inattentive symptoms (adjusted β = 0.31; 95% CI: 0.04, 0.58) per 1-mg/L increase in tap water fluoride. In addition, a significant association between ADHD diagnosis (adjusted OR = 1.21; 95% CI: 1.03, 1.42) or hyperactivity/inattentive symptoms (adjusted β = 0.11; 95% CI: 0.02, 0.58) and community water fluoridation status. No significant associations with urinary fluoride levels.

E.2.6.2. Risk of Bias

- **Author contacts:**
  - Authors were not contacted for additional information because it was not necessary.
- ***Population selection:***
  - *Rating:* Definitely low risk of bias (++)

  - *Summary:* Subjects were part of Cycles 2 and 3 of the Canadian Health Measures Survey. This is a nationally representative sample of residents living in 10 provinces. Specific inclusion criteria were provided. This study was restricted to children 6–17 years of age with different fluoride measurements that consisted of three participant samples. One of the samples was available only in Cycle 3.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that the exposed groups were similar and were recruited with the same methods during the same time frame.

- ***Confounding:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Covariates included in all models included age at testing, sex, ethnicity, BMI, parents' education, total household income, exposure to cigarette smoke inside the home, and log-transformed concurrent blood lead levels. Covariates such as parental behavioral and mental health disorders, quantity and quality of caregiving environment, and co-exposure to arsenic were not discussed. The study used data from the Canadian Health Measures Survey, which consists of a nationally representative sample of Canadians. Most Canadians (~89%) receive water from municipal water supplies, which monitor for levels of arsenic. Therefore, co-exposure to arsenic is not likely an issue in this population. Rationale for selection of covariates was based on relationship to ADHD diagnosis and to fluoride metabolism based on literature review and consultation with an ADHD expert. There is no information of the source of data for covariates, but it is likely the questionnaires from the Canadian Health Measures Survey, which are considered standardized and validated.
  - *Potentially important study-specific covariates:* All key covariates were considered in this study.
    - *Direction/magnitude of effect size:* Not applicable.
  - *Basis for rating:* Probably low risk of bias because there is indirect evidence that the key covariates were considered, co-exposure to arsenic was likely not an issue, and methods used for collecting the information were valid and reliable.

- ***Attrition:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* There is no information indicating that there were any data excluded due to missing covariates. All exclusions of children were described and reasonable (i.e., drinking bottled water when considering city fluoridation as a measure of fluoride exposure). Outliers were stated to be excluded, but methods for determining this were provided, and it was noted that the outliers were 0.27% of the values.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that exclusion of subjects from analyses was adequately addressed, and reasons were documented when subjects were removed from the study or excluded from analyses.

- ***Exposure:***

- *Rating:* Probably low risk of bias (+)
- *Summary:* **Urinary Fluoride:** Spot urine samples were collected under normal non-fasting conditions and analyzed using an Orion pH meter with a fluoride ion-selective electrode after being diluted with an ionic adjustment buffer. Analysis was performed at the Human Toxicology Laboratory of the Institut National de Santé Publique du Québec. The precision and accuracy of the fluoride analyses, including quality control and quality assurance, were described by Health Canada (2015). The limits of detection were 20 µg/L for Cycle 2 and 10 µg/L for Cycle 3 with no values below detection. Fluoride levels were adjusted for specific gravity.

  Water Fluoride in Tap Water: Tap water was collected at the subjects' homes in Cycle 3 only. Samples were analyzed for fluoride concentrations using anion exchange chromatography procedure with an LOD of 0.006 mg/L. Values below the LOD were imputed with LOD/square root(2). Of the 980 samples, 150 (15%) were below detection.

  Chlorinated Water Fluoride Status: This was determined by viewing reports on each city's website or contacting the water treatment plant (provided in supplemental material). Children were excluded if they drank bottled water, had a well, had a home filtration system, lived in the current residence for 2 years or less, or lived in an area with mixed city fluoridation.

  - *Direction/magnitude of effect size:* There is not any specific impact on the direction or magnitude of effect size expected. Urinary fluoride levels are reflective of a recent exposure, but the study authors adjusted to account for dilution. The possibility of exposure misclassification would be similar in all subjects and would be non-differential. There is less potential for exposure misclassification due to tap water or chlorinated water fluoride status, since children who drank bottled water were excluded and children who had a home filtration system were excluded from the chlorinated water status.
- *Basis for rating:* Probably low risk of bias based on indirect evidence that exposure was consistently assessed using well-established methods that directly measured exposure.

- ***Outcome:***
  - *Rating:* Probably high risk of bias (−)
  - *Summary:*

    Strengths and Difficulties Questionnaire (SDQ): The questionnaire was administered to youths under 18 years. Children aged 6–11 years had SDQ ratings provided by parents and guardians, but youths aged 12–17 years completed the questionnaire themselves. Tests consist of 25 items with a 3-point scale. Items were divided into five subscales: emotional problems, conduct problems, hyperactivity-inattention, peer problems, and prosocial behavior. The current study used only the hyperactivity-inattention subscale. Validation of this method was not reported (− for methods).

ADHD: Ninety percent of youths with ADHD are diagnosed after age 6. For children aged 6–11 years, ADHD diagnosis was provided by parents, but youths aged 12–17 years completed the questionnaire themselves. Cycle 2 asked "Do you have a learning disability?"; if the subject answered "yes," he/she was asked to specify the type (four options were available and described). In Cycle 3, parents were asked directly whether they had ADHD, and children 12 years and older were asked whether they had a physician diagnosis of ADHD and, if so, what subtype (− for methods because different methods were used, and only the children 12 years and older in Cycle 3 were asked specifically about a doctor's diagnosis). Both were measured in both cycles. Blinding is likely not an issue as subjects would not have knowledge of the urine or tap water fluoride levels. However, they would likely have knowledge of the city.

- *Basis for rating:* Probably high risk of bias based on indirect evidence that the outcome was assessed using insensitive methods that varied based subject age.

- ***Selective Reporting:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* All outcomes outlined in the abstract, introduction, and methods sections were reported in sufficient detail.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that all measured outcomes were reported.
- ***Other potential threats:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:*
    - *Statistical analyses:* Robust logistic regression was used to examine the association between fluoride exposure and ADHD diagnosis, adjusting for covariates. Box-Tidewell tests were used to check the linearity of the relationship with the continuous predictors. Linear regression was used for the SDQ scores using Huber-White standard errors. Multicollinearity was evaluated using variance inflation factor (VIF) statistics. Outliers with high studentized residuals, high leverage, or large Cook's distance values were removed from all analyses with urinary fluoride. All regressions were tested for interactions between fluoride exposure and age and between fluoride exposure and sex. Sensitivity analyses were conducted to test the different survey cycles. There is no mention of adjustment for the complex survey design using survey weights or bootstrapped weights to ensure appropriate calculation of the estimated variances; however, the overall impact on effect estimates is expected to be minimal.
    - *Other potential concerns:* None identified.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the statistical analyses were appropriate and there were no other potential threats of risk of bias identified.

- ***Basis for classification as low risk-of-bias study overall:*** Probably low risk-of-bias ratings in confounding and exposure. Study strengths include individual exposure measurements and the addressing of key covariates, but was limited by the cross-sectional study design and insensitive outcome measures.

E.2.7. Rocha-Amador et al. (2009)

E.2.7.1. Study Details

- ***Study design:*** Cross-sectional
- ***Population:*** Children aged 6–11 years
- ***Study area:*** Durango, Mexico
- ***Sample size:*** 80 children
- ***Data relevant to the review:*** Associations between visuospatial organization and visual memory (using the Rey-Osterrieth Complex Figure Test, children's version) and urinary fluoride levels in the children.
- ***Reported association with fluoride exposure:*** Yes: Significant correlation between urinary fluoride and visuospatial organization ($r = -0.29$) and visual memory ($r = -0.27$) scores. No significant correlations with arsenic.

E.2.7.2. Risk of Bias

- **Author contacts:**
  - Authors were not contacted for additional information because it was not necessary.
- ***Population selection:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Subjects were from the same population and were recruited during the same time frame using the same methods. Although this study compared three sites with antecedents of environmental pollution to mixtures of either F-As, Pb-As, or DDT-PCBs, authors evaluated each contaminant separately. The only area of interest with F and As contamination is in Durango state (5 de Febrero) where drinking water is polluted naturally with F and As at levels exceeding 6 and 19 times, respectively, the World Health Organization (WHO) limits (WHO 2008). Children attending public schools were screened through personal interviews for study eligibility. Inclusion criteria were children between 6 and 11 years old, living in the study area since birth, whose parents signed the agreement to participate. Children with a neurological disease diagnosed by a physician and reported by the mother were excluded from the study. The final sample for the F-As group was 80. Participation rates were not reported. Selected demographic characteristics are presented in Table 1 of the study.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the populations were similar and recruited during the same time frame using the same methods.
- ***Confounding:***

- *Rating:* Probably high risk of bias (−)
- *Summary:* Covariates included blood lead (PbB), age, sex, and height-for-age z-scores; only age had significant associations and was included in the final analysis. Arsenic was also assessed and analyzed separately from fluoride. Arsenic in urine was analyzed by atomic absorption spectrophotometer coupled to a hydride system (Perkin-Elmer model AAnalyst 100). Although the model did not adjust for arsenic, arsenic in the F-As group was not associated with either outcome; therefore, arsenic co-exposure is not considered a major concern in this study. PbB was analyzed with a Perkin-Elmer 3110 atomic absorption spectrophotometer using a graphite furnace. Authors note that the mean blood lead level in the F-As study area was 5.2 µg/dL, and 8% of the children had values above the reference value of 10 µg/dL. PbB was stated not to affect results and was not included in the final analysis. Other covariate data were obtained during the study interview. Father's education was provided and, in the F-As group, was stated to range from 0–16 years, but this was not considered. Maternal education, smoking, and SES were also not considered. The authors provide an SES score of 5.9 ± 1.4 for the 5 de Febrero region (the fluoride region). It is not clear whether this would vary by fluoride or arsenic levels.
- *Potentially important study-specific covariates:* SES.
  - *Direction/magnitude of effect size:* There are insufficient data to determine the impact on the magnitude or direction of effect size. The impact on the direction of the association would likely depend on the association between fluoride exposure and SES.
- *Basis for rating:* Probably high risk of bias based on indirect evidence that the SES was not considered in the study design or analysis and may have varied by fluoride levels.

- ***Attrition:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Data are complete. All 80 participants stated to be the final sample for the site of interest (F-As) were included in all analyses.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that there was no attrition.
- ***Exposure:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Fluoride in urine (FU) was analyzed according to method 8308 (''fluoride in urine'') from the National Institute for Occupational Safety and Health (NIOSH 1984) with a sensitive specific ion electrode. As a quality control check, reference standard ''fluoride in freeze dried urine'' (NIST SRM 2671a) was analyzed. The accuracy was 97.0% ± 6.0%. Levels of FU and AsU were adjusted for urinary creatinine, which was analyzed by a colorimetric method (Bayer Diagnostic Kit, Sera-Pak1 Plus). However, details on the collection methods were not reported.

        - *Direction/magnitude of effect size:* Spot urine samples in a small sample size (i.e., 80 children) may have some exposure misclassification. Adjusting for dilution reduces the potential for misclassification based on differences in dilution. Exposure misclassification would likely be non-differential.
    - *Basis for rating:* Probably low risk of bias based on indirect evidence that exposure was consistently assessed using well-established methods that directly measured exposure.
- ***Outcome:***
    - *Rating:* Probably low risk of bias (+)
    - *Summary:* IQ was assessed through the Rey-Osterrieth Complex Figure Test (ROCF). This is a less well-established method, although the authors provide citations suggesting it has been validated and standardized for the Mexican population (+ for methods). According to the study report, the neuropsychologist who administered the test was blinded to all exposure types and levels (++ for blinding). Overall rating for methods and blinding = +.
    - *Basis for rating:* Probably low risk of bias based on indirect evidence that the outcome was assessed using instruments that were valid and reliable in the study population, and that the outcome assessor was blind to participants' fluoride exposure.
- ***Selective Reporting:***
    - *Rating:* Definitely low risk of bias (++)
    - *Summary:* All outcomes outlined in the abstract, introduction, and methods were reported in sufficient detail.
    - *Basis for rating:* Definitely low risk of bias based on direct evidence that all measured outcomes were reported.
- ***Other potential threats:***
    - *Rating:* Probably low risk of bias (+)
    - *Summary:*
        - *Statistical analyses:* Statistical analyses used log-transformed exposure variables (although rationale was not provided). Crude and partial correlations were calculated to evaluate associations between serum fluoride levels and TOCF scores. There is no other description of the regression model, and regression diagnostics to evaluate model assumptions are not presented; however, the overall impact on effect estimates is expected to be minimal.
        - *Other potential concerns:* None identified.
    - *Basis for rating:* Probably low risk of bias based on indirect evidence that the statistical analyses were appropriate and there were no other potential threats of risk of bias identified.
- ***Basis for classification as low risk-of-bias study overall:*** Probably low risk-of-bias ratings in exposure and outcome. Study strengths include individual exposure measurements and blinding of outcome assessor to participants' fluoride exposure, but it is limited by the cross-sectional study design, lack of consideration of SES in

the study population, co-exposure with arsenic, and use of spot samples in a small population.

E.2.8. Valdez Jimenez et al. (2017)

E.2.8.1. Study Details

- ***Study design:*** Prospective cohort
- ***Population:*** Infants aged 3–15 months
- ***Study area:*** Durango City and Lagos de Moreno, Jalisco, Mexico
- ***Sample size:*** 65 infants
- ***Data relevant to the review:*** The Bayley Scales of Infant Development II was used to assess Mental Development Index scale and the Psychomotor Development Index scale in children aged 3 to 15 months and evaluated for associations with first and second trimester maternal urine fluoride.
- ***Reported association with fluoride exposure:*** Yes: Significant association between log10-mg/L maternal urinary fluoride and MDI score during first trimester (adjusted $\beta = -19.05$; SE = 8.9) and second trimester (adjusted $\beta = -19.34$; SE = 7.46). No association between maternal fluoride during any trimester and Psychomotor Developmental Index (PDI).

E.2.8.2. Risk of Bias

- **Author contacts:**
  - Authors were not contacted for additional information because it was not necessary.
- ***Population selection:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Subjects were recruited from two endemic areas in Mexico. The study authors do not provide information on the similarities or differences between the two areas, nor do they indicate whether there were different participation rates. However, recruitment methods were the same. Women receiving prenatal care in health centers located in Durango City and Lagos de Moreno, Jalisco, Mexico were recruited in 2013–2014. Participation rates are not likely to be an issue as characteristics were similar between those who participated and those who did not. Although the authors did not provide characteristics by area, the characteristics provided do not indicate any differences that may be biased by the selection. Considering the age range for the non-participants, the mean age for non-participants appears to be incorrect (or the age range is incorrect); however, there does not appear to be a difference that would potentially indicate selection bias.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the exposure groups were similar and were recruited with the same methods in the same time frame, with no evidence of differences or issues with participation/response rates.

- ***Confounding:***
  - *Rating:* Probably high risk of bias (−)
  - *Summary:* Questionnaires were used to obtain information about sociodemographic factors, prenatal history, mother's health status before pregnancy (e.g., use of drugs, vaccines, diseases), and the type of water for drinking and cooking. The marginalization index (MI) was obtained from the National Population Council (CONAPO). Two additional surveys were conducted during the second and third trimester of pregnancy to get information about the mother's health, pregnancy evolution, and sources of water consumption. A survey was also conducted to get information about childbirth (type of birth, week of birth, weight and length of the baby at birth, Apgar score and health conditions of the baby during the first month of life). This information was corroborated with the birth certificate. Linear regression models included gestational age, children's age, marginality index, and type of drinking water. Bivariate analyses were conducted on the other factors, including sex, prior to conducting multivariable regression models. Some important covariates were not considered, including parental mental health, IQ, smoking, and potential co-exposures. Water quality maps indicate a potential for arsenic to be present in the study area.
  - *Potentially important study-specific covariates:* Arsenic is a potential co-exposure in this area of Mexico.
    - *Direction/magnitude of effect size:* If arsenic were present as a co-exposure, it would likely bias the association away from the null.
  - *Basis for rating:* Probably high risk of bias based on indirect evidence that there is a potential for co-exposure with arsenic that was not addressed.
- ***Attrition:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Out of the 90 women selected for inclusion in the study, 65 approved the participation of their infants. The authors provide a table of characteristics between women who consented to their children's cognitive evaluation and those who participated only in biological monitoring. There were no significant differences between the groups. There were fewer women who provided urine during the second and third trimesters. All specified children are included in the relevant analyses.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that exclusion of subjects from analyses was adequately addressed, and reasons were documented when subjects were removed from the study or excluded from analyses.
- ***Exposure:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Fluoride exposure was assessed through morning urine samples and water fluoride levels collected from the children's homes. Sampling methodology was appropriately documented, and water levels were quantified through specific

ion-sensitive electrode assays. QC was described, and accuracy was >90%. Urinary fluoride was corrected by specific gravity.

- *Direction/magnitude of effect size:* Not applicable.

- *Basis for rating:* Definitely low risk of bias based on direct evidence that exposure was consistently assessed using well-established methods that directly measured exposure.

- ***Outcome:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Neurodevelopment was assessed with the Bayley Scales of Infant Development II (BSDI-II) that was noted to be reliable and valid for evaluating children from 3 months to 5 years of age. The average age of children assessed was 8 months, with a range of 3–15 months) (++ for methods). The study report stated that a trained psychologist who was blinded about the mother's fluoride exposure evaluated the infants at home (++ for blinding). Overall rating for methods and blinding = ++.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that the outcome was assessed using instruments that were valid and reliable in the study population, and that the outcome assessor was blind to participants' fluoride exposure.
- ***Selective Reporting:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* All outcomes outlined in the abstract, introduction, and methods were reported. Table 4 of the study displays only data for trimesters 1 and 2. Although third trimester data were collected, they were not reported, likely because they were available for only 29 subjects. No discussion of this was provided.
  - *Basis for rating:* Probably low risk of bias because, although it appears some data were not reported, it is likely because there were insufficient data and not because the authors were selectively reporting the results.
- ***Other potential threats:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:*
    - *Statistical analyses:* Statistical analyses used log10-transformed exposure variables. Normality, homoscedasticity, and linearity assumptions were tested and satisfied for MDI and PDI scores. Bivariate analyses included correlations, t-tests, and ANOVA. Multiple linear regression models by the first and second trimester of pregnancy were used to evaluate the association between maternal fluoride exposure and MDI and PDI scores. The best-fit model was selected using a "stepwise method," and the best-fit line was evaluated using "the curve fitting method." It is not further specified or cited what these methods entailed. Best-fit or goodness-of-fit statistics are not reported. It is unclear how a best-fit model could be selected when the authors state that all models adjusted for the same set of covariates regardless of

significance, and these covariates also appear in the final model—presumably the best-fit model. It is unlikely that a stepwise method would retain all those covariates unless they were forced in the model. Residual analysis was conducted to assess model validity; however, there is no description of the results of the residual analysis. Nonetheless, the impact on effect estimates is expected to be minimal.

        - *Other potential concerns:* No other potential concerns were identified. In the peer-review report, NASEM (2020) cited the following as potential concerns: "the large difference in numbers of males and females in the offspring (20 males, 45 females), and apparently incorrect probabilities were reported for age differences between participants and nonparticipants, high rates of cesarean deliveries and premature births among participants (degree of overlap not reported), and incorrect comparisons of observed prematurity rates with national expected rates." However, these concerns were taken into consideration in other domains (***Selection, Confounding***).
    - *Basis for rating:* Probably low risk of bias based on indirect evidence that the statistical analyses were appropriate and there were no other potential threats of risk of bias identified.
- ***Basis for classification as low risk-of-bias study overall:*** Definitely low risk-of-bias ratings in exposure and outcome. Study strengths include individual exposure measurements and blinding of outcome assessor to participants' fluoride exposure, but it is limited by the cross-sectional study design and lack of accounting for potential co-exposures to arsenic.

E.2.9. Wang et al. (2020a)

E.2.9.1. Study Details

- ***Study design:*** Cross-sectional
- ***Population:*** School children aged 7–13 years
- ***Study area:*** Tongxu County, China
- ***Sample size:*** 325 school children
- ***Data relevant to the review:*** Associations between ADHD and other measures of learning disability with urine fluoride concentrations.
- ***Reported association with fluoride exposure:*** Yes: Significant association between psychosomatic problems and urinary fluoride (per 1-mg/L increase; adjusted $\beta = 4.01$ [95% CI: 2.74, 5.28]) and increased risk of a T-score >70 with urinary fluoride (per 1-mg/L increase; adjusted OR = 1.97 [95% CI: 1.19, 3.27]). No significant associations with ADHD or other measures of learning disability.

E.2.9.2. Risk of Bias

- **Author contacts:**
    - Authors were contacted in July of 2020 to obtain additional information for risk-of-bias evaluation. No response was received.

- ***Population selection:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Subjects were recruited in 2017 from Tongxu County, China. Children were selected from four randomly selected primary schools in the area. Selection was based on specified inclusion rules. It was noted that the living habits and diets of the participants from the four schools were well matched, but details were not provided. The area did not have industrial pollution within 1 km of the living environment of the children, and it was noted that the children were not exposed to other neurodevelopmental toxicants (lead, cadmium, arsenic, or mercury). A table of subject characteristics was provided in the study but not by school or exposure. This was a pilot study, and it was not explicitly stated whether all eligible subjects participated in the study. There is no information on participation rates or whether they varied by school.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the exposed groups were recruited using similar methods during the same time frame and that any differences between the exposed groups were considered in the statistical analyses.
- ***Confounding:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* It was noted that subjects were well matched in terms of living habits and diets, but there were no specifics provided. It was noted that there was no industrial exposure or exposure to other neurotoxins such as lead, cadmium, arsenic, or mercury. Covariates were collected using a standardized and structured questionnaire completed by the children and their guardians under the direction of investigators, but reliability or validity of the questionnaire was not reported. Information collected included age, sex, weight, height, parental education level, and parental migration (or work as migrant workers). IQ scores evaluated by the Combined Raven's Test–the Rural in China were used to represent basic cognitive function. Models were adjusted for age, BMI, sex, mother and father migration, and urinary creatinine. Adjustments were not made for parental education, race/ethnicity, maternal demographics (e.g., maternal age, BMI), parental behavioral and mental health disorders (e.g., ADHD, depression), smoking (e.g., maternal smoking status, secondhand tobacco smoke exposure), reproductive factors (e.g., parity), iodine deficiency/excess, maternal (and paternal) IQ, quantity and quality of caregiving environment (e.g., HOME score), or SES other than parental migration. There is no evidence to suggest that SES would differ substantially among the four rural schools in the same area of China that were randomly selected.
  - *Potentially important study-specific covariates:* SES.
    - *Direction/magnitude of effect size:* The impact on the direction and magnitude of effect size are unknown. It was noted that the subjects were matched in terms of living habits and diet, and this could be an indication that SES was not different among the groups, but details were not provided.

  - *Basis for rating:* Probably low risk of bias because there is indirect evidence that the key covariates were considered, that the methods for collecting the information were valid and reliable, and that co-exposure to arsenic was not an issue in this area.

- ***Attrition:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Data are complete. It was noted that there were 325 subjects included, and results were available on all subjects.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that there was no attrition.
- ***Exposure:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Spot urine samples were collected from each child in the early morning into cleaned polyethylene tubes. Fluoride concentrations were measured using fluoride ion-selective electrode [with reference to Ma et al. (2017); however, that reference cites Zhou et al. (2012)]. Therefore, no QC methods or LODs were available. Fluoride concentrations were creatinine-adjusted.
    - *Direction/magnitude of effect size:* Spot urine samples account for only recent exposure. Although this could cause some exposure misclassification, the number of subjects should help dilute any issues with the non-differential misclassification.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that exposure was consistently assessed using acceptable methods that provide individual levels of exposure.
- ***Outcome:***
  - *Rating:* Probably high risk of bias (NR)
  - *Summary:* Children's behavior was assessed by the Chinese version of Conners' Parent Rating Scale-Revised (CPRS-48). The homogeneity reliability of Cronbach α in the Chinese version of CPRS-48 was 0.932, the correlation of Spearman-brown split-half was 0.900, and the retest reliability of total score was 0.594. Raw scores for each subscale were converted into sex- and age-adjusted T-scores within a mean ± standard deviation (SD) of 50 ± 10. The guardians independently completed the CPRS-48 according to the instruction manual under the direction of trained investigators (++ for methods). Blinding is not reported. Although it is unlikely that the outcome assessors were aware of the fluoride levels in the urine, it is unclear whether subjects were selected based on areas with endemic fluoride or whether parents were aware of fluoride concentrations in the areas (NR for blinding). Overall rating for methods and blinding = NR.
  - *Basis for rating:* Probably high risk of bias based on no information provided to indicate that the outcome assessors were blind to the participants' fluoride exposure.
- ***Selective Reporting:***

  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* All outcomes in the abstract, introduction, and methods are reported in sufficient detail.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that all measured outcomes were reported.
- ***Other potential threats:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:*
    - *Statistical analyses:* Multiple linear regression models were used to assess the association between urinary fluoride exposure and each behavioral outcome. Logistic regression was used to assess the risk of behavioral problems (T-scores >70) due to fluoride exposure. Sensitivity analyses were performed, with models adjusting for combinations of age, BMI, sex, mother migrated, father migrated, and urinary creatinine levels. Regression diagnostics to evaluate model assumptions are not described; however, the overall impact on effect estimates is expected to be minimal.
    - *Other potential concerns:* None identified.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the statistical analyses were appropriate and no other potential threats of risk of bias were identified.
- ***Basis for classification as low risk-of-bias study overall:*** Probably low risk-of-bias ratings in confounding and exposure. Study strengths include individual exposure measurements, but it is limited by the cross-sectional study design and lack of details on blinding of the outcome assessment. All key covariates were considered in the study design or analysis.

Appendix F. Mechanistic Data from Animal Studies

Table of Contents

Figures

A number of animal studies were available that presented mechanistic data in several effect categories (see Figure F-1). Limiting the data to studies with at least one exposure at or below 20 ppm fluoride drinking water equivalents (gavage and dietary exposures were backcalculated into equivalent drinking water concentrations for comparison) still provided a sufficient number of studies for evaluation of several mechanistic endpoints while allowing for a more focused look at exposure levels most relevant to human exposures. The following sections summarize the mechanistic data by effect category. Although there is some evidence of consistency in mechanistic effects, overall these data are insufficient to increase confidence in the assessment of findings from human epidemiological studies.

	Dose Level	
Mechanism	**All**	**≤20 ppm**
Biochemical (brain/neurons)	66	25
Neurotransmitters	53	23
Oxidative stress	78	25
Histopathology	67	30
Apoptosis/cell death	19	7
Inflammation	7	5
Thyroid	50	17
Other	3	2

Figure F-1. Number of Animal Mechanistic Studies for Fluoride by Mechanistic Category and Exposure Level

An interactive version of Figure F-1 and additional study details in Tableau® (https://public.tableau.com/app/profile/ntp.visuals/viz/Animal_Mechanisms_2021/FigureA5-1). The number of studies that evaluated mechanistic effects associated with at least one exposure at or below 20 ppm fluoride is tabulated in the "≤20 ppm" column. The total number of studies per mechanistic category is summarized in the "All" column.

F.1. Neurotransmitters

Neurotransmitter and biochemical changes in the brain and neurons were considered the mechanistic areas with the greatest potential to demonstrate effects of fluoride on the brain of animals in the lower dose range and provide evidence of changes in the brain that may relate to lower IQ in children (see Figure F-2). Twenty of 23 neurotransmitter studies assessed changes in brain cholinesterase activity associated with fluoride exposure at or below 20 ppm fluoride. Acetylcholine is a major neurotransmitter involved in learning, memory, and intelligence (Chen 2012; Gais and Schonauer 2017). AChE is responsible for the breakdown of acetylcholine in the synapses of nerve cells. Changes in cholinesterase, acetylcholine, or AChE could be related to effects on memory. Evidence of an effect varied among the low risk-of-bias studies that assessed changes in cholinesterase or acetylcholine (n = 11 drinking water studies) (Adedara et al. 2017a; Akinrinade et al. 2015a; Baba et al. 2014; Chouhan et al. 2010; Gao et al. 2008b; Gao et al. 2009; Khan et al. 2017; Liu et al. 2010; Mesram et al. 2016; Nkpaa and Onyeso 2018; Sun et al. 2000 [translated in Sun et al. 2008]), with the majority reporting evidence of an effect that is considered inconsistent with the phenotypic outcome (see Quality Assessment of Individual

Studies section for methods on determining which studies pose low risk of bias). Decreases in cholinesterase will cause increases in acetylcholine, which can have a positive effect on learning and memory; however, long-term decreases in cholinesterase can lead to secondary neuronal damage occurring in the cholinergic region of the brain (Chen 2012).

Five of the 11 studies with low risk of bias (Adedara et al. 2017a; Baba et al. 2014; Gao et al. 2009; Khan et al. 2017; Nkpaa and Onyeso 2018) found statistically significant decreases in cholinesterase or AChE in brain homogenates (with some brains dissected into specific regions prior to homogenizing) with fluoride concentrations in drinking water at or below 20 ppm, and four of the five studies found statistically significant decreases in cholinesterase or AChE below 10 ppm. The five studies were conducted in rats (Wistar or Sprague-Dawley) with exposure ranging from 28 days to 6 months. An additional 2 out of 11 studies (Akinrinade et al. 2015a; Gao et al. 2008b) reported decreases in brain homogenate AChE at concentrations at or below 20 ppm fluoride in drinking water, but statistical significance was not reached. These studies were also conducted in rats with exposure for 30 days or 3 months. Gao et al. (2008b) reported a dose-dependent decrease in brain homogenate AChE in the low (5 ppm fluoride) and high (50 ppm fluoride) treatment groups compared with the control group, but the decrease was statistically significant only in the high-dose group. Similarly, Akinrinade et al. (2015a) observed a dose-dependent decrease in percent intensity of AChE immunohistochemistry in the prefrontal cortex associated with 2.1 and 10 ppm sodium fluoride in drinking water, but neither result was statistically significant. Gao et al. (2009) found lower brain homogenate AChE levels in the 5-ppm animals compared with the 50-ppm animals; therefore, the results were not always dose-dependent.

Relative to the above-mentioned studies, 2 of the 11 low risk-of-bias studies observed opposite effects on brain cholinesterase levels. Sun et al. (2000) [translated in Sun et al. (2008)] observed a significant increase in brain cholinesterase in Kunming mice associated with fluoride drinking water concentrations from 10 to 100 mg/L but did not observe a dose response. Chouhan et al. (2010) did observe a dose-related increase in AChE levels in brain homogenate of Wistar rats with sodium fluoride concentrations of 1 to 100 ppm for 12 weeks and noted statistically significant results at 1, 50, and 100 ppm but not at 10 ppm.

Mesram et al. (2016) did not assess changes in AChE but observed a significant decrease in acetylcholine levels in cerebral cortex homogenate through 30 days of age in rats treated in utero with 20 ppm sodium fluoride, which may suggest an increase in AChE levels. Likewise, Liu et al. (2010) did not assess changes in AChE but measured nicotinic acetylcholine receptors (nAChRs) in brain homogenate of rats following drinking water fluoride exposure, which the authors stated could modulate physiological and pharmacological functions that are involved in learning- and memory-related behaviors. Significant decreases in the protein expressions of nAChR subunits at 2.26 ppm fluoride were observed; however, the corresponding receptor subunit mRNAs did not exhibit any changes (Liu et al. 2010).

The studies that assessed other neurotransmitters of the brain and neurons were too heterogeneous or limited in number to make any determination on mechanism, even before limiting the review of the data to low risk-of-bias studies. There were only five studies that evaluated dopamine and/or metabolites (Banala et al. 2018; Chouhan et al. 2010; Reddy et al. 2014; Sudhakar and Reddy 2018; Tsunoda et al. 2005). Four of the studies observed decreases in dopamine levels in the brain with exposures of less than 20 ppm fluoride (Banala et al. 2018;

Chouhan et al. 2010; Reddy et al. 2014; Sudhakar and Reddy 2018); however, the fifth study (Tsunoda et al. 2005) observed increased dopamine and metabolites at fluoride exposures below 20 ppm (with statistical significance achieved only for the metabolite homovanillic acid in one brain region). No differences from the control group were observed at levels above 20 ppm fluoride. Other neurotransmitters were evaluated at or below 20 ppm fluoride exposure, but generally only in a couple of studies.

F.2. Biochemistry (Brain/Neurons)

Similar to the above, the endpoints measured in brain biochemistry studies were too heterogeneous or limited in number to make any determination on potential relevance of mechanism, even before limiting the review of the data to low risk-of-bias studies (see Figure F-2). Endpoints related to biochemical changes in the brain or neurons included carbohydrate or lipid changes, RNA or DNA changes, changes in gene expression, or changes in protein expression. For the most part, only a single study was available for any given endpoint. The largest body of evidence on biochemistry was on protein level in various brain regions. Eleven low risk-of-bias studies were identified that evaluated protein levels; however, few studies evaluated the same proteins or areas of the brain. In the few cases in which the same protein was evaluated, results were not always consistent. These data are insufficient to increase confidence or support a change to hazard conclusions.

F.3. Histopathology

Histological data can be useful in determining whether effects are occurring in the brain at lower fluoride concentrations; however, author descriptions of these effects may be limited, thereby making it difficult to directly link histological changes in the brain to learning and memory effects. Histopathology of the brain was evaluated in 31 studies with concentrations at or below 20 ppm fluoride, of which 15 were considered low risk-of-bias studies (Adedara et al. 2017b; Akinrinade et al. 2015a; Bhatnagar et al. 2002; Bhatnagar et al. 2011; Chouhan et al. 2010; Guner et al. 2016; Jia et al. 2019; Jiang et al. 2014; Lou et al. 2013; McPherson et al. 2018; Mesram et al. 2016; Nageshwar et al. 2018; Niu et al. 2018; Pulungan et al. 2016; Zhao et al. 2019). In all but one low risk-of-bias study [Pulungan et al. (2016); gavage], animals were exposed to fluoride via drinking water. All low risk-of-bias studies were conducted in rodents, and all but three were conducted in rats (Wistar [seven studies], Sprague-Dawley [four studies], Long-Evans hooded [one study]). Overall, the low risk-of-bias studies that evaluated histopathology in the brain had low potential for bias for key questions regarding randomization and exposure characterization; however, eight studies were rated as probably high risk of bias for the key risk-of-bias question regarding outcome assessment based on lack of reporting of blinding of outcome assessors and/or inadequate description of outcome measures or lesions. Moreover, low image quality in some of the studies hampered the ability to verify the quality of the data. Further technical review of the 15 low risk-of-bias studies was conducted by a board-certified pathologist. Based on confidence in the results for each study, the technical reviewer further categorized the low risk-of-bias studies as studies with higher or lower confidence in the outcome assessment, which is reflected in the following summary of the brain histopathology results. Main limitations of the histopathology data identified by the pathologist included lack of information on methods of euthanasia and fixation. Perfusion fixation is generally considered the

best practice for lesions of the central nervous system in addition to complete fixation of the brain prior to its removal from the skull (Garman et al. 2016). Four of the low risk-of-bias studies reported that they used this method (Bhatnagar et al. 2002; Bhatnagar et al. 2011; McPherson et al. 2018; Pulungan et al. 2016). Two of the low risk-of-bias studies handled the brains before fixation was complete, which can produce artifacts that can resemble dead neurons (Nageshwar et al. 2018; Zhao et al. 2019). Fixation and brain removal details were inadequately described in the remaining low risk-of-bias studies.

Although there was heterogeneity in the endpoints reported (e.g., cell size, shape, and counts; nuclei fragmentation; increased vacuolar spaces) and some variation in the consistency of the evidence based on the area of the brain evaluated, the majority of the low risk-of-bias studies (11 of 14 drinking water studies) found some histological change in the brain of rats or mice treated with fluoride at concentrations at or below 20 ppm, of which 8 studies reported histological changes in the brain at or below 10 ppm. Histological changes in the hippocampus (one of the areas of the brain most evaluated for histological changes) associated with fluoride exposure at or below 20 ppm were reported in three of four low risk-of-bias studies with higher confidence in the outcome assessment (Bhatnagar et al. 2002; Bhatnagar et al. 2011; Guner et al. 2016) and in three of four low risk-of-bias studies with lower confidence in the outcome assessment (Jiang et al. 2014; Nageshwar et al. 2018; Niu et al. 2018). McPherson et al. (2018) was the only drinking water study (with higher confidence in the histopathology outcome assessment) that did not observe any histological changes in hippocampus at 10 or 20 ppm fluoride in male Long-Evans hooded rats exposed in utero through adulthood (>PND 80). Although there are too few studies to definitively explain the inconsistency in results, McPherson et al. (2018) also did not observe any associations between fluoride exposure and impairments to learning and memory, which is inconsistent with the majority of developmental exposure studies that observed learning and impairments associated with fluoride exposure for other strains of rats. Similarly, histological changes in the cortex were reported in three of the four low risk-of-bias drinking water studies with higher confidence in the outcome assessment (Akinrinade et al. 2015a; Bhatnagar et al. 2011; Chouhan et al. 2010) and in three of four low risk-of-bias studies with lower confidence in the outcome assessment (Lou et al. 2013; Mesram et al. 2016; Nageshwar et al. 2018).

Histological changes were also consistently reported in other areas of the brain in studies with higher confidence in the outcome assessment, including the amygdala, caudate putamen, cerebellum, and hypothalamus, although each of these areas of the brain was evaluated in only one low risk-of-bias study (Bhatnagar et al. 2011; Guner et al. 2016). Pulungan et al. (2016), one of two low risk-of-bias studies with higher confidence in the outcome assessment that did not report histological changes in the brain, observed a decreasing trend in the number of pyramidal cells in the prefrontal cortex with increasing dose, but this was not changed at concentrations below 20 ppm (the study administered sodium fluoride via gavage; the 5-mg/kg/day dose was considered equivalent to 15.3 ppm fluoride in drinking water), nor were any of the results statistically significant.

F.4. Oxidative Stress

Oxidative stress is considered a general mechanistic endpoint that cannot be specifically linked to neurodevelopmental or cognitive effects in humans; however, like histopathology, it may help in identifying changes in the brain occurring at lower concentrations of fluoride. Oxidative stress

in the brain was evaluated in 25 studies that examined concentrations at or below 20 ppm fluoride, of which 15 studies had low potential for bias (Adedara et al. 2017a; Adedara et al. 2017b; Akinrinade et al. 2015b; Bartos et al. 2018; Chouhan and Flora 2008; Chouhan et al. 2010; Gao et al. 2008a; Gao et al. 2009; Guner et al. 2016; Khan et al. 2017; Mesram et al. 2016; Nageshwar et al. 2018; Nkpaa and Onyeso 2018; Shan et al. 2004; Zhang et al. 2015a). All of the low risk-of-bias studies were conducted in rats (mainly Wistar or Sprague-Dawley) and administered fluoride via drinking water with exposure durations ranging from 28 days to 7 months. Although there was heterogeneity in the endpoints reported (i.e., varying measures of protein oxidation, antioxidant activity, lipid peroxidation, and reactive oxygen species [ROS]) and some variation in the consistency of the evidence based on the endpoint, the majority of the studies (13 of 15) (Adedara et al. 2017a; Adedara et al. 2017b; Akinrinade et al. 2015b; Bartos et al. 2018; Gao et al. 2008a; Gao et al. 2009; Guner et al. 2016; Khan et al. 2017; Mesram et al. 2016; Nageshwar et al. 2018; Nkpaa and Onyeso 2018; Shan et al. 2004; Zhang et al. 2015a) found evidence of oxidative stress in the brains of rats treated with fluoride at concentrations at or below 20 ppm, of which 10 studies reported oxidative stress in the brain below 10 ppm fluoride. The most consistent evidence of oxidative stress in the brain was reported through changes in antioxidant activity. Eleven of the 12 low risk-of-bias studies that evaluated antioxidant activity reported an effect at concentrations at or below 20 ppm (Adedara et al. 2017a; Adedara et al. 2017b; Akinrinade et al. 2015b; Bartos et al. 2018; Gao et al. 2008a; Gao et al. 2009; Guner et al. 2016; Khan et al. 2017; Mesram et al. 2016; Nageshwar et al. 2018; Nkpaa and Onyeso 2018). Decreases in antioxidant activity using measures of superoxide dismutase (SOD) activity were reported in seven of eight low risk-of-bias studies (Adedara et al. 2017a; Adedara et al. 2017b; Akinrinade et al. 2015b; Khan et al. 2017; Mesram et al. 2016; Nageshwar et al. 2018; Nkpaa and Onyeso 2018), and, among these seven studies, all that also measured changes in catalase (CAT) activity (n = 6 studies) also reported decreased activity (Adedara et al. 2017a; Adedara et al. 2017b; Khan et al. 2017; Mesram et al. 2016; Nageshwar et al. 2018; Nkpaa and Onyeso 2018). A decrease in total antioxidant capacity (T-AOC) as a measure of antioxidant activity was also consistently reported in two low risk-of-bias studies (Gao et al. 2008a; Gao et al. 2009), and a decrease in glutathione peroxidase (GPx) activity was reported in two of three low risk-of-bias studies (Adedara et al. 2017b; Nkpaa and Onyeso 2018).

Relative to the above-mentioned studies, 2 of the 15 low risk-of-bias studies (Chouhan and Flora 2008; Chouhan et al. 2010) did not observe statistically significant effects on oxidative stress in the brain with concentrations at or below 20 ppm fluoride; however, the measure of oxidative stress evaluated in Chouhan and Flora (2008) and Chouhan et al. (2010) (glutathione [GSH] to oxidized glutathione [GSSG] ratio as an indication of antioxidant activity and ROS levels) were not evaluated in any other low risk-of-bias study. Chouhan and Flora (2008) observed a dose-dependent increase in ROS levels associated with 10, 50, and 100 mg/L sodium fluoride in drinking water; however, results were not statistically significant at any dose. In Chouhan et al. (2010), the levels of ROS were significantly higher at 50 ppm sodium fluoride in drinking water, but statistical significance was not met at doses below 20 ppm fluoride (1 and 10 ppm sodium fluoride) or at 100 ppm sodium fluoride; yet, hydrogen peroxide levels as a measure of ROS were found to be significantly increased at 15 ppm sodium fluoride in drinking water in studies conducted by another group of authors (Adedara et al. 2017a; Adedara et al. 2017b).

F.5. Apoptosis/Cell Death

Seven low risk-of-bias studies were identified that evaluated apoptosis with concentrations at or below 20 ppm fluoride. Results from these studies were inconsistent and were insufficient for evaluating fluoride-induced apoptosis. These data are insufficient to increase confidence or support a change to hazard conclusions.

F.6. Inflammation

Five low risk-of-bias studies were identified that evaluated potential effects of fluoride on inflammation with concentrations at or below 20 ppm. The inflammation markers were too heterogeneous or limited in number to make any determination on potential relevance of mechanism, even before limiting the review of the data to low risk-of-bias studies. These data are insufficient to increase confidence or support a change to hazard conclusions.

F.7. Thyroid

Seventeen studies were identified that evaluated potential effects of fluoride on the thyroid with concentrations at or below 20 ppm (see Figure F-1). These animal thyroid data are not further described because this endpoint has been directly evaluated in a number of human studies that have failed to identify consistent evidence to suggest that thyroid effects are a requisite mechanism by which fluoride causes neurodevelopmental or cognitive effects in humans.

Mechanism	Mechanism Subcategory	Direction of Effect ↑	↓	NS	Grand Total
Biochemistry (brain/neurons)	Carbohydrate/lipid-related		1	1	2
	Gene expression		1		1
	Protein levels associated with brain function	8	7	7	11
	Other biochemical	2			2
Neurotransmitters	Cholinesterase	2	7	3	11
	Dopamine and metabolites		1		1
	Other neurotransmitters	2	2	1	2
Oxidative stress	Antioxidant activity	1	10	4	12
	Lipid peroxidation byproduct	7		4	11
	Protein oxidation	2		1	2
	ROS	2		2	4

Figure F-2. Number of Low Risk-of-bias Animal Studies That Evaluated Biochemical, Neurotransmission, and Oxidative Stress Effects at or below 20 ppm by Mechanism Subcategory and Direction of Effect

An interactive version of Figure F-2 and additional study details in Tableau® (https://public.tableau.com/app/profile/ntp.visuals/viz/Fluoride_Animal_SelectMechanisms_2021/FigureA5-2). This figure displays study counts for low risk-of-bias studies, as these counts are most relevant to the text in this section. Counts for high risk-of bias studies or all studies combined can be accessed in the interactive figure in Tableau®. Study counts are tabulated by significance—statistically significant increase (↑), statistically significant decrease (↓), or not significant (NS). For example, the "↑" column displays numbers of unique studies with at least one endpoint in the mechanistic subcategory with significantly increasing results at fluoride exposure levels of ≤20 ppm. These columns are not mutually exclusive (i.e., a study may report on multiple endpoints with varying results within a single mechanistic subcategory and therefore may be reflected in the counts for the "↑", "↓", and NS columns but would be counted only once in the Grand Total column). Endpoints, species, strain, sex, and exposure duration are available for each study in the interactive figure in Tableau®.

Appendix G. Protocol History and Revisions

Date	Activity or Revision
December 14, 2016	**Draft evaluation protocol reviewed:** sent to technical advisors for peer review
April 10, 2017	**Draft human risk-of-bias protocol reviewed:** sent to technical advisors for peer review

National Toxicology Program
U.S. Department of Health and Human Services

DRAFT NTP MONOGRAPH ON THE

STATE OF THE SCIENCE CONCERNING FLUORIDE EXPOSURE AND NEURODEVELOPMENTAL AND COGNITIVE HEALTH EFFECTS: A SYSTEMATIC REVIEW

October 5, 2021

Division of the National Toxicology Program
National Institute of Environmental Health Sciences
National Institutes of Health

U.S. DEPARTMENT OF HEALTH AND HUMAN SERVICES

FOREWORD

The National Toxicology Program (NTP), established in 1978, is an interagency program within the Public Health Service of the U.S. Department of Health and Human Services. Its activities are executed through a partnership of the National Institute for Occupational Safety and Health (part of the Centers for Disease Control and Prevention), the Food and Drug Administration (primarily at the National Center for Toxicological Research), and the National Institute of Environmental Health Sciences (part of the National Institutes of Health), where the program is administratively located. NTP offers a unique venue for the testing, research, and analysis of agents of concern to identify toxic and biological effects, provide information that strengthens the science base, and inform decisions by health regulatory and research agencies to safeguard public health. NTP also works to develop and apply new and improved methods and approaches that advance toxicology and better assess health effects from environmental exposures.

NTP conducts literature-based evaluations to determine whether exposure to environmental substances (e.g., chemicals, physical agents, and mixtures) may be associated with adverse health effects. These evaluations result in hazard conclusions or characterize the extent of the evidence and are published in the NTP Monograph series, which began in 2011. NTP Monographs serve as an environmental health resource to provide information that can used to make informed decisions about whether exposure to a substance may be of concern for human health.

NTP conducts these health effects evaluations following pre-specified protocols that apply the general methods outlined in the "Handbook for Conducting a Literature-Based Health Assessment Using the OHAT Approach for Systematic Review and Evidence Integration."[1] The protocol describes project-specific procedures tailored to each systematic review in a process that facilitates evaluation and integration of scientific evidence from published human, experimental animal, and mechanistic studies.

Systematic review procedures are not algorithms and the methods require scientific judgments. The key feature of the systematic review approach is the application of a transparent framework to document the evaluation methods and the basis for scientific judgements. This process includes steps to comprehensively search for studies, select relevant evidence, assess individual study quality, rate confidence in bodies of evidence across studies, and then integrate evidence to develop conclusions for the specific research question. Draft monographs undergo external peer review prior to being finalized and published.

NTP Monographs are available free of charge on the NTP website and cataloged in PubMed, a free resource developed and maintained by the National Library of Medicine (part of the National Institutes of Health). Data for these evaluations are included in the Health Assessment and Workspace Collaborative.

For questions about the monographs, please email NTP or call 984-287-3211.

[1]OHAT is the abbreviation for Office of Health Assessment and Translation, which has become the Health Assessment and Translation group in the Integrative Health Assessment Branch of the Division of the National Toxicology Program at the National Institute of Environmental Health Sciences.

PREFACE

The National Toxicology Program (NTP) conducted a systematic review of the published scientific literature because of public concern for the potential association between fluoride exposure and adverse neurodevelopmental and cognitive health effects.

NTP initially published a systematic review of the experimental animal literature in 2016 that was subsequently expanded to include human epidemiology studies, mechanistic studies, and newer experimental animal literature. Because of the high public interest in fluoride's benefits and potential risks, the NTP asked the National Academies of Science, Engineering, and Medicine (NASEM) to conduct an independent evaluation of the *draft NTP Monograph on Fluoride Exposure and Neurodevelopmental and Cognitive Health Effects*" (September 6, 2019) and the revised draft (September 16, 2020), which addressed the NASEM committee's recommendations for improvement. The NASEM committee determined that, "Overall the revised monograph seems to include a wealth of evidence and a number of evaluations that support its main conclusion, but the monograph falls short of providing a clear and convincing argument that supports its assessments…" Thus, the NTP has removed the hazard assessment step and retitled this systematic review of fluoride exposure and neurodevelopmental and cognitive health effects as a "state-of-the-science" document to indicate the change. This state-of-the-science document does not include the meta-analysis of epidemiology studies or hazard conclusions found in previous draft monographs; however, it provides a comprehensive and current assessment of the scientific literature on fluoride as an important resource to inform safe and appropriate use.

The NTP has responded to the NASEM committee's comments on the revised draft (September 16, 2020) in a separate document (place holder for URL) and revised relevant sections of this monograph.

ANIMAL MECHANISTIC DATA FIGURES:

ABSTRACT

Background: A 2006 evaluation by the National Research Council (NRC) found support for an association between consumption of high levels of naturally occurring fluoride in drinking water and adverse neurological effects in humans and recommended further investigation.[2] The evidence reviewed at the time was from dental and skeletal fluorosis-endemic regions of China. Since the NRC review, the number and location of studies examining cognitive and neurobehavioral effects of fluoride in humans has grown considerably, including several recent North American prospective cohort studies evaluating prenatal fluoride exposures.

NTP previously published a systematic review of the evidence from experimental animal studies of the effects of fluoride on learning and memory in 2016. The previous systematic review found a low-to-moderate level of evidence that learning and memory deficits occur in non-human mammals exposed to fluoride.

Objective: To conduct a systematic review of the human, experimental animal, and mechanistic literature to evaluate the extent and quality of the evidence linking fluoride exposure to neurodevelopmental and cognitive effects in humans.

Method: A systematic review protocol was developed and utilized following the Office of Health Assessment and Translation's (OHAT's) standardized systematic review approach for conducting literature-based health assessments. This review addresses the state of the science with regard to whether exposure to fluoride could present a potential hazard (i.e., has the potential to cause harm at any exposure level). Benefits of fluoride with respect to oral health are not addressed in this monograph.

Results: Examination of newer experimental animal literature, including studies carried out at the NTP, did not provide information that adds clarity to the findings of the 2016 review. Eight low risk-of-bias studies evaluated fluoride exposure and mechanistic data in humans, including thyroid hormone levels in adults and/or children, thyroid conditions in children and/or adults, and thyroid diseases in adults. The findings of these studies and other human studies of brain histopathology or other biochemical changes do not provide evidence of a consistent mechanism by which fluoride may cause adverse neurological effects.

This systematic review identified studies of cognitive or neurodevelopmental effects in both adults and children, which were evaluated separately. In adults, only two cross-sectional studies examining cognitive effects were available. The literature in children was more extensive and was separated into studies assessing IQ and studies assessing other cognitive neurodevelopmental outcomes. Eight of nine high quality studies examining other cognitive neurodevelopmental outcomes reported lower performance in a neurological outcome associated with fluoride exposure. Sixty-six studies assessed the association between fluoride exposure and IQ in children. Of the 19 high quality IQ studies in children, 18 reported an inverse association with fluoride exposure. These 18 studies, which include 3 prospective cohort studies and 15 cross-sectional studies, were conducted in 5 different countries. Forty-one of the

[2]NRC (National Research Council). 2006. *Fluoride in Drinking Water: A Scientific Review of EPA's Standards*. Washington, DC: The National Academies Press. Available at: http://www.nap.edu/catalog/11571/fluoride-in-drinking-water-a-scientific-review-of-epas-standards.

47 low quality studies in children also found evidence of an inverse relationship between fluoride exposure and IQ.

Discussion: The animal studies provide little insight into the question of whether fluoride exposure affects IQ. Human mechanistic studies were too heterogenous and limited in number to make any determination on biological plausibility. The body of evidence from studies on adults is also limited and provides low confidence that fluoride exposures are associated with adverse effects on adult cognition. There is, however, extensive literature on IQ effects in children. There is also some evidence that fluoride exposure is associated with other neurodevelopmental and cognitive effects although, because of the heterogeneity of the outcomes, there is low confidence in the literature for these other effects. The body of evidence from epidemiological studies that assess IQ in children is large, presents a consistent pattern of effects, and provides moderate confidence that fluoride exposures are associated with lower IQ in children.

INTRODUCTION

The NTP's Office of Health Assessment and Translation (OHAT) conducted a systematic review to evaluate the evidence that exposure to fluoride is associated with neurodevelopmental or cognitive effects. There are numerous human and animal studies reporting neurodevelopmental and cognitive health effects of exposure to excess fluoride. As noted by the National Research Council (NRC) in their 2006 report, although the studies lacked sufficient detail to fully assess their quality and relevance to the U.S. populations, the consistency of the results suggesting that fluoride may be neurotoxic warrants additional research (NRC 2006).

Fluoride salts are added to community water systems and dental products in the United States (e.g., toothpaste, mouth rinses, and supplements) for the prevention of dental caries. Approximately 67% of the U.S. population receives fluoridated water through a community drinking water system (CDC 2013). In other countries fluoride supplementation has been achieved by fluoridating food products such as salt, or milk. Fluoride supplementation has been recommended to prevent bone fractures (Jones *et al.* 2005). Fluoride also can occur naturally in drinking water. Other sources of human exposure include other foods and beverages, industrial emissions, pharmaceuticals, and pesticides (e.g., cryolite, sulfuryl fluoride). Soil ingestion is another source of fluoride exposure in young children (US EPA 2010).

The U.S. Public Health Service (PHS) first recommended communities add fluoride to drinking water in 1962. PHS guidance is advisory, not regulatory, which means that while PHS recommends community water fluoridation as a public health intervention, the decision to fluoridate water systems is made by state and local governments.[3] For community water systems that add fluoride, PHS now recommends a fluoride concentration of 0.7 milligrams/liter (mg/L) (equal to 0.7 parts per million [ppm]). Under the Safe Drinking Water Act, the U.S. Environmental Protection Agency (EPA) sets maximum exposure level standards for drinking water quality. The current enforceable drinking water standard for fluoride, or the maximum contaminant level (MCL), is 4.0 mg/L. This level is the maximum amount of fluoride contamination (naturally occurring not from water fluoridation) that is allowed in water from public water systems and is set to protect against increased risk of skeletal fluorosis, a condition characterized by pain and tenderness of the major joints. EPA also has a non-enforceable secondary drinking water standard of 2.0 mg/L, which is recommended to protect children against the tooth discoloration and/or pitting that can be caused by severe dental fluorosis during the formative period prior to eruption of the teeth. Although the secondary standard is not enforceable, EPA requires that public water systems notify the public if the average levels exceed 2.0 mg/L (NRC 2006). The World Health Organization (WHO) set a safe water guideline of 1.5 mg/L (first established in 1984 and reaffirmed in 1993 and 2011), which is recommended to protect against increasing risk of dental and skeletal fluorosis (WHO 2011).

As of April 2020, 1.08% of persons living in the United States (~ 3.5 million people) were served by community water systems (CWS) containing ≥ 1.1 mg/L naturally occurring fluoride. CWS supplying water with ≥ 1.5 mg/L naturally occurring fluoride served 0.59% of the U.S. population (~ 1.9 million

[3]For many years, most fluoridated community water systems used fluoride concentrations ranging from 0.8 to 1.2 mg/L (US DHHS 2015).

people), and systems supplying water with ≥ 2 mg/L naturally occurring fluoride served 0.31% of the U.S. population (~1 million people) (https://www.cdc.gov/fluoridation/data-tools/reporting-system.html).

Commonly cited health concerns related to fluoride are bone fractures and skeletal fluorosis, lower intelligence quotient (IQ) and other neurological effects, cancer, and endocrine disruption. Effects on neurological function, endocrine function (e.g., thyroid, parathyroid, pineal), metabolic function (e.g., glucose metabolism), and carcinogenicity were assessed in the 2006 NRC report Fluoride in Drinking Water: A Scientific Review of EPA's Standards (NRC 2006). The NRC review considered adverse effects of water fluoride, focusing on a range of concentrations (2–4 mg/L) above the current 0.7-mg/L recommendation for community water fluoridation. The NRC report concluded that the Maximum Contaminant Level Goal (MCLG), also 4 mg/L should be lowered to protect against severe enamel fluorosis and to reduce the risk of bone fractures associated with skeletal fluorosis (NRC 2006). Other than severe fluorosis, the NRC did not find sufficient evidence of negative health effects at fluoride levels below 4.0 mg/L; however, the NRC concluded that the consistency of the results of IQ deficits in children exposed to fluoride at 2.5 to 4 mg/L in drinking water from a few epidemiological studies of Chinese populations appeared significant enough to warrant additional research on the effects of fluoride on intelligence. The NRC report noted several challenges to evaluating the literature, citing deficiencies in reporting quality, lack of consideration of all sources of fluoride exposure, incomplete consideration of potential confounding, selection of inappropriate control subject populations in epidemiological studies, absence of demonstrated clinical significance of reported endocrine effects, and incomplete understanding of the biological relationship between histological, biochemical, and molecular alterations with behavioral effects (NRC 2006).

In 2016, NTP conducted a systematic review of the evidence from experimental animal studies on the potential effects of fluoride exposure on learning and memory (NTP 2016). The NTP (2016) systematic review found a low-to-moderate level of evidence that learning and memory deficits occur in experimental animals exposed to fluoride. Based on the findings in NTP (2016), NTP decided to conduct additional animal studies before carrying out a full systematic review to incorporate human, animal, and potentially relevant mechanistic evidence in order to reach hazard identification conclusions for fluoride and learning and memory effects. As the NTP (2016) report on the experimental animal evidence focused on learning and memory and developed confidence ratings for bodies of evidence by life stage of exposure (i.e., exposure during development or adulthood), this report also evaluates two different age groups in humans (i.e., children and adults) with a focus on cognitive neurodevelopmental effects in children and cognitive effects in adults in order to address potential differences in the health impact based on timeframe of exposure (i.e., during development or during adulthood). The evaluation of experimental animal studies in this report has been conducted separately from the 2016 experimental animal assessment, but like the 2016 assessment, it has assessed mainly learning and memory effects in experimental animal studies to determine whether the findings inform the assessment of cognitive neurodevelopmental effects in children and cognitive effects in adults.

A committee convened by the National Academy of Sciences, Engineering, and Medicine (NASEM) reviewed earlier drafts of this monograph (September 6, 2019 and September 16, 2020) (NASEM 2020, 2021). The current document incorporates changes in regard to those reviews, and responses to the 2020 review are available at (placeholder to cite NTP 2021 Response to NASEM comments).

OBJECTIVE AND SPECIFIC AIMS

Objective

The overall objective of this evaluation was to undertake a systematic review to develop NTP hazard identification conclusions on the association between exposure to fluoride and neurodevelopmental and cognitive effects based on assessing levels of evidence from human and non-human animal studies in consideration of the degree of support from mechanistic data. However, the NASEM Committee reviews (NASEM 2020, 2021) of the 2019 and 2020 drafts of the monograph indicated that, "Overall the revised monograph seems to include a wealth of evidence and a number of evaluations that support its main conclusion, but the monograph falls short of providing a clear and convincing argument that supports its assessments…" For this reason, the methods were revised to remove the hazard assessment step (i.e., the section to Integrate Evidence to Develop Hazard Identification Conclusions). In addition, a meta-analysis of the epidemiology studies examining children's IQ in relation to fluoride exposure added to the 2020 draft in response to NASEM comments (NASEM 2020) will be submitted as a separate publication and is not part of this document.

Therefore, the objective of this revised document is to undertake a systematic review of the literature concerning the association of fluoride exposure and neurodevelopmental and cognitive effects based on evaluating evidence from human and non-human animal studies with consideration of mechanistic understanding.

Specific Aims

- Identify literature that assessed neurodevelopmental and cognitive health effects, especially outcomes related to learning, memory, and intelligence, following exposure to fluoride in human, animal, and relevant in vitro/mechanistic studies.
- Extract data on potential neurodevelopmental and cognitive health effects from relevant studies.
- Assess the internal validity (risk of bias) of individual studies using pre-defined criteria.
- Assess effects on thyroid function to help evaluate potential mechanisms of impaired neurological function.
- Summarize the extent and types of health effects evidence available.
- Describe limitations of the systematic review, strengths and limitations of the evidence base, identify areas of uncertainty, as well as data gaps and research needs for neurodevelopmental and cognitive health effects of fluoride.

Dependent on the extent and nature of the available evidence:

- Synthesize the evidence using a narrative approach.
- Rate confidence in the body of evidence for human and animal studies separately according to one of four statements: High, Moderate, Low, or Very Low/No Evidence Available.

METHODS

Problem Formulation and Protocol Development

The research question and specific aims stated above were developed and refined through a series of problem formulation steps including:

(1) receipt of nomination from the public in June 2015 to conduct analyses of fluoride and developmental neurobehavioral toxicity;

(2) analysis of the extent of evidence available and the merit of pursuing systematic reviews, given factors such as the extent of new research published since previous evaluations and whether these new reports address or correct the deficiencies noted in the literature (NRC 2006, OEHHA 2011, SCHER 2011);

(3) request for information in a Federal Register notice (dated October 7, 2015);

(4) consideration of comments providing a list of studies to review through Federal Register notice and public comment period from October 7, 2015 to November 6, 2015;

(5) release of draft concept titled *Proposed NTP Evaluation on Fluoride Exposure and Potential for Developmental Neurobehavioral Effects* in November 2015;

(6) presentation of draft concept at the NTP Board of Scientific Counselors (BSC) meeting on December 1−2, 2015;

(7) consideration of comments on NTP's draft concept from the NTP BSC meeting in December 2015; and

(8) consideration of input on the draft protocol from review by technical advisors.

The protocol used to conduct this systematic review was posted in June 2017 with updates posted in May 2019 and September 2020 (https://ntp.niehs.nih.gov/go/785076).[4] The protocol served as the complete methods followed for the conduct of this systematic review. The OHAT Handbook for Conducting a Literature-Based Health Assessment (http://ntp.niehs.nih.gov/go/38673) is a source of general systematic review methods that were selected and tailored in developing this protocol. Options in the OHAT handbook that were not specifically referred to in the protocol were not part of the methods for the systematic review.

A brief summary of the methods is presented below. Although the methods were revised to remove the hazard assessment step and meta-analysis from this document, the protocol was not further revised.

PECO Statements

PECO (**P**opulation, **E**xposure, **C**omparators and **O**utcomes) statements were developed as an aid to identify search terms and inclusion/exclusion criteria as appropriate for addressing the overall research question (effects on neurodevelopmental or cognitive function and thyroid associated with fluoride

[4]NTP conducts systematic reviews following pre-specified protocols that describe the review procedures selected and applied from the general methods outlined in the OHAT Handbook for Conducting a Literature-Based Health Assessment (http://ntp.niehs.nih.gov/go/38673). The protocol describes project-specific procedures tailored to each systematic review that supersede the methods in the OHAT Handbook.

exposure) for the systematic review (Higgins and Green 2011).The PECO statements are listed below for human, animal, and in vitro/mechanistic studies (see **Table 1**, **Table 2**, and **Table 3**).

Using the PECO statements, the evaluation searched for evidence of neurodevelopmental or cognitive function, and thyroid effects associated with fluoride exposure from human studies, controlled exposure animal studies, and mechanistic/in vitro studies. Mechanistic data can come from a wide variety of studies that are not intended to identify a disease phenotype. This source of experimental data includes in vitro and in vivo laboratory studies directed at cellular, biochemical, and molecular mechanisms that attempt to explain how a substance produces particular adverse health effects. The mechanistic data were first organized by general categories (e.g., biochemical effects in the brain and neurons, neurotransmitters, oxidative stress, etc.) to evaluate the information available. Categories focused on were those with more robust data at levels of fluoride more relevant to human exposure. The intent was not to develop a mechanism for fluoride induction of learning and memory effects, but to evaluate whether a plausible series of mechanistic events exists to support effects observed in the low-dose region (below approximate drinking water equivalent concentrations of 20 ppm for animal studies) that may strengthen the hazard conclusion.

Table 1. Human PECO (Population, Exposure, Comparator and Outcome) Statement

PECO Element	Evidence
Population	Humans without restriction as to age or sex, geographic location, or life stage at exposure or outcome assessment
Exposure	Exposure to fluoride based on administered dose or concentration, biomonitoring data (e.g., urine, blood, other specimens), environmental measures (e.g., air, water levels), or job title or residence. Relevant forms are those used as additives for water fluoridation: • Fluorosilicic acid (also called hydrofluorosilicate; Chemical Abstracts Service Registry Number [CASRN] 16961-83-4) • Sodium hexafluorosilicate (also called disodium hexafluorosilicate or sodium fluorosilicate; CASRN 16893-85-9) • Sodium fluoride (CASRN 7681-49-4) • Other forms of fluoride that readily dissociate into free fluoride ions (e.g., potassium fluoride, calcium fluoride, ammonium fluoride)
Comparators	Comparable populations not exposed to fluoride or exposed to lower levels of fluoride (e.g., exposure below detection levels)
Outcomes	Neurodevelopmental outcomes including learning, memory, intelligence, other forms of cognitive behavior, other neurological outcomes (e.g., anxiety, aggression, motor activity), and biochemical changes in the brain or nervous system tissue; or measures of thyroid function, biochemical changes, or thyroid tissue

Table 2. Animal PECO Statement	
PECO Element	**Evidence**
Population	Non-human mammalian animal species (whole organism)
Exposure	Exposure to fluoride based on administered dose or concentration, and biomonitoring data (e.g., urine, blood, other specimens). Relevant forms are those used as additives for water fluoridation: • Fluorosilicic acid (also called hydrofluorosilicate; CASRN 16961-83-4) • Sodium hexafluorosilicate (also called disodium hexafluorosilicate or sodium fluorosilicate; CASRN 16893-85-9) • Sodium fluoride (CASRN 7681-49-4) • Other forms of fluoride that readily dissociate into free fluoride ions (e.g., potassium fluoride, calcium fluoride, ammonium fluoride)
Comparators	Comparable animals that were untreated or exposed to vehicle-only treatment
Outcomes	Neurodevelopmental outcomes including learning, memory, intelligence, other forms of cognitive behavior, other neurological outcomes (e.g., anxiety, aggression, motor activity), and biochemical changes in the brain or nervous system tissue; or measures of thyroid function, biochemical changes, or thyroid tissue

Table 3. In Vitro/Mechanistic PECO Statement	
PECO Element	**Evidence**
Population	Human or animal cells, tissues, or biochemical reactions (e.g., ligand binding assays)
Exposure	Exposure to fluoride based on administered dose or concentration. Relevant forms are those used as additives for water fluoridation: • Fluorosilicic acid (also called hydrofluorosilicate; CASRN 16961-83-4) • Sodium hexafluorosilicate (also called disodium hexafluorosilicate or sodium fluorosilicate; CASRN 16893-85-9) • Sodium fluoride (CASRN 7681-49-4) • Other forms of fluoride that readily dissociate into free fluoride ions (e.g., potassium fluoride, calcium fluoride, ammonium fluoride)
Comparators	Comparable cells or tissues that were untreated or exposed to vehicle-only treatment
Outcomes	Endpoints related to neurological and thyroid function, including neuronal electrophysiology; mRNA, gene, or protein expression; cell proliferation or death in brain or thyroid tissue/cells; neuronal signaling; synaptogenesis, etc.

Literature Search

Main Literature Search

Search terms were developed to identify all relevant published evidence on developmental neurobehavioral toxicity or thyroid-related health effects potentially associated with exposure to fluoride by reviewing Medical Subject Headings for relevant and appropriate neurobehavioral and thyroid-related terms, and by extracting key neurological and thyroid-related health effects and

developmental neurobehavioral terminology from reviews and a sample of relevant studies[5]. A combination of relevant subject headings and keywords were subsequently identified. A test set of relevant studies was used to ensure the search terms retrieve 100% of the test set. Six electronic databases were searched (see **Main Literature Database Search**) using a search strategy tailored for each database (specific search terms used for the PubMed search are presented in **Appendix 1**; the search strategy for other databases are available in the protocol (https://ntp.niehs.nih.gov/go/785076). A search of PubChem indicated that sodium fluoride was not found in either the Tox21 or ToxCast databases; therefore, these databases were not included in the search. No language restrictions or publication year limits were imposed. These six databases were searched in December 2016 and the search was regularly updated during the review process through April 1, 2019.

An additional search was conducted on May 1, 2020, where human epidemiology studies with primary neurodevelopmental or cognitive outcomes (learning, memory, and intelligence) were prioritized during screening. The review of the 2020 search results focused only on the human studies because they formed the basis of the conclusions in the September 6, 2019, draft. A supplemental literature search of Chinese-language databases (described below) was also conducted.

Publications identified in these searches are categorized as "references identified through database searches" in **Figure 2.** Studies identified from other sources or manual review that might impact conclusions were considered under "references identified through other sources" in **Figure 2**. Literature searches for this systematic review were conducted independently from the literature search conducted for NTP (2016). The current literature search strategy was based on the search terms used for NTP (2016) and refined for the current evaluation, including the addition of search terms to identify human studies. Although the review process identified studies prior to 2015, the current assessment did not evaluate the studies published prior to 2015 and relied on the NTP (2016) assessment. The focus of the literature searches for this systematic review was to identify and evaluate relevant animal studies that were published since completion of the literature searches for the NTP (2016) assessment in addition to the human and mechanistic data that were not previously evaluated.

Supplemental Chinese Database Literature Search

In order to identify non-English-language studies that might not appear in databases for the main literature search, additional searches were developed for non-English-language databases. We were unable to find definitive guidance on the most comprehensive, highest quality, or otherwise most appropriate non-English-language databases for health studies of fluoride. Therefore, we chose databases that identified non-English-language studies that we were aware of – those previously identified from other resources (e.g., Chinese-language studies from the Fluoride Action Network website). Multiple non-English language databases were explored before finding two databases (CNKI and Wanfang) that covered studies previously identified from other sources. These two Chinese electronic databases were searched in May 2020 with no language restrictions or publication year limits. Search terms from the main literature search were refined to focus on human epidemiology studies. The CNKI and Wanfang databases have character limits in the search strings; therefore, key terms were prioritized using text analytics to identify the most prevalent terms from neurodevelopmental or cognitive human epidemiology studies previously identified as relevant. Search strings were designed to capture known relevant studies that were previously identified from searching other resources without identifying large numbers of non-relevant studies [the search strategy for both databases is available in

[5]The terms "study" and "publication" are used interchangeably in this document to refer to a published work drawn from an original body of research conducted on a defined population.

the protocol (https://ntp.niehs.nih.gov/go/785076)]. Publications retrieved were compared to publications retrieved from the main literature search and duplicates were removed. The remaining relevant publications are categorized as "references identified through database searches" in **Figure 2**.

New animal and mechanistic references retrieved were scanned for evidence that might extend the information currently in the September 6, 2019 draft. Although additional studies were identified, data that would materially advance the animal and mechanistic findings were not identified; therefore, these studies were not extracted nor were they added to the draft. A primary goal of the screening of the newly-retrieved human references in the supplemental search of Chinese databases was to identify null, or no-effect, studies that evaluated primary neurodevelopmental or cognitive outcomes (i.e., learning, memory, and intelligence) that may have been missed in previous searches that did not include the Chinese databases. NTP also wanted to examine whether the non-English studies on the Fluoride Action website had been selectively presented to only list studies reporting effects of fluoride; therefore, identifying null, or no-effect, studies was of particular interest. Newly-retrieved human references were reviewed to identify studies that might impact conclusions with priority given to identifying and translating null studies that may have been missed using previous approaches. Null studies that were identified were translated and included.

Databases Searched

Main Literature Database Search

- EMBASE
- PsycINFO (APA PsycNet)
- PubMed (NLM)
- Scopus (Elsevier)
- Web of Science (Thomson Reuters, Web of Science indexes the journal Fluoride)

Supplemental Chinese Database Literature Search

- CNKI
- Wanfang

Searching Other Resources

The reference lists of all included studies; relevant reviews, editorials and commentaries; and the Fluoride Action Network website (http://fluoridealert.org/) were manually searched for additional relevant publications.

Unpublished Data

Unpublished data were eligible for inclusion provided the owner of the data was willing to have the data made public and peer reviewed (see protocol for more details https://ntp.niehs.nih.gov/go/785076).

Study Selection

Evidence Selection Criteria

In order to be eligible for inclusion, studies had to satisfy eligibility criteria that reflect the PECO statement in **Table 1**, **Table 2**, and **Table 3**. The following additional exclusion criteria were applied (see protocol for additional details; https://ntp.niehs.nih.gov/go/785076):

(1) Case studies and case reports.

(2) Articles without original data (e.g., reviews, editorials, or commentaries). Reference lists from these materials, however, were reviewed to identify potentially relevant studies not identified from the database searches. New studies identified were assessed for eligibility for inclusion.

(3) Conference abstracts, theses, dissertations, and other non-peer reviewed reports.

Screening Process

References retrieved from the literature search were independently screened by two trained screeners at the title and abstract level to determine whether a reference met the evidence selection criteria. Screening procedures following the evidence selection criteria in the protocol were pilot-tested with experienced contract staff overseen by NTP. For citations with no abstract or non-English abstracts, articles were screened based on title relevance (title would need to indicate clear relevance); number of pages (articles ≤ 2 pages were assumed to be conference reports, editorials, or letters unlikely to contain original data); and/or PubMed Medical Subject Headings (MeSH). Using this approach, literature was manually screened for relevance and eligibility against the evidence selection criteria using a structured form in SWIFT-Active Screener. While the human screeners review studies, SWIFT-Active Screener aids in the process by employing a machine-learning software program used to priority-rank studies for screening (Howard *et al.* 2020). SWIFT-Active Screener also refines a statistical model that continually ranks the remaining studies according to their likelihood for inclusion. In addition, SWIFT-Active Screener employs active learning to continually incorporate user feedback during title and abstract screening to predict the total number of included studies, thus providing a statistical basis for a decision about when to stop screening (Miller *et al.* 2016). Title and abstract screening was stopped once the statistical algorithm in SWIFT-Active Screener estimated that 98% of the predicted number of relevant studies were identified.

Studies that were not excluded during the title and abstract screening were further screened for inclusion with a full-text review by two independent reviewers using DistillerSR® by Evidence Partners, a web-based, systematic-review software program with structured forms and procedures to ensure standardization of the process. Screening conflicts were resolved through discussion and consultation with technical advisor(s), if necessary. During full-text review, studies that were considered relevant were tagged to the appropriate evidence streams (i.e., human, animal, and/or in vitro). Studies tagged to human or animal evidence streams were also categorized by outcome as primary neurodevelopmental or cognitive outcomes (learning, memory, and intelligence); secondary neurobehavioral outcomes (anxiety, aggression, motor activity, or biochemical); or related to thyroid effects. In vitro data were tagged as being related to neurological effects or thyroid effects. Translation assistance was sought to assess the relevance of non-English studies. Following full-text review, the remaining studies were "included" and used for the evaluation.

Evaluation of SWIFT-Active Screener Results

During the initial title and abstract screening of 20,883 references using SWIFT-Active Screener, approximately 38%[6] of the 20,883 studies were manually screened in duplicate to identify an estimated

[6]Howard *et al.* (2020) evaluated the performance of the SWIFT-Active Screener methods for estimating total number of relevant studies using 26 diverse systematic review datasets that were previously screened manually by reviewers. The authors found that on average, 95% of the relevant articles were identified after screening 40% of the total reference list when using SWIFT-Active Screener. In the document sets with 5,000 or more references, 95% of the relevant articles were identified after screening 34% of the available references, on average, using SWIFT-Active Screener.

98.6% of the predicted number of relevant studies using the statistical algorithm in SWIFT-Active Screener (13,023 references were not screened). SWIFT-Active Screener predicted that there were 739 relevant studies during the initial title and abstract screening, of which 729 studies were identified and moved to full-text review. The SWIFT-Active statistical algorithm predicted that 10 relevant studies at the title and abstract level (10 represents 1.4% × 739 predicted relevant studies; or 739 predicted relevant studies minus 729 identified relevant studies during screening) were not identified by not screening the remaining 13,023 studies.

To further consider the impact of using SWIFT-Active Screener for this systematic review, NTP evaluated the SWIFT-Active screening results to gain a better understanding of the relevance of the last group of studies that were screened before 98% predicted recall (i.e., 98% of the predicted number of relevant studies were identified). The goal was to determine the likelihood of having missed important studies by not screening all of the literature. To do this, NTP evaluated subsets of studies screened in SWIFT-Active for trends and followed those studies through to full-text review for a final determination of relevance and potential impact (i.e., whether the studies had data on primary outcomes). Based on this evaluation, NTP estimates that the use of SWIFT-Active Screener may have resulted in missing 1–2 relevant human studies and 1–2 relevant animal studies with primary neurodevelopmental or cognitive outcomes. Therefore, the use of SWIFT-Active Screener saved considerable time and resources and is expected to miss very few potentially relevant publications.

Screening of the May 2020 Literature Search Update

For the May 1, 2020, literature search, only primary human epidemiology studies were identified for data extraction. The study screening and selection process was focused on the human studies with primary outcomes for the evaluation because they form the basis of the conclusions. Animal in vivo, human secondary outcome-only, and human and animal mechanistic references were identified as part of the screening process. These studies were then scanned for evidence that might extend the information in the September 6, 2019 draft. All included studies from the May 2020 literature search update appear in **Appendix 2**; however, other than the primary human epidemiology studies, data from the new studies were not extracted unless it was believed they would materially advance the findings.

Note that NTP is aware of a conference abstract by Santa-Marina *et al.* on a Spanish cohort study that looked at fluoride exposure and neuropsychological development in children (Santa-Marina *et al.* 2019). NTP conducted a targeted literature search in April 2021 to see if the data from this study had been published. When no publication was found, NTP contacted the study authors to inquire about the publication of their data. The response from the study authors indicated that the study report was being finalized but had not yet been sent to a journal for review; therefore, it was not considered here.

Supplemental Chinese Database Searches and Human Epidemiology Studies

Supplemental searches were conducted in non-English-language databases (CNKI and Wanfang). One focus of the screening of these supplemental search results was to identify null or no-effect studies that evaluated primary neurodevelopmental or cognitive outcomes (learning, memory, and intelligence) that may have been missed in previous approaches or may have been absent from the Fluoride Action Network website. Of the 906 references that were identified in the supplemental Chinese database searches, 13 relevant studies published in Chinese with primary neurological outcomes were identified during title and abstract screening (which were not identified through the main literature searches). Based on information in the titles and abstracts of these 13 studies, Kang *et al.* (2011) was the only null study with primary neurological outcomes that was identified through the supplemental Chinese database searches. NTP had this study translated to English, and the study was included. Note that Kang

et al. (2011) is also identified by the Fluoride Action Network as a null study, but their website does not include an English translation of the study. Full texts were not found for four studies after an extensive search. Among the eight studies for which full texts were retrieved, one study evaluated adults, and the remaining seven studies contained results that would likely add to the body of evidence showing an inverse association between fluoride exposure and IQ in children. An epidemiologist fluent in Chinese evaluated the key risk-of-bias questions for observational human studies (i.e., confounding, exposure characterization, and outcome assessment) for the seven studies considered likely to add to the body of evidence in children. The review indicated that all seven studies would fall into the high risk-of-bias category. Author inquiries were conducted in Chinese to obtain missing information relevant to the assessment of the key risk-of-bias questions, but these inquiries did not result in additional information that would alleviate the risk-of-bias concerns. Because the body of evidence is already large, and because time was a factor in the revision of the monograph, these studies were not translated or included as this information on additional high risk-of-bias studies would likely not materially advance the human findings.

Data Extraction

Data were collected (i.e., extracted) from included studies by one member of the evaluation team and checked by a second member of the team for completeness and accuracy. Any discrepancies in data extraction were resolved by discussion or consultation with a third member of the evaluation team.

Data extraction was completed using the Health Assessment Workspace Collaborative (HAWC), an open source and freely available web-based interface application.[7] Data extraction elements are listed separately for human, animal, and in vitro studies in the protocol (https://ntp.niehs.nih.gov/go/785076). Data for primary and secondary outcomes as well as thyroid hormone level data were extracted from human studies. Studies evaluating only goiters or thyroid size were not extracted. All primary outcomes and functional neurological secondary outcomes (e.g., motor activity) were extracted from animal studies identified since the NTP (2016) report. For animal mechanistic data, studies were tiered based on exposure dose (with preference given to fluoride drinking water equivalent exposures, which were calculated using the method described in the NTP (2016) report) of 20 ppm or less as deemed most relevant to exposures in humans), exposure duration or relevant time window (i.e., developmental), exposure route (with preference given to oral exposures over injection exposures), and commonality of mechanism (e.g., inflammation, oxidative stress, changes in neurotransmitters, and histopathological changes were considered pockets of mechanistic data). Data were not extracted from in vitro studies; however, these studies were evaluated for data that could inform the biological plausibility of the human and animal results. Thyroid data were also reviewed but not extracted. The data extraction results for included studies are publicly available and can be downloaded in Excel format through HAWC (https://hawcproject.org/assessment/405/). Methods for transforming and standardizing dose levels and results from behavioral tests in experimental animals are detailed in the protocol (https://ntp.niehs.nih.gov/go/785076).

In 2016, NTP conducted a systematic review of the evidence from experimental animal studies on the potential effects of fluoride exposure on learning and memory (NTP 2016). The literature searches for the current assessment identified and evaluated relevant animal studies published since the 2016

[7]HAWC (Health Assessment Workspace Collaborative): A Modular Web-based Interface to Facilitate Development of Human Health Assessments of Chemicals (https://hawcproject.org/portal/).

assessment and also included human and mechanistic data that were not previously evaluated. Although literature search activities for the current assessment identified experimental animal studies prior to 2015, the current assessment did not re-evaluate studies published prior to 2015 and relied on the NTP (2016) assessment.

Quality Assessment of Individual Studies

Risk of bias was assessed for individual studies using a tool developed by OHAT that outlines a parallel approach to evaluating risk of bias from human, animal, and mechanistic studies to facilitate consideration of risk of bias across evidence streams with common terms and categories. The risk-of-bias tool is comprised of a common set of 11 questions that are answered based on the specific details of individual studies to develop risk-of-bias ratings for each question. Study design determines the subset of questions used to assess risk of bias for an individual study (see **Table 4**). When evaluating the risk of bias for an individual study, the direction and magnitude of effect of any specific bias is considered.

Assessors were trained with an initial pilot phase undertaken to improve clarity of rating criteria and to improve consistency among assessors. Studies were independently evaluated by two trained assessors who answered all applicable risk-of-bias questions with one of four options in **Table 5** following pre-specified criteria detailed in the protocol (https://ntp.niehs.nih.gov/go/785076). The criteria describe aspects of study design, conduct, and reporting required to reach risk-of-bias ratings for each question and specify factors that can distinguish among ratings (e.g., what separates “definitely low” from “probably low” risk of bias).

Key Risk-of-bias Questions

In the OHAT approach, some risk-of-bias questions or elements are considered potentially more important when assessing studies because these issues are generally considered to have a greater impact on estimates of the effect size or on the credibility of study results in environmental health studies. There are three Key Questions for observational human studies: confounding, exposure characterization, and outcome assessment. Based on the complexity of the possible responses for these questions in epidemiology studies, considerations made and methods used for evaluating the Key Questions are provided below. There are also three Key Questions for experimental animal studies: randomization, exposure characterization, and outcome assessment. In addition, for animal developmental studies, failure to consider the litter as the unit of analysis was also a key risk-of-bias concern. When there was not enough information to assess the potential bias for a risk-of-bias question and authors did not respond to an inquiry for further information, a conservative approach was followed, and the studies were rated probably high risk of bias for that question.

Risk-of-bias Considerations for Human Studies

The risk of bias of individual studies in the body of evidence was considered in developing confidence ratings. The key risk-of-bias questions (i.e., confounding, exposure characterization, and outcome assessment for human studies) are discussed in the consideration of the body of evidence. For this assessment, the key risk-of-bias questions, if not addressed appropriately, are considered to potentially have the greatest impact on the results. The other risk-of-bias questions were also taken into consideration and were used to identify any other risk-of-bias concerns that may indicate serious issues with the studies. No study was excluded based on concerns for risk of bias; however, the low risk-of-bias studies generally drive conclusions on confidence in the results across the body of evidence. Human

evidence was evaluated with and without high risk-of-bias studies to assess the impact of these studies on confidence in the association.

High risk-of-bias studies: Studies rated probably high risk of bias for at least two key risk-of-bias questions or definitely high for any single question are considered studies with higher potential for bias (i.e., high risk-of-bias studies) and to be of low quality.

Low risk-of-bias studies: The remaining studies (i.e., other than the high risk-of-bias studies) were considered to have lower potential for bias (i.e., low risk of bias) and to be of high quality. **Appendix 4** describes strengths and limitations of the low risk-of-bias/high quality studies identified during the assessment and clarifies why they are considered to pose low risk of bias. Details on the statistical analyses are provided in the "Other potential threats" domain in order to evaluate the adequacy of the statistical approach for individual studies.

Given the number non-English-language studies in this assessment, the potential for the translation to introduce bias was examined as described below, and it was determined that translation of non-English studies did not impact evaluation of risk of bias. Thirty-two of 92 studies included in the entire human body of evidence on neurodevelopmental and cognitive effects were initially published in a foreign language (mainly Chinese) and were either translated and published in volume 41 of the journal *Fluoride* (n = 19) or were translated by the Fluoride Action Network (n = 13) (http://fluoridealert.org/researchers/translations/complete_archive/). Most of these studies were considered to have high potential for bias due to lack of information across the key risk-of-bias questions. Therefore, in order to assess if the lack of information relevant to key risk-of-bias concerns was the result of a loss in translation, the original Chinese publications and the translated versions of the five studies that had the most potential for being included in the low risk-of-bias group of studies were reviewed to determine if any of the risk-of-bias concerns could be addressed (An *et al.* 1992, Chen *et al.* 1991 [translated in Chen *et al.* 2008], Du *et al.* 1992 [translated in Du *et al.* 2008], Guo *et al.* 1991 [translated in Guo *et al.* 2008a], Li *et al.* 2009). For all five studies, the translations were determined to be accurate, and there was no impact of the translations on the key risk-of-bias concerns.

Confounding

Potential confounding variables and/or effect modifiers that were considered key for all studies, populations, and outcomes included child's age, child's sex, and socioeconomic status (e.g., maternal education, household income, marital status, crowding). Additional potential confounding variables and/or effect modifiers considered important for this evaluation depending on the study population and outcome included race/ethnicity; maternal demographics (e.g., maternal age, body mass index [BMI]); parental behavioral and mental health disorders (e.g., attention deficit hyperactivity disorder [ADHD], depression); smoking (e.g., maternal smoking status, secondhand tobacco smoke exposure); reproductive factors (e.g., parity); nutrition (e.g., BMI, growth, anemia); iodine deficiency/excess; minerals and other chemicals in water associated with neurotoxicity (e.g., arsenic, lead); maternal and paternal IQ; and quantity and quality of caregiving environment (e.g., Home Observation Measurement of the Environment [HOME] score). To be assigned a rating of probably low risk of bias for the key risk-of-bias question regarding confounding, studies were not required to address every potential confounder listed; however, studies were required to address the three key covariates for all studies, the potential for co-exposures if applicable (e.g., arsenic and lead, both of which could affect cognitive function), and any other potential confounders considered important for the specific study population and outcome. For example, studies of populations in China, India, and Mexico, where there is concern for exposures to high fluoride and high arsenic, were required to address arsenic. If the authors did not

directly specify that arsenic exposures were evaluated, groundwater quality maps were evaluated (https://www.gapmaps.org/Home/Public#) in order to identify areas of China, India, and Mexico where arsenic is a concern (Podgorski and Berg 2020). If no arsenic measurements were available for the area, the arsenic groundwater quality predictions from the global arsenic 2020 map were used (Podgorski and Berg 2020). If an area had less than 50% probability of having arsenic levels greater than 10 µg/L (the WHO guideline concentration), the area was considered not to have an issue with arsenic that needed to be addressed by the study authors.

Exposure

Exposure was assessed using a variety of methods in the human body of evidence. Studies provided varying levels of details on the methods used and employed different exposure characterization methods to group study subjects into exposed and reference groups. Exposure metrics included spot urine (from children or mothers during at least one trimester of gestation), serum, individual drinking water, intake from infant formula, estimated total exposure dose, municipal drinking water (with residence information), evidence of dental or skeletal fluorosis, area of residence (endemic versus a non-endemic fluorosis area with or without individual validation of exposure), burning coal (with or without fluoride), and occupation type.

Urinary fluoride levels measured during pregnancy and in children include all ingested fluoride and are considered a valid measure to estimate total fluoride exposure (Villa *et al.* 2010, Watanabe *et al.* 1995); however, the type and timing of urinary sample collection is important to consider. Urinary fluoride is thought to reflect recent exposure but can be influenced by the timing of exposure (e.g., when water was last consumed, when teeth were last brushed). When compared to 24-hour urine samples, spot urine samples are more prone to the influence of timing of exposure and can also be affected by differences in dilution; however, many studies attempted to account for dilution either using urinary creatinine or specific gravity. Good correlations between 24-hour samples and urinary fluoride concentrations from spot samples adjusted for urinary dilution have been described (Zohouri *et al.* 2006). Despite potential issues with spot urine samples, if authors made appropriate efforts to reduce the concern for bias (e.g., accounting for dilution), studies that used this metric were generally considered to have probably low risk of bias for exposure.

Analytical methods to measure fluoride in biological or water samples also varied, some of which included atomic absorption, ion selective electrode methods, colorimetric methods, or the hexamethyldisiloxane microdiffusion method. Individual-level measures of exposure were generally considered more accurate than group-level measures; however, using group-level measures (e.g., endemic versus non-endemic area) in an analysis was less of a concern if the study provided water or urine fluoride levels from some individuals to verify that there were differences in the fluoride exposure between groups. Studies that provided results by area but also reported individual urinary or serum fluoride concentrations or other biochemical measures, including dental fluorosis in the children or urinary levels in mothers during pregnancy, were considered to have probably low risk of bias.

Outcome

Studies included in this evaluation used a wide variety of methods to measure IQ and other cognitive effects. Measures of IQ were generally standardized tests of IQ; however, for these standardized methods to be considered low potential for bias they needed to be conducted in the appropriate population or modified for the study population. Because results of many of the tests to measure neurodevelopment and cognitive function can be subjective, it was important that the outcome assessors were blind to the fluoride exposure when evaluating the results of the tests. If the study reported that the assessor was blind to the exposure, this was assumed to mean that the outcome assessor did not have any knowledge of the exposure, including whether the study subjects were from high-fluoride communities. If cross-sectional studies collected biomarker measurements at the time of an IQ assessment, this was considered indirect evidence that the outcome assessor would not have knowledge of the fluoride exposure unless there was also potential for the outcome assessor to have knowledge of varying levels of fluoride by study area. In cases where the study did not specify that the outcome assessors were blind, the study authors were contacted and asked if the outcome assessors were blind to exposure. When authors responded and indicated that outcome assessors were blind to exposure or that it was not likely that they would have had knowledge of exposure, this was considered direct or indirect evidence, respectively, that blinding was not a concern for those studies.

Any discrepancies in ratings between assessors were resolved by a senior technical specialist and through discussion when necessary to reach the final recorded risk-of-bias rating for each question along with a statement of the basis for that rating. Members of the evaluation team were consulted for assistance if additional expertise was necessary to reach final risk-of-bias ratings based on specific aspects of study design or performance reported for individual studies. Study procedures that were not reported were assumed not to have been conducted, resulting in an assessment of “probably high” risk of bias. Authors were queried by email to obtain missing information and responses received were used to update risk-of-bias ratings.

Table 4. OHAT Risk-of-bias Questions and Applicability by Study Design						
Risk-of-bias Questions	**Experimental Animal***	**Human Controlled Trials****	**Cohort**	**Case-Control**	**Cross-Sectional*****	**Case Series**
1. Was administered dose or exposure level adequately randomized?	X	X				
2. Was allocation to study groups adequately concealed?	X	X				
3. Did selection of study participants result in the appropriate comparison groups?			X	X	X	
4. Did study design or analysis account for important confounding and modifying variables?			X	X	X	X
5. Were experimental conditions identical across study groups?	X					
6. Were research personnel blinded to the study group during the study?	X	X				
7. Were outcome data complete without attrition or exclusion from analysis?	X	X	X	X	X	
8. Can we be confident in the exposure characterization?	X	X	X	X	X	X
9. Can we be confident in the outcome assessment (including blinding of outcome assessors)?	X	X	X	X	X	X
10. Were all measured outcomes reported?	X	X	X	X	X	X
11. Were there no other potential threats to internal validity?	X	X	X	X	X	X

*Experimental animal studies are controlled exposure studies. Non-human animal observational studies can be evaluated using the design features of observational human studies such as cross-sectional study design.

**Human Controlled Trials are studies in humans with controlled exposure (e.g., Randomized Controlled Trials, non-randomized experimental studies)

***Cross-sectional studies include population surveys with individual data (e.g., NHANES) and surveys with aggregate data (i.e., ecological studies).

Table 5. The Four Risk-of-bias Rating Options	
Answers to the risk-of-bias questions result in one of the following four risk-of-bias ratings	
++	***Definitely Low*** *risk of bias*: There is direct evidence of low risk-of-bias practices
+	***Probably Low*** *risk of bias*: There is indirect evidence of low risk-of-bias practices **OR** it is deemed that deviations from low risk-of-bias practices for these criteria during the study would not appreciably bias results, including consideration of direction and magnitude of bias
– NR	***Probably High*** *risk of bias*: There is indirect evidence of high risk-of-bias practices (indicated with "-") **OR** there is insufficient information provided about relevant risk-of-bias practices (indicated with "NR" for not reported). Both symbols indicate probably high risk of bias.
––	***Definitely High*** *risk of bias*: There is direct evidence of high risk-of-bias practices

Organizing and Rating Confidence in Bodies of Evidence

Health Outcome Categories for Neurodevelopmental and Cognitive Effects

After data were extracted from all studies, the health effects results within the category of neurodevelopmental or cognitive effects were grouped across studies to develop bodies of evidence or collections of studies with data on the same or related outcomes. The grouping of health effect results was not planned a priori. The vast majority of the human studies evaluated IQ in children as the single outcome; therefore, the discussion of cognitive neurodevelopmental effects in children focuses on IQ studies with supporting information from data on other endpoints. Cognitive function in adults was evaluated separately. Consistent with the NTP (2016) assessment, the primary focus within the animal study body of evidence was on animal studies with endpoints related to learning and memory.

Considerations for Pursuing a Narrative or Quantitative Evidence Synthesis

This evaluation provides only a narrative review of the data; however, heterogeneity within the available evidence was evaluated to determine if a quantitative synthesis (i.e., meta-analysis) is appropriate. Choi *et al.* (2012) and Duan *et al.* (2018) conducted meta-analyses and found that high fluoride exposure was associated with lower IQ scores. Choi *et al.* (2012) was able to determine a risk ratio for living in an endemic fluorosis area but was unable to develop a dose-response relationship. Duan *et al.* (2018) suggested a significant non-linear dose-response relationship between fluoride dose and intelligence with the relationship stated to be most evident with exposures from drinking water containing above 4 mg/L (or 4 ppm). Duan *et al.* (2018) found similar results as Choi *et al.* (2012) for the standardized mean difference; however, the majority of the available studies in both analyses compare populations with high fluoride exposure to those with lower fluoride exposure (with the lower exposure levels frequently in the range of drinking water fluoridation in the United States). NTP conducted a meta-analysis and is preparing it as a separate report for publication.

Confidence Rating: Assessment of Body of Evidence

The quality of evidence for neurodevelopmental and cognitive function outcomes was evaluated using the GRADE system for rating the confidence in the body of evidence (Guyatt *et al.* 2011, Rooney *et al.* 2014). More detailed guidance on reaching confidence ratings in the body of evidence as "high," "moderate," "low," or "very low" is provided in the protocol (https://ntp.niehs.nih.gov/go/785076). In brief, available human and animal studies on a particular health outcome were initially grouped by key study design features, and each grouping of studies was given an initial confidence rating by those features. Starting at this initial rating (see column 1 of **Figure 1**), potential downgrading of the confidence rating was considered for factors that decrease confidence in the results (see column 2 of **Figure 1**). Potential upgrading of the confidence rating was considered for factors that increase confidence in the results (see column 3 of **Figure 1**). Short descriptions of the factors that can decrease or increase confidence in the body of evidence for human studies are provided below (see protocol [https://ntp.niehs.nih.gov/go/785076] for additional details related to the human body of evidence, as well as considerations for experimental animal studies).

Factors to Consider for Potential Downgrading

- Risk of bias—addresses whether the body of evidence did not account for critical factors in study quality or design including confounding bias, selection bias, exposure assessment, and outcome assessment. Consideration for downgrading the confidence rating is based on the entire body of evidence, and the evidence is downgraded when there is substantial bias across most studies that could lead to decreased confidence in the results and where the studies without substantial bias could not support the confidence rating. Individual studies are evaluated for risk of bias based on a set of criteria (as discussed above); magnitude and direction of the bias are also considered.

- Unexplained inconsistency—addresses inconsistencies in results across studies of similar populations and design that can be determined by assessing similarity of point estimates and extent of overlap between confidence intervals or more formally through statistical tests of heterogeneity. Sensitivity analysis can be used to assess the impact of specific variables on the outcome. Inconsistencies that can be plausibly explained by characteristics of the studies (e.g., sex-associated differences) are typically not used to support a downgrade. A downgrade would only be applied when there is an inconsistency that cannot be explained and results in reduced confidence in the body of evidence.

- Indirectness—addresses generalizability and relevance to the objective of the assessment. All exposure levels and scenarios encountered in human studies are considered direct (i.e., applicable, generalizable, and relevant to address the objective of the assessment); therefore, a downgrade for indirectness would not be applied to bodies of evidence from human studies.

- Imprecision—addresses confidence associated with variability in quantitative measures such as effect sizes. Typically, 95% confidence intervals are used as the primary method to assess imprecision, but considerations can also be made on whether studies were adequately powered. Meta-analyses can also be used to determine if the data are imprecise. When a meta-analysis is not appropriate or feasible, imprecision can be based on variability around the effect estimate. A downgrade would occur if the body of evidence was considered to be imprecise based on a meta-analysis or if serious or very serious imprecision was consistently present in

the body of evidence. A downgrade is especially likely if imprecision raised questions as to whether an overall effect was significant.

- Publication bias—downgrade if strongly detect publication bias. Publication bias is difficult to detect but may be evident if major sections of the research community are not publishing (e.g., absence of industry, academia, or government studies) on a topic or if there are multiple instances where data from conference abstracts are never published in peer-reviewed journals. In addition, there are methods included in conducting a meta-analysis to detect if there is potential for publication bias, including the use of fit-and-trim models, which help identify how publication bias may affect the results of the meta-analysis. Although a meta-analysis is not included in this systematic review, there are two published meta-analyses (Duan *et al.* 2018, Choi *et al.* 2012) in addition to one conducted by NTP (manuscript development in progress) that can be used to address publication bias.

Factors to Consider for Potential Upgrading

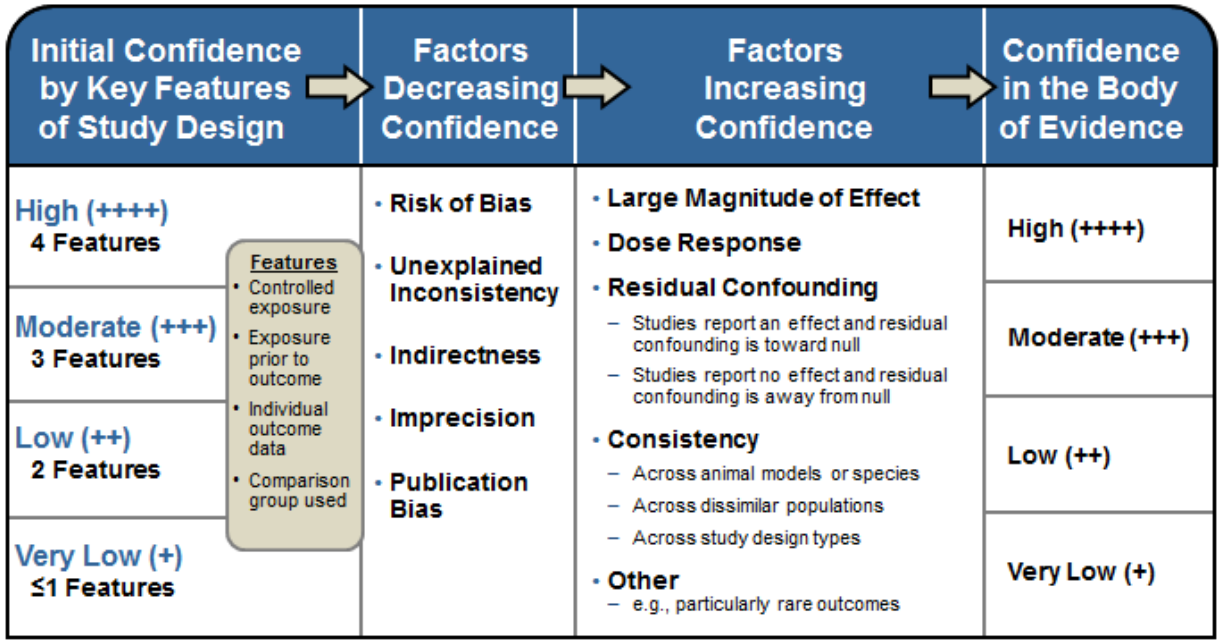
- Large magnitude of effect—factors to consider include the outcome being measured and the dose or exposure range assessed. The confidence can be upgraded if the body of evidence is suggestive of a large magnitude of effect. GRADE provides guidance on what can be considered a large magnitude of effect based on relative risk (i.e., suggests one upgrade in confidence if relative risk is greater than 2 and two upgrades in confidence if greater than 5). However, not all studies provide data as a risk estimate, and smaller changes, such as increases in blood pressure, may have greater impact on health at the population level. Consideration for an upgrade is not based on a single study, and what constitutes a large magnitude of effect will depend on the outcome and the potential public health impact.

- Dose response—patterns of dose response are evaluated within and across studies. Confidence will be increased when there is sufficient evidence of a dose-response pattern across multiple studies in the body of evidence.

- Consistency—does not apply in this evaluation. The consideration of a potential upgrade for consistency is primarily for non-human animal evidence where it would be applied to address increased confidence based on observation of consistent effects across multiple non-human animal species. For human evidence, this factor would generally not be applied. Human studies are instead evaluated for issues of consistency that could result in downgrading confidence for unexplained inconsistency (see Factors to Consider for Potential Downgrading above).

- Consideration of residual confounding—applies to observational studies and refers to consideration of unmeasured determinants that are likely to be distributed unevenly across groups. Residual confounding can push results in either direction, but confidence in the results is increased when the body of evidence is biased by factors that counter the observed effect and would cause an underestimation of the effect. Confounding that would cause an overestimation of the effect is considered under the risk-of-bias considerations for decreasing confidence.

Figure 1. Assessing Confidence in the Body of Evidence



Confidence ratings were assessed by the evaluation team for accuracy and consistency, and discrepancies were resolved by consensus and consultation with technical advisors as needed. Confidence ratings for the primary outcomes are summarized in evidence profile tables for each outcome.

RESULTS

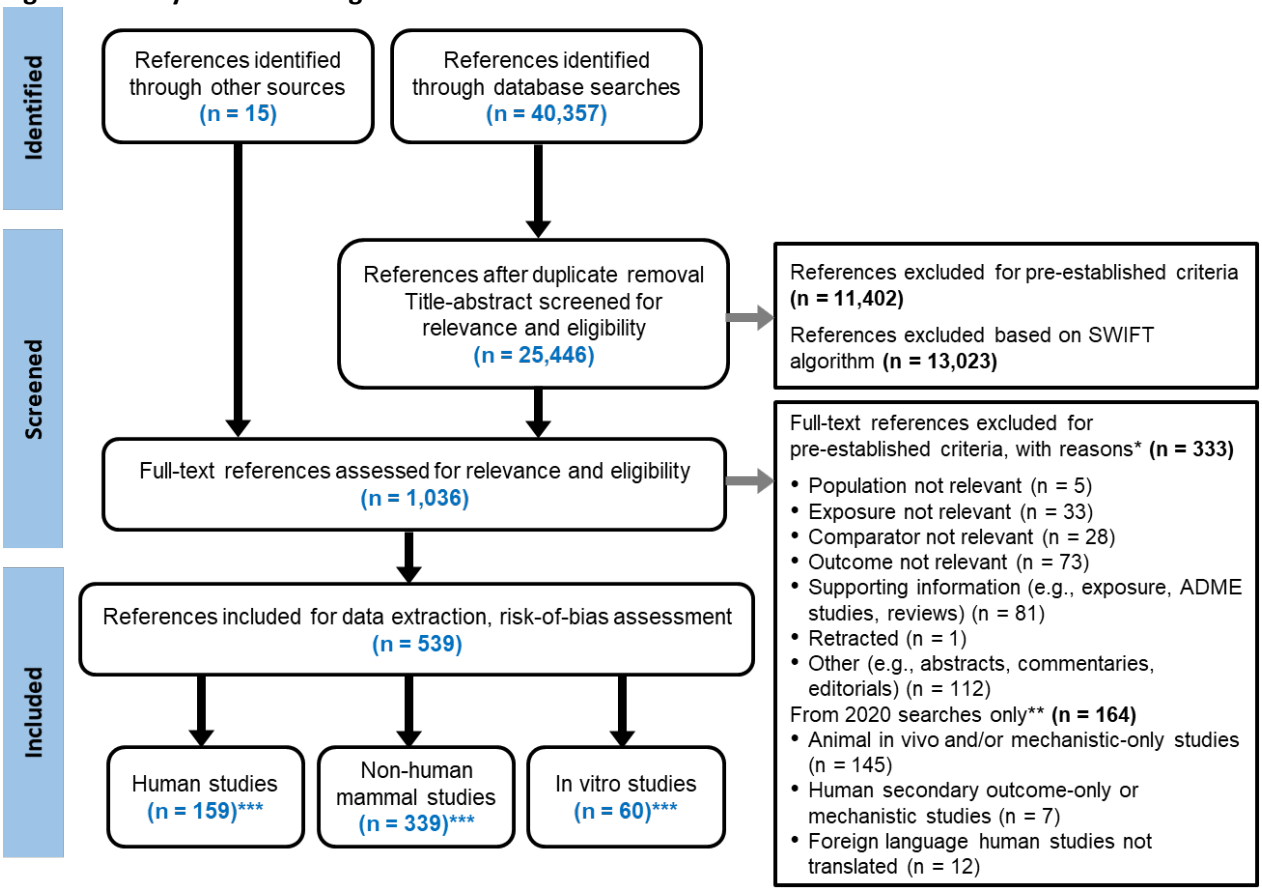
Literature Search Results

The electronic database searches retrieved 25,522 unique references with 15 additional references identified by technical advisors or from reviewing reference lists in published reviews and included studies. During title and abstract screening, 1,036 references were moved to full-text review and 24,501 were excluded (11,478 by manual screening for not satisfying the PECO criteria and 13,023 based on the SWIFT algorithm). Among the 1,036 references that underwent full-text review, 539 studies were considered PECO relevant (see **Appendix 2** for list of included studies). A few studies assessed data for more than one evidence stream (human, non-human mammal, and/or in vitro), and several studies assessed more than one type of outcome (e.g., primary and secondary outcomes). Included studies breakdown as follows:

- 159 human studies (78 primary only; 13 secondary only; 5 primary and secondary; 6 primary and thyroid; 2 secondary and thyroid; and 55 thyroid only);
- 339 non-human mammal studies (7 primary only; 186 secondary only; 67 primary and secondary; 6 primary, secondary, and thyroid; 4 secondary and thyroid; and 69 thyroid only); and,
- 60 in vitro/mechanistic studies (48 neurological and 12 thyroid).

Additional details on the screening results are provided in **Appendix 2**. These screening results are outlined in a study selection diagram that reports numbers of studies excluded at each stage and documents the reason for exclusion at the full text review stage (see **Figure 2**) [using reporting practices outlined in Moher *et al.* (2009)].

Figure 2. Study Selection Diagram[a]



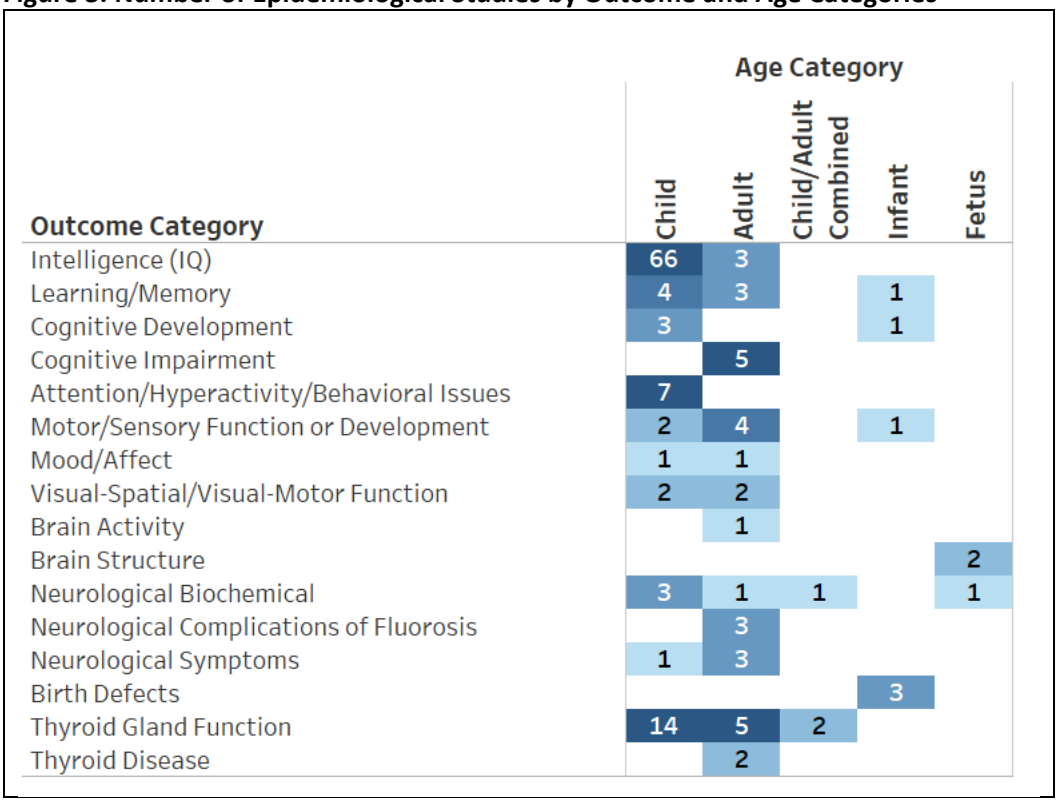
Notes:
[a]An interactive PRISMA is available here: https://hawcproject.org/summary/visual/assessment/405/Figure-2/.
* Studies may have been excluded for more than one reason; the first reason identified was recorded.
** Includes all studies from all literature searches, see **Methods** section for extraction and search update information.
*** Publications may contain more than on evidence stream, so the numbers will not total the 539 included studies.

Human Neurodevelopmental and Cognitive Data

The body of literature that evaluates the association between fluoride exposure and neurodevelopmental and cognitive effects in humans is relatively robust with a large number of studies (n = 92) that cover a wide array of endpoints (see **Figure 3**). Sixty-six human studies investigated IQ in children. Additional studies evaluated learning and memory (n = 8 studies) or other cognitive development effects (e.g., total neurobehavioral scores and total mental capacity index in children,

cognitive impairment in adults; n = 14 studies).[8] For this review, the evidence in children and adults was evaluated separately to address potential differences in the health impact of fluoride exposure during development versus adulthood.

Figure 3. Number of Epidemiological Studies by Outcome and Age Categories[a]



Notes:
[a]Interactive figure and additional study details in Tableau®.
(https://public.tableau.com/profile/ntp.visuals#!/vizhome/Fluoride_Epi_2021Update/Figure5?publish=yes)
Choi *et al.* (2015) used subtests of the omnibus IQ test reported by the authors as Wechsler Intelligence Scale for Children-Revised (WISC-IV) to evaluate visuospatial abilities (using block design) and executive function (using digit span). These endpoints are included in the intelligence (IQ) outcome category as they are subsets of the IQ tests.
Three additional publications based on subsamples (i.e., 50–60 children) of the larger Yu *et al.* (2018) cohort were identified (Zhao *et al.* 2020, Zhao *et al.* 2019, Zhou *et al.* 2019) and are not included in the counts of this figure.

Because the majority of studies evaluated intelligence, the following section focuses on IQ effects in children followed by separate discussions on other measures of cognitive function and neurobehavioral effects in children and cognitive effects in adults. Congenital neurological malformations and neurological complications of fluorosis are not considered further due to the limited number of studies and the heterogeneity of outcomes evaluated in these studies.

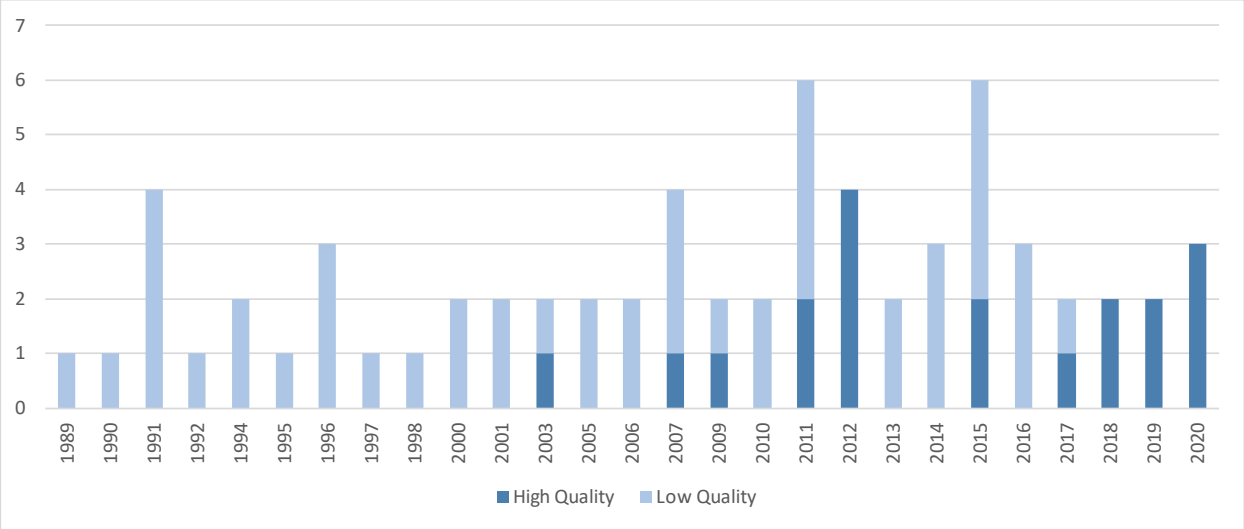
IQ in Children

Sixty-six epidemiological studies were identified that evaluated the effects of fluoride exposure on children's IQ. Nineteen of the 66 IQ studies were determined to have low potential for bias (i.e., were of

[8]Some studies are included in more than one endpoint category (e.g., IQ and other cognitive developmental effects); therefore, these counts are not mutually exclusive.

high quality). Looking across the literature, there has been a progression over the years in the quality of studies conducted to assess the association between fluoride exposure and IQ in children, with more recent studies including better study designs, larger sample sizes, and more sophisticated statistical analysis. Older studies often had limitations related to study design or methods, and most of the high risk-of-bias studies (i.e., studies of low quality) were published prior to the 2006 NRC evaluation of fluoride in drinking water. In contrast, 18 of the low risk-of-bias studies were published after the 2006 NRC evaluation of fluoride in drinking water, and over half of those 18 studies were published between 2015 and 2020 (**Figure 4**).

Figure 4. Number of High- and Low-quality Studies of Fluoride Exposure and IQ in Children by Year of Publication



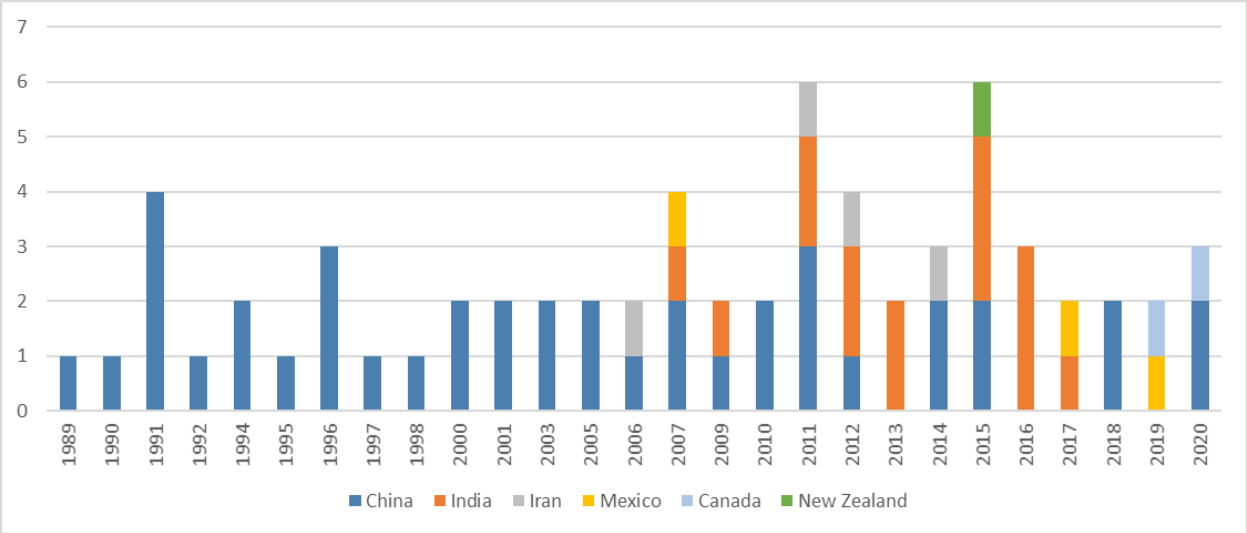
There are several characteristics of recent studies that contribute to higher study quality in the overall body of literature on children's IQ and fluoride including:

- Demonstration that exposure occurred prior to outcome assessment (an important factor when considering confidence in study results; see **Figure 1**) either by study design (e.g., for prospective cohort studies) or analysis (e.g., prevalence of dental fluorosis in children, limiting study populations to children who lived in the same area for long periods of time).
- Improved reporting of key study details that are necessary to evaluate study quality and allow for a more precise analysis of risk of bias.
- Increased consideration of potential confounders (e.g., socioeconomic status) and potential co-exposures (e.g., arsenic or lead intake).
- Increased use of individual-level exposure measures (urine or water), as well as prenatal fluoride exposure, to assess either individual-level fluoride exposure or—if still using group-level data—to confirm that regions being compared had differences in fluoride exposure.
- Utilization of more sophisticated sampling techniques for the study populations (e.g., stratified multistage random sampling).
- Application of more sophisticated regression approaches (e.g., piecewise linear regression models, multi-level regression with random effects, or generalized additive models for longitudinal measurements of fluoride).
- For studies using individual-level exposure measures, application of more sophisticated regression techniques to account for clustering at the cohort level by using cohort as a fixed or

random effect and by accounting for numerous potential confounders that capture the cohort effect.

In addition, newer studies represent more diverse study populations across several countries (**Figure 5**), whereas all identified peer-reviewed studies that were published prior to 2006 took place in a single country (China). The majority of high quality, low risk-of-bias studies exhibit these important study design and analysis characteristics, as discussed further in subsequent sections.

Figure 5. Number of Studies of Fluoride Exposure and IQ in Children by Country and Year of Publication



All available studies were considered in this evaluation; however, review of the body of evidence focused on the high quality, low risk-of-bias studies for two main reasons. First, there are fewer limitations and greater confidence in the results of the high quality studies. Second, there are a relatively large number of high quality studies (n = 19), such that the body of evidence from these studies could be used to evaluate confidence in the association between fluoride exposure and changes in children's IQ. Therefore, the remainder of the discussion on IQ in children focuses on the 19 studies with low risk of bias. The high risk-of-bias studies are discussed briefly relative to their overall support of findings from the low risk-of-bias studies.

Low Risk-of-bias IQ Studies

Overview of Studies

Nineteen studies with low potential for bias evaluated the association between fluoride exposure and IQ in children. These IQ studies were conducted in multiple study populations across 5 countries and included more than 7,000 children. Specifically, of the 19 low risk-of-bias studies of IQ in children:

- 10 were conducted in 4 areas of China on 7 study populations[9];
- 3 were conducted in 3 areas of Mexico on 3 study populations;

[9]In this document, "study population" refers to a defined population on which an original body of research was conducted. The published work drawn from that original body of research is often referred to as a "study." IQ studies that report on the same study populations are identified in **Table 6**.

- 2 were conducted in Canada using the same study population;
- 3 were conducted in 3 areas of India on 3 study populations; and
- 1 was conducted in Iran.

Most studies measured fluoride in the drinking water or urine (child or maternal) with a few that measured fluoride in serum. The IQ studies used a variety of tests to measure IQ. Because IQ tests should be culturally relevant, the IQ tests used often differed between studies reflecting adjustments for the range in populations studied (e.g., western vs. Asian populations). In some cases, different IQ tests were used to study similar populations. Overall, these studies used IQ tests appropriate for the population and were age appropriate.

Table 6 provides a summary of study characteristics and key IQ and fluoride findings for the 19 low risk-of-bias studies. Several of these studies conducted multiple analyses and reported results on multiple endpoints. The purpose of the table is to summarize key findings (independent of whether an effect is indicated) from each study and is not meant to be a comprehensive summary of all results from each study. For each study, results are summarized for each exposure measure assessed, but results from multiple analyses using the same exposure measure may not all be presented unless results from multiple analyses yielded conflicting results.

Table 6. Studies on IQ in Children[a,b]

Study	Study Design (Location/Subjects) [n]	Exposure Measures and Summary Statistics	Assessment Timing	Outcome and Methods	Summary of IQ Results[c,d]
China					
Xiang *et al.* (2003a)[1]	Cross-sectional Wamiao and Xinhuai villages (Sihong County)/school children [512]	Drinking water Mean (SD): 0.36 (0.15) (control), 2.47 (0.79) (high fluoride) mg/L Children's urine Mean (SD): 1.11 (0.39) (control), 3.47 (1.95) (high fluoride) mg/L Village of residence (non-endemic v. endemic fluorosis)	Children (ages 8–13 years)	IQ: Combined Raven's Test for Rural China	Significant dose-related effect of fluoride on IQ score based on drinking water quintile levels with significantly lower IQ scores observed at water fluoride levels of 1.53 mg/L or higher; % of subjects with IQ < 80 was significantly increased at water levels 2.46 mg/L or higher; significant inverse correlation between IQ and urinary fluoride (Pearson correlation coefficient of −0.164); mean IQ scores for children in non-endemic region (100.41 ± 13.21) significantly higher than endemic region (92.02 ± 13.00) No statistical adjustment for confounders
Ding *et al.* (2011)	Cross-sectional Inner Mongolia (Hulunbuir City)/elementary school children [331]	Children's urine Range: 0.1–3.55 mg/L Drinking water (reported but not used in analyses) Mean (SD): 1.31 (1.05) mg/L	Children (ages 7–14 years)	IQ: Combined Raven's Test for Rural China	Significant association between urinary fluoride and IQ score (each 1-mg/L increase was associated with a lower IQ score of 0.59 points; 95% CI: −1.09, −0.08) Adjusted for child's age
Xiang *et al.* (2011)[1]	Cross-sectional Wamiao and Xinhuai villages (Sihong County)/school children [512]	Children's serum Mean (SD): 0.041 (0.009) (control), 0.081 (0.019) (high fluoride) mg/L	Children (ages 8–13 years)	IQ: Combined Raven's Test for Rural China	Significant linear trend across quartiles of serum fluoride and children's IQ score < 80 (adjusted ORs for Q1 and Q2; Q1 and Q3; and Q1 and Q4, respectively: 1; 2.22 [95% CI: 1.42, 3.47]; and 2.48 [95% CI: 1.85, 3.32]); significant effects at ≥0.05 mg/L serum fluoride Adjusted for child's age and gender
Wang *et al.* (2012)[1]	Cross-sectional Wamiao and Xinhuai villages (Sihong County)/school children [526]	Children's total fluoride intake Mean (SD): 0.78 (0.13) (control), 3.05 (0.99) (high fluoride) mg/day Village of residence (non-endemic v. endemic fluorosis) Drinking water (reported for villages but not used in analyses) Mean (SD): 0.36 (0.11) (control), 2.45 (0.80) (high fluoride) mg/L	Children (ages 8–13 years)	IQ: Combined Raven's Test for Rural China	Significantly lower mean IQ in the endemic versus non-endemic regions, as reported in Xiang *et al.* (2003a); when high exposure group was broken into 4 exposure groups based on fluoride intake, a dose-dependent decrease in IQ and increase in % with low IQ observed; significant correlation between total fluoride intake and IQ (r = −0.332); for IQ < 80, adjusted OR of total fluoride intake was 1.106 (95% CI: 1.052, 1.163) Adjusted for child's age and gender

Table 6. Studies on IQ in Children[a,b]

Study	Study Design (Location/Subjects) [n]	Exposure Measures and Summary Statistics	Assessment Timing	Outcome and Methods	Summary of IQ Results[c,d]
Choi *et al.* (2015)	Cross-sectional Mianning County/1st grade children [51]	Drinking water GM: 2.20 mg/L Children's urine GM: 1.64 mg/L Severity of fluorosis (Dean Index)	Children (ages 6–8 years)	IQ: WISC-IV (square root block design and digit span)	Compared to normal/ questionable fluorosis, moderate/severe fluorosis significantly associated with lower total (adjusted β = −4.28; 95% CI: −8.22, −0.33) and backward (adjusted β = −2.13; 95% CI: −4.24, −0.02) digit span scores; linear correlations between total digit span and log-transformed urinary fluoride (adjusted β = −1.67; 95% CI: −5.46, 2.12) and log-transformed drinking water fluoride (adjusted β = −1.39; 95% CI: −6.76, 3.98) observed but not significant; forward digit span had similar results as backward and total, but was not statistically significant; squareroot block design not significantly associated with any measure of fluoride exposure Adjusted for child's age, child's gender, parity, illness before 3 years old, household income last year, and caretaker's age and education
Zhang *et al.* (2015b)	Cross-sectional Tianjin City (Jinnan District)/school children [180]	Drinking water Mean: 0.63 (control), 1.40 (endemic fluorosis) mg/L (SD not reported) Children's urine Mean (SD): 1.1 (0.67) (control), 2.4 (1.01) (endemic fluorosis) mg/L Children's serum Mean (SD): 0.06 (0.03) (control), 0.18 (0.11) (endemic fluorosis) mg/L	Children (ages 10–12 years)	IQ: Combined Raven's Test for Rural China	Significant correlation between IQ score and children's serum fluoride (r = −0.47) and urinary fluoride (r = −0.45); significant difference in mean IQ score for high-fluoride area (defined as >1 mg/L in drinking water; 102.33 ± 13.46) compared with control area (109.42 ± 13.30); % of subjects with IQ < 90 significantly increased in high-fluoride area (28.7%) vs. low-fluoride area (8.33%); not significantly associated with water fluoride as a continuous variable Adjusted for child's age and gender, if applicable
Cui *et al.* (2018)	Cross-sectional Tianjin City (districts Jinghai and Dagang)/school children [323]	Children's urine Range (log-transformed): −1.2–2.2	Children (ages 7–12 years)	IQ: Combined Raven's Test for Rural China	Significant correlation between IQ score and log-transformed urinary fluoride (adjusted β = −2.47; 95% CI: −4.93, −0.01) Adjusted for child age, mother's education, family member smoking, stress, and anger

Table 6. Studies on IQ in Children[a,b]

Study	Study Design (Location/Subjects) [n]	Exposure Measures and Summary Statistics	Assessment Timing	Outcome and Methods	Summary of IQ Results[c,d]
Yu *et al.* (2018)[2]*	Cross-sectional Tianjin City (7 towns)/children [2,886]	Drinking water Mean (SD): 0.50 (0.27) (normal), 2.00 (0.75) (high) mg/L Children's urine Mean (SD): 0.41 (0.49) (normal), 1.37 (1.08) (high) mg/L	Children (ages 7–13 years)	IQ: Combined Raven's Test for Rural China	Significant difference in mean IQ scores in high water fluoride areas (>1.0 mg/L; 106.4 ± 12.3 IQ) compared to the normal water fluoride areas (≤1.0 mg/L; 107.4 ± 13.0); distribution of the IQ scores also significantly different (p = 0.003); every 0.5-mg/L increase in water fluoride was associated with a 4.29 lower IQ score (95% CI: −8.09, −0.48) between 3.40 and 3.90 mg/L; no significant association between 0.2 and 3.40 mg/L; every 0.5-mg/L increment of urinary fluoride was associated with a 2.67 lower IQ score (95% CI: −4.67, −0.68) between 1.60 and 2.50 mg/L but not at 0.01–1.60 mg/L or 2.50–5.54 mg/L. Adjusted for child's age, child's gender, maternal education, paternal education, and low birth weight
Cui *et al.* (2020)	Cross-sectional Tianjin City (all districts)/school children (potentially some overlap with Cui *et al.* (2018)) [498]	Children's urine <1.6–≥2.5 mg/L	Children (ages 7–12 years)	IQ: Combined Raven's Test	Decreasing mean (± SD) IQ score with increasing urinary fluoride levels (statistical significance not reached based on a one-way ANOVA) <1.6 mg/L: 112.16 ± 11.50 1.6-2.5 mg/L: 112.05 ± 12.01 ≥2.5 mg/L: 110 ± 14.92 No statistical adjustment for confounders
Wang *et al.* (2020b)[2]	Cross-sectional Tianjin City (villages not specified)/school children [571]	Drinking water Mean (SD): 1.39 (1.01) mg/L Children's urine Mean (SD): 1.28 (1.30) mg/L	Children (ages 7–13 years)	IQ: Combined Raven's Test for Rural China	Significant associations between IQ and water and urinary fluoride concentrations in boys and girls combined based on both quartiles and continuous measures (water: 1.587 decrease in IQ score per 1-mg/L increase; urine: 1.214 decrease in IQ score per 1-mg/L increase); no significant modification effect of gender Adjusted for child's age, child's gender, BMI, maternal education, paternal education, household income, and low birth weight

Seraj *et al.* (2012)	Cross-sectional Makoo/school children [293]	Drinking water Mean (SD): 0.8 (0.3) (normal), 3.1 (0.9) (medium), 5.2 (1.1) (high) mg/L	Children (ages 6–11 years)	IQ: Raven's Colored Progressive Matrices	Significant correlation between water fluoride and IQ score (adjusted β = −3.865; CIs not reported); significantly higher mean IQ score in normal area (97.77 ± 18.91) compared with medium (89.03 ± 12.99) and high (88.58 ± 16.01) areas Adjusted for child's age, child's gender, child's education level, mother's education level, father's education level, and fluorosis intensity

Studies with the same number superscript are based on the same study population.

*Three additional publications based on subsample (i.e., 50–60 children) of the larger Yu *et al.* (2018) cohort were identified (Zhao *et al.* 2020, Zhou *et al.* 2019, Zhao *et al.* 2019); however, these publications focused on mechanistic considerations and are not included in the study totals for IQ because the main study by Yu *et al.* (2018) is considered a better representation of the IQ results.

[a]Includes low risk-of-bias studies.

[b]Definitions: ANOVA: analysis of variance; **GM**: geometric mean; **HOME**: Home Observation Measurement of the Environment; **IQ**: intelligence quotient; **WASI**: Wechsler Abbreviated Scale of Intelligence (Spanish version); **WISC-IV**: Wechsler Intelligence Scale for Children-Revised (as reported by Choi *et al.* 2015).

[c]Associations between IQ and fluoride levels were reported quantitatively, as possible. For studies with multiple analyses and results, the table summarizes key findings and is not a comprehensive summary of all findings. Results also indicate when a study found no association between IQ and fluoride, provided as a qualitative statement of no association.

[d]See **Figure D1** through **Figure D7** for additional study results.

Summary of Results

Overall Findings

The results from 18 of the 19 high quality (low risk-of-bias) studies (3 prospective cohort and 15 cross-sectional studies from 13 different study populations) that evaluated IQ in children provide consistent evidence that exposure to fluoride is associated with lower IQ scores (see "Summary of IQ Results" in **Table 6**)(Bashash *et al.* 2017, Choi *et al.* 2015, Ding *et al.* 2011, Rocha-Amador *et al.* 2007, Saxena *et al.* 2012, Seraj *et al.* 2012, Xiang *et al.* 2003a, Xiang *et al.* 2011, Zhang *et al.* 2015b, Yu *et al.* 2018, Green *et al.* 2019, Cui *et al.* 2018, Cui *et al.* 2020, Wang *et al.* 2020b, Wang *et al.* 2012, Sudhir *et al.* 2009, Till *et al.* 2020, Trivedi *et al.* 2012). Only one study did not observe evidence of an association between fluoride exposure and IQ; however, results were not provided in a manner that allowed for a direct comparison with other low risk-of-bias studies (see **Appendix 4** for details). A strength of the findings across 18 of 19 low risk-of-bias studies was the consistent association between increased fluoride levels (generally above the WHO Drinking Water Quality Guideline [1.5 mg/L] (WHO 2011)) and lower IQ scores among studies of varying study designs, exposure measures, and study populations. In studies that analyzed the sexes separately (n = 5 studies with 2 studies reporting on the same study population), consistent findings of lower IQ associated with fluoride exposure were generally reported for both sexes. There is some indication of differential susceptibility between sexes, but ultimately it is unclear if one gender is more susceptible to the effects of fluoride exposure than the other due to too few high quality studies that analyzed exposure and outcome by gender separately and a lack of consistent findings that one gender is more susceptible. The body of evidence from the 19 low risk-of-bias studies is described in further detail below. Prospective cohort studies are discussed first, as this study design can establish a temporal relationship between exposure and outcome which would contribute to demonstrating causality, therefore, providing the strongest evidence for an association between fluoride exposure during development and IQ in children.

Results by Study Design

Prospective cohort studies

As discussed above, all three prospective cohort studies found an association between increasing maternal or children's fluoride exposure and lower IQ in children (Green *et al.* 2019, Till *et al.* 2020, Bashash *et al.* 2017). Two of the studies (Green *et al.* 2019, Till *et al.* 2020) were based on the same study population, but the authors used different measures of fluoride exposure to evaluate IQ. Multiple analyses were conducted in each prospective study and, although not every analysis found a statistically significant association, together the three studies provided consistent evidence that maternal fluoride levels were associated with lower IQ scores in the children.

Bashash *et al.* (2017) observed a statistically significant association (p-value = 0.01) between lower IQ scores in children and prenatal fluoride exposure measured by maternal urinary fluoride (measured during all three trimesters and included if at least one measurement was available). An increase of 0.5 mg/L of maternal urinary fluoride was associated with a 2.5-point lower IQ score [95% CI: −4.12, −0.59] in boys and girls combined (see **Figure D7**). This study also reported an inverse association between IQ level and children's urinary fluoride levels (single spot urine sample); however, this specific result did not achieve statistical significance (a 0.5-mg/L increase of child urinary fluoride was associated with a 0.89-point lower IQ score [95% CI: −2.63, 0.85]) (Bashash *et al.* 2017).

Green *et al. (*2019) also reported inverse associations between IQ scores in children and multiple measures of prenatal fluoride exposure, including maternal urinary fluoride, maternal fluoride intake, and water fluoride concentrations in the Maternal-Infant Research on Environmental Chemicals cohort,

consisting of 10 cities in Canada. Green *et al. (*2019) observed a statistically significantly lower IQ for boys associated with maternal urinary fluoride averaged across trimesters (4.49-point lower IQ score [95% CI: −8.38, −0.60; p-value = 0.02] in IQ per 1-mg/L increase in maternal urinary fluoride); however, results were not significant in boys and girls combined (1.95-point lower IQ [95% CI: −5.19, 1.28]) and were positive in girls (2.40-point increase [95% CI: −2.53, 7.33] in IQ). Other measures of prenatal exposure (maternal fluoride intake or water fluoride concentrations) were associated with lower IQ scores in boys and girls combined; the authors found no significant effect measure modification between child sex and fluoride exposure in these analyses so did not report boys and girls separately (Green *et al.* 2019). Specifically, when evaluating the association between estimated maternal fluoride intake based on maternal water and beverage consumption during pregnancy and IQ in children, a 1-mg increase in daily maternal consumption of fluoride during pregnancy was associated with a significantly lower IQ score of 3.66 points in boys and girls combined (95% CI: −7.16, −0.15; p-value = 0.04). Similarly, water fluoride concentrations for pregnant women from fluoridated areas (mean water fluoride levels of 0.59 ± 0.08 mg/L) versus pregnant women from non-fluoridated areas (mean water fluoride levels of 0.13 ± 0.06 mg/L) were associated with a significant 5.29-point lower IQ score per 1-mg/L increase in fluoride in both boys and girls combined (95% CI: −10.39, −0.19; p-value < 0.05) (Green *et al.* 2019).

In a study of the same study population as Green *et al.* (2019) that used fluoride intake from formula or water concentrations in formula-fed versus breastfed infants, Till *et al.* (2020) observed significantly lower performance IQ scores with higher fluoride regardless of the comparison used (p-values <= 0.004). They did not observe any effect on verbal IQ, and full-scale IQ was only significantly lower in formula-fed infants using water fluoride concentrations as the exposure measure (p-value = 0.03). Breastfed infants and fluoride intake from formula also showed inverse associations but were not significant.

Taken together, the three prospective cohort studies (based on two study populations) indicate consistency across different types of analysis and across two study populations that fluoride exposure during development is associated with lower IQ scores.

Cross-sectional studies

As with the prospective cohort studies, the cross-sectional studies reported a consistent association between fluoride exposure and lower IQ scores in children. Fifteen of the 16 low risk-of-bias cross-sectional studies provide consistent evidence that exposure to fluoride is associated with lower IQ scores. Fourteen of these 15 studies (with the exception of Cui *et al.* 2020) reported significant associations.

Cross-sectional studies can have limitations in assessing causality, as the study design often cannot ensure that exposure preceded outcome. This uncertainty reduces confidence in study findings compared to prospective cohort studies—which, by design, establish that exposure occurred prior to outcome—and is captured in the outcome assessment. In some cases, cross-sectional studies do provide indicators of prior exposure (e.g., prevalence of dental fluorosis, limiting study populations to subjects who lived in the same area for long periods of time). Evidence that exposure occurred prior to the outcome of interest increases the confidence in results and any potential association reported in these studies. Of the 16 low risk-of-bias cross-sectional studies, 12 studies established that exposure preceded the outcome assessment (Choi *et al.* 2015, Ding *et al.* 2011, Seraj *et al.* 2012, Yu *et al.* 2018, Sudhir *et al.* 2009, Rocha-Amador *et al.* 2007, Saxena *et al.* 2012, Wang *et al.* 2020b, Wang *et al.* 2012, Xiang *et al.* 2011, Xiang *et al.* 2003a, Soto-Barreras *et al.* 2019). Five studies from different study populations indicated that a large portion of the exposed children had dental fluorosis (ranging from 43–100%) at the time of the assessment (Choi *et al.* 2015, Ding *et al.* 2011, Seraj *et al.* 2012, Yu *et al.* 2018, Sudhir *et*

al. 2009). Because dental fluorosis occurs when fluoride is consumed during enamel formation (usually during the first 6–8 years of life), the presence of dental fluorosis suggests that exposures to fluoride occurred prior to the outcome assessment. Nine studies from six study populations (including Yu *et al.* (2018), Sudhir *et al.* (2009) listed above) excluded subjects that had not lived in the study area for a specified period of time, sometimes since birth (Rocha-Amador *et al.* 2007, Saxena *et al.* 2012, Yu *et al.* 2018, Wang *et al.* 2020b, Wang *et al.* 2012, Xiang *et al.* 2011, Xiang *et al.* 2003a, Soto-Barreras *et al.* 2019, Sudhir *et al.* 2009). Because these areas were generally known to be fluoride-endemic areas for long periods of time, it can generally be assumed that in these nine studies, exposure occurred prior to the outcome. Taken together, 12 cross-sectional studies from 9 study populations provide indicators of prior exposure.

Cross-sectional study variations

Overall, the cross-sectional studies provide consistent evidence that fluoride exposure is associated with lower IQ scores in the children. Several cross-sectional studies conducted multiple analyses (e.g., reported results for multiple exposure metrics, endpoints, subpopulations). Although some of these variations are heterogeneous and are not comparable across studies, the consistent results across multiple metrics increase our confidence in the data. **Table 6** summarizes key results for each of the low risk-of-bias cross-sectional studies, and a few examples of the within-study variations in results are provided below.

Nine cross-sectional studies (from 6 study populations) assessed the association between IQ and multiple exposure measures (Choi *et al.* 2015, Saxena *et al.* 2012, Rocha-Amador *et al.* 2007, Wang *et al.* 2020b, Yu *et al.* 2018, Zhang *et al.* 2015b, Xiang *et al.* 2003a, Xiang *et al.* 2011, Wang *et al.* 2012). Lower IQ was consistently observed across exposure measures in these studies; however, Choi *et al.* (2015), a small pilot study (n = 51), reported a variation in statistical significance by exposure measure (see **Figure D7**). Choi *et al.* (2015) also observed some variation in results by outcome assessed (i.e., square root block design and digit span [forward, backward, and total]). It was the only cross-sectional study that did not provide a full IQ score, but instead provided results by specific subtests. The study authors observed a consistent inverse association between fluoride exposure and results from the digit span subtest (which specifically assesses executive function); however, results from the square root block design, a subtest of the WISC-IV omnibus IQ test that specifically assesses visuospatial function, was not associated with fluoride exposure. Note that Rocha-Amador *et al*. (2009) also assessed visuospatial function, and the authors reported a significant association (p-value < 0.001) between fluoride exposure and decreased visuospatial constructional ability using the Rey-Osterrieth Complex Figure (ROCF) Test. Ultimately, too few studies were identified that reported results by subtest of omnibus IQ tests or assessed domains other than IQ (e.g., visuospatial function) to examine or explain the variation by outcome observed in Choi *et al.* (2015). The only other studies that provided a breakdown of the full IQ score were the prospective cohort studies by Green (2019) and Till (2020), which provided results for full-scale IQ as well as results for performance and verbal IQ. In both of these studies, verbal IQ was not associated with fluoride exposure, but performance and full-scale IQ were associated with fluoride exposure. There are too few studies to evaluate if there is a specific aspect of IQ testing that is affected by exposure to fluoride, but the studies nonetheless provide consistent evidence that fluoride exposure is associated with lower IQ.

Yu *et al.* (2018) reported an overall association between lower IQ and higher fluoride exposure across multiple analyses, but observed some variation in IQ results by urinary exposure level. The authors reported inverse associations between IQ and children's medium-range urinary fluoride levels (1.60–2.50 mg/L) and children' high-range urinary fluoride levels (2.50–5.54 mg/L) although change in IQ score

was greater in the medium-range urinary fluoride group (2.67 points lower [95% CI: −4.67, −0.68]) for every 0.5-mg/L increment of urinary fluoride, than in the high-range urinary fluoride group (0.84 points lower [95% CI: −2.18, 0.50]) (see **Figure D7**). No association was reported at low-range urinary fluoride levels (0.01–1.60 mg/L). Note that Yu *et al.* (2018) also reported an inverse association between IQ and drinking water fluoride levels at 3.40–3.90 mg/L (4.29-point lower IQ score [95% CI: −8.09, −0.48]) for every 0.5-mg/L increment of water fluoride; a 0.04-point lower IQ score [95% CI: −0.33, 0.24] was observed for 0.5-mg/L increments of water fluoride at levels of 0.20–3.40 mg/L). The variation by exposure level in urine could not be verified in the analysis of drinking water exposures because there were only two water exposure groups (low and high). In a second study (Wang *et al.* 2020b), authors conducted a categorical analysis using urinary fluoride quartiles with reported betas per quartile. As observed in Yu *et al.* (2018), there were decreasing trends in IQ within each quartile; however, unlike Yu *et al.* (2018), Wang *et al.* (2020b) observed a larger decrease in IQ with each increasing urinary quartile and observed similar results using water fluoride quartiles (Wang *et al.* 2020b). Note that Wang *et al.* (2020b) cannot be compared directly to Yu *et al.* (2018) for evaluation at the higher exposure levels because the two studies do not use the same categorical exposure ranges. Although additional studies may have looked at different exposure levels, none of these studies provided results in the same manner as Yu *et al.* (2018) and Wang *et al.* (2020b) (i.e., betas by exposure category). Instead, these other studies provided an overall beta or mean IQ scores by exposure level. Despite the noted variations among these studies, the overall results still support a consistent association between fluoride exposure and lower IQ.

Two studies (Cui *et al.* 2018, Zhang *et al.* 2015b) observed associations between lower IQ in children and exposure to fluoride, with variations in results in subpopulations of children with different polymorphisms (see **Figure D7**). These were the only two studies that considered polymorphism as a subanalysis. Cui *et al.* (2018) observed a significant association between log-transformed children's single spot urinary fluoride and lower IQ scores (2.47-point lower IQ scores [95% CI: −4.93, −0.01; p-value = 0.049] per unit increase in urinary fluoride), and the association was strongest in subjects with a TT polymorphism (compared to children with a CC or CT polymorphism) in the dopamine receptor D2 (DRD2) gene (12.31-point lower IQ score [95% CI: −18.69, −5.94; p-value < 0.001] per unit increase in urinary fluoride) which, according to the authors, probably resulted in a reduced D2 receptor density (Cui *et al.* 2018). Similarly, Zhang *et al.* (2015b) observed a significant association between lower IQ scores and children's single spot urinary fluoride (2.42-point lower IQ scores [95% CI: −4.59, −0.24; p-value = 0.030] per unit increase in urinary fluoride), and the association was strongest in subjects with a val/val polymorphism (compared to children who carried the heterozygous or homozygous variant genotypes [met/val or met/met]) in the catechol-O-methyltransferase (COMT) gene (9.67-point lower IQ score [95% CI: −16.80, −2.55; p-value = 0.003] per unit increase in urinary fluoride).

Overall, the cross-sectional studies support a consistent pattern of findings that increased fluoride exposure is associated with lower IQ scores in children. Slight within-study variations occur that may be associated with study variables such as IQ domains or subsets of IQ tests in a few studies that conducted multiple analyses, but these variations are heterogenous and cannot be further explored with the available studies. Despite these few variations, the overall evidence of an effect on IQ is apparent.

Exposure Measure and Study Population Factors

Low risk-of-bias studies provide consistent evidence that increased fluoride levels are associated with lower IQ scores across studies using different exposure measures. In addition to water fluoride levels, studies measured fluoride exposure using single serum samples in children (Xiang *et al.* 2011, Zhang *et al.* 2015b), single spot urine samples in children (Xiang *et al.* 2003a, Rocha-Amador *et al.* 2007, Ding *et*

al. 2011, Saxena *et al.* 2012, Zhang *et al.* 2015b, Cui *et al.* 2018, Yu *et al.* 2018, Wang *et al.* 2020b), and prenatal maternal urinary measures (Bashash *et al.* 2017, Green *et al.* 2019), all of which were demonstrated to be consistently associated with lower IQ scores (see **Figure D6** and **Figure D7**). Urine levels encompass all sources of fluoride exposure and provide a better measure of the totality of exposure. As noted previously, even though some studies measured single spot samples, which may not be representative of peak exposure, these studies generally provided evidence that fluoride exposure had been occurring for some time. The consistency in the study results across studies that used different measures of fluoride exposure and different lifestages at which fluoride was measured helps strengthen the body of evidence.

The low risk-of-bias studies provide consistent evidence that increased fluoride levels are associated with lower IQ scores across studies of different study populations. These 19 high quality studies represent diverse populations (n = 15 study populations) across 5 countries. Eighteen of the 19 studies conducted in Canada (n = 2), China (n = 10), India (n = 3), Mexico (n = 2), and Iran (n = 1) provide evidence that exposure to fluoride is associated with lower IQ scores; 1 study conducted in Mexico did not observe an association but reported results in a manner that did not allow for a direct comparison with the other studies (see **Appendix 4** for details). The overall consistency in the study results across study populations adds strength to the body of evidence.

Exposure Levels

As described in this section, the body of evidence for studies assessing the effect of fluoride exposure on IQ in children provides consistent evidence of an association between fluoride exposure and lower IQ in children; however, there is less certainty in the data at lower fluoride exposures (e.g., <1.5 mg/L in drinking water or equivalent total fluoride exposures from all sources). In the September 6, 2019, draft of this monograph, NTP conducted a qualitative analysis of children's IQ studies that 1) evaluated lower fluoride exposures (<1.5 mg/L) in drinking water and/or urine and 2) provided information to evaluate dose response (i.e., provided three or more fluoride exposure groups or a dose-response curve in their publication) in the lower fluoride exposure range. Nine low risk-of-bias studies met these criteria. Based on a qualitative review of these studies, the evidence of an association between fluoride exposure below 1.5 mg/L and lower IQ in children appeared less consistent than results of studies at higher exposure levels.

A draft quantitative dose-response meta-analysis was prepared and included in the September 16, 2020, draft monograph (NTP 2020). This meta-analysis is undergoing further refinement in preparation for separate publication and may further inform a discussion on the association between fluoride exposure levels and IQ in children.

Gender Considerations

Gender differences were examined in five of the low risk-of-bias studies (in four study populations) (Green *et al.* 2019, Wang *et al.* 2020b, Trivedi *et al.* 2012, Xiang *et al.* 2003a, Wang *et al.* 2012). In general, gender differences were difficult to assess for trends within different study populations because few studies in the body of evidence analyzed exposure and stratified results by gender. Although these five studies reported IQ scores separately for boys and girls, only two of these studies analyzed fluoride exposure for boys and girls separately (Green *et al.* 2019, Wang *et al.* 2020b), which is essential for evaluating whether a differential change in IQ by gender may be related to higher susceptibility in one gender or higher exposure in that gender. The remaining three studies stratified results by gender (Trivedi *et al.* 2012, Xiang *et al.* 2003a, Wang *et al.* 2012), but the analyses were based on area-level exposure data (e.g., low fluoride village compared to high fluoride village) and not drinking water or

urinary fluoride concentrations. In the five studies that reported results by gender separately, consistent findings of lower IQ associated with fluoride exposure were generally reported for both sexes. There was some variation in the results between sexes across study populations and exposure measures, but there is insufficient evidence to determine if one gender is more susceptible to the effects of fluoride exposure than the other.

Green *et al.* (2019) observed a significant inverse association between maternal urinary fluoride levels and IQ scores in boys (p-values <= 0.04) but not girls in a Canadian population. Green *et al.* (2019) did not find any sex differences in the association between IQ and water fluoride concentrations. Wang *et al.* (2020b) evaluated Chinese boys and girls separately and combined and observed statistically significant decreasing trends in IQ in all groups by urinary fluoride quartiles (p-values for trend <= 0.035) (see **Figure D7**). Similarly, when evaluated as a continuous variable, spot urinary fluoride levels (per 1-mg/L increase) were significantly associated with lower IQ scores in girls (−1.379 [95%CI: −2.628, −0.129; p-value = 0.031]), boys (−1.037 [95% CI: −2.040, −0.035; p-value = 0.043]), and in the sexes combined (−1.214 [95%CI: −1.987, −0.442; p-value = 0.002]). Based on water fluoride quartiles, Wang *et al.* (2020b) found that there was a significant trend in the sexes combined although the decreasing trend in boys and girls separately did not achieve statistical significance (p-values = 0.077 and 0.055, respectively). When water fluoride levels were evaluated as a continuous variable (per 1-mg/L increase), there were significant associations between lower IQ scores in girls (−1.649 [95%CI: −3.201, −0.097]; p-value = 0.037), boys (−1.422 [95%CI: −2.792, −0.053; p-value = 0.042]), and the sexes combined (−1.587 [95%CI: −2.607, −0.568]; p-value = 0.002).

The remaining three studies that reported results by gender based comparisons of areas of high and low urinary or water fluoride did not report exposure levels separately for boys and girls, which decreases the utility of the data to evaluate differential susceptibility by gender. Trivedi *et al.* (2012) observed significantly lower IQ in children in high fluoride Indian villages compared to low fluoride villages with decreases observed in boys and girls separately or combined (p-values <= 0.05) (see **Figure D2**). Xiang *et al.* (2003a) and Wang *et al.* (2012) provide data on the same study population in China. There was a significantly lower IQ in the high fluoride area compared to the low fluoride area in boys and girls separately and in the sexes combined (p-values < 0.01), although the difference was greater in girls. Because fluoride exposure was not analyzed for boys and girls separately, it is unclear if the greater change in IQ scores in girls than boys could be attributable to higher susceptibility to fluoride exposure in girls or differences in fluoride exposure by gender.

In summary, it is unclear if one gender is more susceptible to the effects of fluoride exposure than the other due to a limited number of studies that analyzed exposure and outcome by gender and a lack of a consistent pattern of findings that one gender is more susceptible. Green *et al.* (2019) did not observe an association between maternal urinary fluoride levels and IQ scores in girls but did observe a significant association in boys. Although this is an indication of higher sensitivity in boys in this analysis, the authors did not detect this gender difference using other measures of prenatal exposure (maternal fluoride intake or water fluoride concentrations). Wang *et al.* (2020b) and Trivedi *et al.* (2012) reported statistically significant associations in both boys and girls without indication that one gender may be more susceptible. Although Xiang *et al.* (2003a) and Wang *et al.* (2012) reported a greater change in IQ in girls than boys, the studies used area-level exposure data and authors did not determine if fluoride exposure differed in boys versus girls. Therefore, it is unclear if this differential result by gender is an indication of higher susceptibility in girls or if it could be explained by a difference in exposure by gender. Overall, there are too few studies that analyzed exposure and outcome by gender separately to properly evaluate if there is differential susceptibility to fluoride exposure by gender, and results from

the five low risk-of-bias studies that do evaluate gender differences indicate that there is no consistent difference by gender across the different study populations.

Summary of Key Findings for Low Risk-of-bias Children's IQ Studies

In summation, the high quality studies (i.e., studies with low potential for bias) demonstrate consistently lower IQ scores with higher fluoride exposure (e.g., greater than the WHO Drinking Water Quality Guideline [≥1.5 mg/L] (WHO 2011) or equivalent total exposures from all sources). The consistency in association is observed among studies of varying study designs, exposure measures, and study populations. Although some studies that conducted multiple analyses observed within-study variations in results (e.g., differences between subsets of IQ tests), these variations were unique to individual studies and do not detract from the overall consistency in the findings that higher fluoride is associated with lower IQ scores.

High Risk-of-bias IQ Studies

The results from 47 studies with high potential for bias that evaluated IQ in children provide consistent supporting evidence of decrements in IQ associated with exposures to fluoride. Forty-one of the 47 studies reported an association between high fluoride exposure and lower IQ scores in children.

Risk of Bias for IQ Studies in Children

The confidence in the human body of evidence was based on studies with the lowest potential for bias. A total of 19 studies on IQ in children had little or no risk-of-bias concerns, representing a relatively large body of evidence for low risk-of-bias studies (i.e., 15 study populations across 5 countries evaluating more than 7,000 children). These 19 studies are considered low risk of bias because they were rated probably low or definitely low risk of bias for at least two of the three key risk-of-bias questions and did not have any other risk-of-bias concerns that would indicate serious issues with the studies. Thirteen of the 19 studies were rated definitely low or probably low risk of bias for all risk-of-bias questions, and the remaining 6 studies were rated probably high risk of bias for a single question that was judged to have minimal impact on overall potential for bias. None of the 19 studies had a rating of definitely high risk of bias for any question. Risk-of-bias ratings for individual studies for all questions are available in **Figure A3-1** through **Figure A3-4**, with risk-of-bias ratings for IQ studies in children available in **Figure A3-5** through **Figure A3-8** and **Appendix 4**. Although the low risk-of-bias studies had minimal or no concerns, the studies with high overall potential for bias had a number of risk-of-bias concerns, including potential confounding, poor exposure characterization, poor outcome assessment, and, in many cases, potential concern with participant selection. The key risk-of-bias questions are discussed below.

Confounding for IQ Studies in Children

Low Risk-of-bias Studies

As discussed above, there are 19 studies considered to have low risk of bias when assessed across all risk-of-bias domains. Sixteen of 19 low risk-of-bias studies were considered to have low potential for bias due to confounding because the authors addressed potential confounders through study design or analysis. All 16 of these studies addressed the three key potential confounders for all studies: child's age, child's sex, and socioeconomic status. Co-exposures as potential confounders were addressed through study design or analysis in most of the low risk-of-bias studies and were ultimately not considered a concern in 18 of 19 studies (further discussed below). Other potential confounders, including health factors, smoking, and parental characteristics, were also addressed in many of the low risk-of-bias studies (see **Figure 6**).

Co-exposures to arsenic and lead were not considered a concern in 18 of 19 low risk-of-bias studies either because studies addressed the potential co-exposures, the co-exposures were not considered an issue in the study population, or the impact of the potential bias on the results was not a concern. Potential confounding related to co-exposure to arsenic was accounted for or determined not to be of concern in 15 of 19 low risk-of-bias studies, and all 15 studies observed an association between lower IQ and fluoride exposure. Co-exposure to arsenic was not accounted for in four low risk-of-bias studies and was the main potential concern in these studies; however, three of these studies (Xiang *et al.* 2011, Wang *et al.* 2012, Xiang *et al.* 2003a) were still considered low risk of bias for confounding due to the fact that arsenic was observed in the low fluoride comparison areas (which would bias the effect toward the null), but an effect was still observed. In this case, the lack of adjustment for arsenic strengthens the evidence for an association and does not represent a potential concern. The other study did not address arsenic and as noted above was in an area that had potential for arsenic exposure to occur Soto-Barreras *et al.* (2019) and is the only low risk-of-bias study that did not observe an association between lower IQ and fluoride exposure. Fourteen studies considered co-exposure to lead and all observed an association between lower IQ and fluoride exposure. Five studies did not consider co-exposures to lead; however, for all of these studies co-exposure to lead was considered unlikely to have an impact in these study populations as there was no evidence that lead was prevalent or occurring in relation to fluoride (Cui *et al.* 2018, Cui *et al.* 2020, Till *et al.* 2020, Trivedi *et al.* 2012, Soto-Barreras *et al.* 2019).

There is considerable variation in the specific confounders considered across the 19 low risk-of-bias studies. The consistency of results across these low risk-of-bias studies suggests that confounding is not a concern in this body of evidence. Each of the 18 low risk-of-bias studies that observed an association between fluoride and IQ (see **Summary of Results** section above) considered a unique combination of potential confounders. The findings of these studies consistently provide evidence of an association between lower IQ in children and exposure to fluoride regardless of the inclusion or absence of consideration for any one or combination of potential confounders of interest. For example, maternal or family member smoking was addressed in 7 of the 19 low risk-of-bias studies, and this did not appear to affect the conclusions. All 7 studies that accounted for smoking found evidence of an association between fluoride exposure and lower IQ scores as did 11 of the 12 studies that did not account for smoking. Similarly, all 16 studies that addressed the three key confounders (age, sex, SES) (16 of 16 studies), and two of the three studies that did not fully account for them, also found evidence of an association between lower IQ scores and fluoride exposure. In summary, when considering the impact of each potential confounder (or combinations of potential confounders considered) on the consistency of results, no trends are discernable that would suggest that bias due to confounding has impacted or would explain the consistency in findings across the body of evidence that fluoride exposure is associated with lower IQ in children.

Five of the low risk-of-bias studies confirmed the robustness of the results by conducting sensitivity analyses (Bashash *et al.* 2017, Green *et al.* 2019, Yu *et al.* 2018, Wang *et al.* 2020b, Till *et al.* 2020), and none of the sensitivity analyses adjusting for additional confounders found meaningful shifts in the association between fluoride exposure and IQ or other measures of cognitive function. Bashash *et al.* (2017) found that adjusting for HOME score increased the association between maternal urinary fluoride and children's IQ. Green *et al.* (2019) reported that adjusting for lead, mercury, manganese, perfluorooctanoic acid, and arsenic concentrations did not substantially alter the associations with IQ. Sensitivity analyses by Yu *et al.* (2018) that adjusted for covariates (including age, sex, and socioeconomic status) did not find differences in the results compared to the primary analyses. Wang *et al.* (2020b) found the results of the sensitivity analysis to be the same as the results from the primary

analysis. Till *et al.* (2020) observed that adjusting for maternal urinary fluoride levels had little effect on the results.

Among the 19 low risk-of-bias studies, three studies were identified that have potential for bias due to confounding (Ding *et al.* 2011, Soto-Barreras *et al.* 2019, Cui *et al.* 2020). This was mainly due to lack of details on confounders considered key for all studies (i.e., age, sex, and SES). See **Appendix 4** for further discussion of the risk-of-bias concerns regarding confounding for individual studies. Although these three studies have some potential for bias due to confounding, these studies are considered to have low potential for bias overall, as they have low potential for bias for the other two key risk-of-bias questions (exposure characterization and outcome assessment), and no other major concerns for bias were identified. Consistent with the 16 studies that adequately addressed confounding, two of these three studies also provide evidence of an association between fluoride exposure and lower IQ scores in children.

Taken together and considering the consistency in the results despite the variability across studies in potential confounders considered, bias due to confounding is not believed to be a concern in the body of evidence. The potential for the consistency in results to be attributable to bias due to confounding in the 19 low risk-of-bias studies is considered low.

Figure 6. Potential Confounders Considered in Low Risk-of-bias IQ Studies Conducted in Children

Study (Location)[1]	Potential Confounding Factors Considered[2]																Notes	Reported Effect of Fluoride[4]
	Subject Characteristics				Other Exposures					Socioeconomic Factors		Parental Characteristics				Other[3]		
	Age	Sex	Race/Ethnicity	Health Factors[3]	Arsenic	Smoking	Iodine	Lead	Other[3]	SES	Caregiving Environment (e.g., HOME score)	Demographics[3]	Reproductive Factors[3]	Health Factors[3]	IQ			
Overall RoB Rating for Confounding: Probably Low																		
Bashash 2017 (Mexico)	√	√	–	–	√	√	–	√	√	√	√	√	√	–	√	√	Other exposures: Hg, Ca Demographics: maternal age Reproductive: parity, birth order, birth weight, gestational age at delivery Other: cohort	Yes

Notes:

[1]Includes all low risk-of-bias IQ studies in children. Studies are organized as those with an overall risk-of-bias rating for confounding as probably low (green) followed by those with an overall risk-of-bias rating for confounding as probably high (yellow).

[2]Potential confounding factors and/or effect modifiers represented here are those considered important for this evaluation. See study details provided in HAWC for information on additional confounders.

Factors outlined in blue are key potential confounders for all studies (subject age, subject sex, SES) and arsenic (which is of particular importance to some study populations).
A √ indicates that a factor was considered (and may or may not have been adjusted for in final model). For arsenic, a √ might also be used when arsenic was not expected to be an issue because there is no evidence to indicate that the co-exposure was prevalent or occurring in relation to fluoride. See risk-of-bias explanations in **Appendix 4** (or HAWC) for details. A hyphen (–) indicates that the factor was not considered.
[3]See the "Notes" column for additional details.
[4]Extent of reported effects varies by study. "Yes" indicates that study authors provided evidence of an association between lower IQ scores and fluoride exposure.
[5]Study reported lower IQ scores with increasing fluoride exposure, but the results did not achieve statistical significance.

High Risk-of-bias Studies

Most high risk-of-bias studies (n = 47) considered potential confounders to some degree through study design or analysis; however, when considering the full scale of potential concerns of bias due to confounding, all but three of these studies were rated probably or definitely high risk of bias for not adequately addressing potential confounders. The majority of high risk-of-bias studies accounted for one or two of the three potential confounding variables considered key for all studies (age, sex, SES) but did not address all three, while also not addressing other potential confounders considered important for the specific study population and outcome. Potential confounding related to important co-exposures (e.g., arsenic) was often not addressed in high risk-of-bias studies. In studies where there was high exposure to fluoride via drinking water with high naturally-occurring fluoride or from the use of coal-containing fluoride, most researchers did not account for potential exposures to arsenic, which is commonly found in coal and drinking water in fluoride-endemic areas of China and Mexico.

Despite the lack of adequate consideration of confounders in the vast majority of high risk-of-bias studies, the results across most of these studies (41 of 47) consistently provide evidence of an association between fluoride exposure and IQ, supporting the results observed in the low risk-of-bias studies. This finding suggests that confounding is likely less of a concern for the body of evidence as a whole than for any individual study. Although the high risk-of-bias studies may have more potential for bias due to confounding compared to the low risk-of-bias studies, the consistent IQ findings across high and low risk-of-bias studies indicate that the results cannot be explained based on bias due to confounding.

Exposure Characterization in IQ Studies

Low Risk-of-bias Studies

In general, there were few if any risk-of-bias concerns regarding exposure characterization in the low risk-of-bias studies. These studies mainly had individual exposure data based on urine or water measures with appropriate analyses. Although there are concerns related to using urine samples (see **Risk-of-bias Considerations for Human Studies** section for details), many studies provide evidence to suggest that urinary fluoride is a reasonable measure of exposure. Using three methods to account for urine dilution, Till *et al.* (2018) reported that adjusted risk estimates did not differ from unadjusted estimates. Analyzing the same study population as Till *et al.* (2018), Green *et al.* (2019) found that adjusting for time of urine collection or time of collection since last void during pregnancy did not substantially affect associations with IQ results in either boys or girls. In addition, adjusting the maternal urinary fluoride for creatinine did not substantially alter the association observed (Green *et al.* 2019). To provide a more accurate and sensitive measurement of maternal urinary fluoride than a single measurement provides, Green *et al.* (2019) only included participants with valid fluoride measurements at all trimesters in their analysis. Other studies also measured urinary fluoride multiple times throughout pregnancy (Bashash *et al.* 2017). Some studies demonstrated correlations between the urinary fluoride

and fluoride in the drinking water, fluorosis, or estimated dose based on drinking water concentrations and consumption (Green *et al.* 2019, Saxena *et al.* 2012, Zhang *et al.* 2015b, Ding *et al.* 2011, Choi *et al.* 2015, Yu *et al.* 2018). Till *et al.* (2018) demonstrated that there was a linear association between urinary fluoride concentrations in pregnant women and drinking water fluoride concentrations regardless of method to correct for urine dilution or whether or not adjustments were made for dilution. Bashash *et al.* (2017) excluded exposure outliers but found that doing so did not substantively change the results. Taken together, these studies suggest that urinary fluoride is a reasonable measure of exposure despite some of the potential issues.

All but one low risk-of-bias study was rated probably or definitely low risk of bias for exposure assessment. Seraj *et al.* (2012) had potential exposure misclassification and was rated probably high risk of bias for exposure assessment. Villages were categorized as normal (0.5–1 ppm), medium (3.1 ± 0.9 ppm), or high (5.2 ± 1.1 ppm) based on average fluoride content in drinking water in varying seasons over a 12-year period. Mild fluorosis observed in children in the normal fluoride level group indicates that there may have been higher exposure in this group at some point in the past; however, this would bias the results towards the null, and the children in the normal fluoride group had a significantly higher IQ score compared to the medium and high fluoride groups ($p = 0.001$). There were also significant associations between lower IQ scores and fluorosis intensity (p-value = 0.014) and water fluoride concentration when evaluated as a continuous variable (p-values < 0.001). Although there is potential for exposure bias, the apparent exposure misclassification and inclusion of children with higher fluoride exposure in the normal group indicate that the association may be greater than observed in this study.

High Risk-of-bias Studies

A frequent, critical limitation among the high risk-of-bias studies was lack of information regarding exposure or poor exposure characterization. Many of the high risk-of-bias studies only compared subjects living in two regions with differing levels of fluoride exposure, and although most of them did provide some differentiation in levels of fluoride between the areas, limited or no individual exposure information was reported. Among studies that provided drinking water levels of fluoride in two areas being compared, sufficient information to determine if the individual study subjects were exposed to these levels was often not reported. Some studies also lacked information on fluoride analysis methods and timing of the exposure measurements. In some cases (n = 3), study areas that were considered endemic for dental and/or skeletal fluorosis were compared to non-endemic areas, or high-fluoride areas were compared to low-fluoride areas, with no other information provided on fluoride levels in the areas (Sun *et al.* 1991, Li *et al.* 2003 [translated in Li *et al.* 2008c], Ren *et al.* 1989 [translated in Ren *et al.* 2008]). Although living in an area endemic for fluorosis could be an indicator of exposure, these studies did not specify if the study subjects themselves had fluorosis. Another study used only dental fluorosis as a measure of fluoride exposure in subjects that were all from an endemic area with similar drinking water fluoride levels (Li *et al.* 2010). In one case, multiple sources of fluoride exposure were assessed separately without properly controlling for the other sources of exposure, which could bias the results (Broadbent *et al.* 2015). Broadbent *et al.* (2015) assessed fluoride exposure in three ways: use of community water in fluoridated area versus non-fluoridated area, use of fluoride toothpaste (never, sometimes, always), or use of fluoride tablets prior to age 5 (ever, never). The same children were used for each analysis without accounting for fluoride exposure through other sources. For example, there were 99 children included in the non-fluoridated area for the community water evaluation, but there is no indication that these 99 children were not some of the 139 children that ever used supplemental fluoride tablets or the 634 children that always used fluoride toothpaste. Therefore, comparing fluoridated areas to non-fluoridated areas without accounting for other sources of exposure that might occur in these non-fluoridated areas would bias the results towards the null.

Outcome Assessment for IQ Studies

Low Risk-of-bias Studies

The low risk-of-bias studies have few concerns regarding outcome assessment. Eighteen of the 19 studies used appropriate methods for measuring IQ in the study population being assessed, and blinding of outcome assessors was not a concern. Fourteen of the studies reported blinding of the outcome assessors, or correspondence with the study authors indicated that it was not likely an issue. For the remainder of the studies, it was assumed that the outcome assessors were most likely blind because exposure was assessed via urine or drinking water obtained at the same time as the outcome assessment in general population studies. One IQ study (Sudhir *et al.* 2009) had concerns for potential bias in the outcome assessment due to lack of information to determine if blinding at the time of the outcome assessment was a concern (see **Appendix 4** for details).

High Risk-of-bias Studies

Among the studies with high risk of bias, the main limitation in the outcome assessment was the lack of reporting on blinding of the outcome assessor (i.e., whether the outcome was assessed without knowledge of exposure). Although there is little concern that the children's knowledge of their own exposure would bias the way they took the IQ tests, there is potential for bias if the tests were administered by an interviewer, or if the scoring of results could be subjective (e.g., drawing tests), and the interviewer or scorer had knowledge of the children's exposure. Most of the studies did not provide sufficient information on the person scoring or administering the tests or other information on the assessment methods to alleviate concerns for potential interviewer or reviewer bias.

High risk-of-bias studies were mainly carried out in two separate populations without information provided that the tests were conducted in a central location, and in many cases the methods indicated that the tests were conducted at the schools in the study area indicating that there was likely knowledge of the exposure. In some cases, the outcomes were not considered sensitive measures (e.g., Seguin Form Board Test to test for IQ), or the test was not considered appropriate for the study population (e.g., a test validated in a western population was used on a rural Chinese population).

Confidence Assessment of Findings on IQ in Children

There is moderate confidence in the body of evidence that fluoride exposure is associated with lower IQ in children based on the consistent evidence of an association between high total fluoride exposure (mainly greater than the WHO Drinking Water Quality Guideline [≥1.5 mg/L] (WHO 2011), but also high exposure via fluoridated salt and food) and lower IQ. Eighteen of the 19 studies reported associations between lower IQ scores and higher fluoride levels. These studies were conducted in 5 different countries on more than 7,000 children from 15 different study populations demonstrating consistency across multiple populations. There is consistency in results across study design with associations observed in the prospective cohort studies (n = 3) and cross-sectional studies with 12 of the cross-sectional studies providing evidence of prior long-term, chronic fluoride exposure. There is also consistency in results across studies using different exposure measures, including urinary and drinking water fluoride. The initial moderate confidence rating in the body of evidence is based on 15 studies that have 3 of the 4 key features shown in **Figure 1** (i.e., where exposure occurred prior to outcome, that evaluated individual-based outcomes and used a comparison group). Factors to consider for increasing or decreasing the confidence in the body of evidence are provided in **Figure 1**. Discussion of these factors for upgrading or downgrading the confidence in the evidence is presented below.

- **Risk of bias**: Only studies that were considered to have low risk of bias were included in the moderate confidence rating; therefore, there was no downgrade for risk-of-bias concerns.

- **Unexplained inconsistencies:** The data are consistent and there was no downgrade for this factor. In terms of IQ data, 18 studies observed lower IQ with higher fluoride exposure. The one study that did not observe an effect did not provide results in a comparable manner and is not considered unexplained.

- **Indirectness:** IQ in humans is a direct measure of the effect of interest and therefore no adjustment in confidence is warranted.

- **Imprecision:** There is no evidence of imprecision that would warrant a downgrade. Eighteen studies reported lower IQ with higher fluoride, and no issues with imprecision were identified to challenge the significance of the effect.

- **Publication bias:** There is no strong evidence of publication bias; therefore, no downgrade was applied for publication bias. Two published meta-analyses (Duan *et al.* 2018, Choi *et al.* 2012) did not indicate strong evidence of publication bias. The draft meta-analysis conducted by NTP in the September 16, 2020, draft monograph found no publication bias among the low risk-of-bias studies (NTP 2020). Among high risk-of-bias studies, adjusting for publication bias using the trim-and-fill analysis estimated that, in the absence of publication bias, the inverse direction of effect and statistical significance remained, thus indicating that there was no need to downgrade for publication bias.

- **Large magnitude of effect:** Although some individual studies indicate a large magnitude of effect, the magnitude of effect was not the same across all studies. Therefore, the overall data would not support an upgrade due to a large magnitude of effect.

- **Dose-response:** There is evidence of a dose-response relationship that could justify an upgrade to the confidence in the body of evidence. However, many of the studies that provide data to evaluate dose response were judged to be high risk of bias. In addition, the data appear less clear in the lower dose range. The refined NTP meta-analysis (in preparation) may further inform this issue.

- **Residual confounding:** Xiang *et al.* (2003a), Xiang *et al.* (2011), and Wang *et al.* (2012) studied the same population where arsenic occurred in the area with low fluoride, but did not occur in the area with high fluoride. This would have biased the results toward the null, but there were significantly lower IQ scores in the area with high fluoride. The remaining studies do not provide enough information to consider residual confounding as an impactful factor for the body of evidence. Therefore, the overall data would not support an upgrade due to residual confounding.

- **Consistency:** The high quality studies demonstrate a consistent pattern of findings that fluoride exposure is associated with lower IQ scores in children; however, the consideration of a potential upgrade for consistency in the methods is primarily for non-human animal evidence where it would be applied to address increased confidence for consistent effects across multiple non-human animal species. For human evidence, it is generally not applied and the data would only be considered in deciding whether to downgrade for unexplained inconsistency. Therefore, no upgrade is applied for consistency.

Although the OHAT approach for evidence integration allows for the initial confidence in the body of evidence to be increased from moderate to high confidence based on evidence of a dose response,

these procedures are not algorithms and require scientific judgments. The NTP judgement is that the magnitude of effect and the overall strength and quality of the human literature base provide a moderate confidence in the body of evidence that fluoride is associated with lower IQ in children (see **Discussion** section for strengths and limitations of the evidence base). Note that additional, well-designed prospective cohort studies with individual-level exposure data and outcome measures could provide increased confidence in the association between lower IQ in children and fluoride exposure.

Other Neurodevelopmental or Cognitive Effects in Children

Low Risk-of-bias Studies

Overview of Studies

Nine low risk-of-bias studies evaluated the association between fluoride exposure and cognitive neurodevelopmental effects other than IQ in children. These 9 studies were conducted in multiple study populations in three countries, specifically:

- 3 were conducted in 3 areas of China on 3 study populations;
- 4 were conducted in 2 areas of Mexico on 3 study populations; and
- 2 were conducted in Canada using the same study population.

There is considerable heterogeneity across studies, particularly in the different health outcomes evaluated and ages assessed. Most studies measured fluoride in the drinking water or urine (child or maternal) with one study using severity of dental fluorosis as an exposure measure in addition to drinking water and children's urine. Two of the studies were conducted on infants, with one evaluating effects within 72 hours of birth (Li *et al.* 2004 [translated in Li *et al.* 2008a]) and the other evaluating effects at 3 to 15 months of age (Valdez Jimenez *et al.* 2017). The remaining studies were conducted in children of varying ages ranging from 4 to 17 years. Other cognitive neurodevelopmental outcomes assessed include neurobehavioral effects in infants, learning and memory impairment, and learning disabilities such as attention deficit hyperactivity disorder (ADHD). Few studies measured the same health outcomes, used the same outcome assessment methods, or evaluated the same age groups.

Table 7 provides a summary of study characteristics and key findings related to other cognitive neurodevelopmental outcomes and fluoride exposure for the nine low risk-of-bias studies. The different tests conducted and the populations on which the tests were conducted are also indicated in **Table 7**. Several of these studies conducted multiple analyses and reported results on multiple endpoints. The purpose of the table is to summarize key findings (independent of whether an effect was found) from each study and is not meant to be a comprehensive summary of all results. For each study, results are summarized for each exposure measure assessed. Results from multiple analyses using the same exposure measure may not all be presented unless conflicting results were reported.

Riddell *et al.* (2019)[2]	Cross-sectional General population/ Canadian Health Measures Survey (Cycles 2 and 3) [3,745]	Drinking water Mean (SD): 0.23 (0.24) mg/L; non-fluoridated water-0.04 (0.06) mg/L, fluoridated water-0.49 (0.22) Community water fluoridation status (yes or no) Children's urine Mean (SD): 0.61 (0.39) mg/L; non-fluoridated water-0.46 (0.32) mg/L, fluoridated water-0.82 (0.54)	Children (ages 6–17 years)	Hyperactivity/inattention: Strengths and Difficulties Questionnaire (SDQ) ADHD: parent or self-reported physician diagnosis	Significantly increased risk of ADHD with fluoride in tap water (adjusted OR = 6.10 per 1-mg/L increase; 95% CI: 1.60, 22.8) or community water fluoridation status (1.21; 95% CI: 1.03, 1.42), but not with urinary fluoride; similar results observed with attention symptoms based on the SDQ scores Adjusted for child's age, child's gender, child's BMI, ethnicity, parental education, household income, blood lead, and smoking in the home

Studies with the same number superscript are based on the same study population.

[a]Includes low risk-of-bias studies.

[b]Definitions: **ADHD**: attention-deficit/hyperactivity disorder; **BMI**: body mass index; **GCI**: General Cognitive Index; **GM**: geometric mean; **HOME**: Home Observation Measurement of the Environment; **IQ**: intelligence quotient; **MSCA**: McCarthy Scales of Children's Abilities; **WASI**: Wechsler Abbreviated Scale of Intelligence (Spanish version); **WISC-IV**: Wechsler Intelligence Scale for Children-Revised (as reported by Choi *et al.* 2015); **WRAML**: Wide Range Assessment of Memory and Learning; **WRAVMA**: Wide Range Assessment of Visual Motor Ability.

[c]Associations between other cognitive neurodevelopmental outcomes in children and fluoride levels were reported quantitatively, as possible. For studies with multiple analyses and results, the table summarizes key findings and is not a comprehensive summary of all findings. Results also indicated when a study found no association, provided as a qualitative statement of no association.

Summary of Results

Overall Findings

Although discussed together in this section, there are various health outcomes assessed in the nine low risk-of-bias studies of other neurodevelopmental outcomes, including neurobehavioral scores in infants (2 studies), cognitive tests in children other than IQ (3 studies), and ADHD or learning disabilities (4 studies) in children. Altogether, the results from eight of nine low risk-of-bias studies (three prospective cohort studies and five cross-sectional studies from seven different study populations) provide evidence of significant associations between fluoride exposure and cognitive neurodevelopmental outcomes in children other than decrements in IQ (see **Figure D8** through **Figure D10**) (Bashash *et al.* 2017, Valdez Jimenez *et al.* 2017, Bashash *et al.* 2018, Li *et al.* 2004 [translated in Li *et al.* 2008a], Rocha-Amador *et al.* 2009, Barberio *et al.* 2017b, Wang *et al.* 2020a, Riddell *et al.* 2019). Only one cross-sectional study did not find a significant association between fluoride exposure and a measure of cognitive neurodevelopment (Choi *et al.* 2015).

Although there is heterogeneity in the outcomes assessed and a limited number of directly comparable studies, the data provide additional evidence (beyond the consistent evidence of an association between fluoride exposure and IQ) of an effect of fluoride exposure on cognitive neurodevelopment. The body of evidence from the nine low risk-of-bias studies is described in further detail below and are grouped into outcome categories of studies that are most comparable.

Results in Infants

Two studies evaluated neurobehavioral effects in infants either shortly after birth or at 3 to 15 months of age (Li *et al.* 2004 [translated in Li *et al.* 2008a], Valdez Jimenez *et al.* 2017). Both studies observed a significant association between higher fluoride exposure and lower neurobehavioral scores. In neonates (1–3 days old), the high fluoride group (3.58 ± 1.47 mg/L fluoride based on spot maternal urine collected just prior to birth) had significantly lower total neurobehavioral assessment scores (36.48 ± 1.09 versus 38.28 ± 1.10 in controls; p-value < 0.05) and total behavioral capacity scores (10.05 ± 0.94 versus 11.34 ± 0.56 in controls; p-value < 0.05) compared to the control group (1.74 ± 0.96 mg/L fluoride) as measured by a standard neonatal behavioral neurological assessment (NBNA) method (Li *et al.* 2004 [translated in Li *et al.* 2008a]). In infants 3 to 15 months of age, the Mental Development Index (MDI)—which measures functions including hand-eye coordination, manipulation, understanding of object relations, imitation and early language development—was significantly inversely correlated with maternal urinary fluoride in both the first and second trimesters (adjusted βs = −19.05 with standard error of 8.9 for first trimester [p-value = 0.04] and −19.34 with standard error of 7.46 for second trimester [p-value = 0.013]) (Valdez Jimenez *et al.* 2017). Note that this study did not find an association between maternal fluoride during any trimester and Psychomotor Developmental Index (PDI), which measures gross motor development (adjusted βs = 6.28 and 5.33 for first and second trimesters, respectively; no variance provided) (Valdez Jimenez *et al.* 2017).

Results for Cognitive Tests Other Than IQ in Children

Three studies conducted tests on cognitive function in children that were not part of an IQ test. None of the studies conducted the same tests, but two of the three studies observed associations between fluoride exposure and lower test scores. The General Cognitive Index (GCI) of the McCarthy Scales of Children's Abilities (MSCA) in 4-year-old children was significantly inversely associated with maternal creatinine-adjusted urinary fluoride levels during pregnancy (collected during each trimester) (adjusted β = −3.15 [95% CI: −5.42, −0.87; p-value = 0.01] in a model adjusting for main covariates including gestational age, weight at birth, sex, maternal smoking, and indicators of socioeconomic status). The

association remained even after adjusting for maternal bone lead (adjusted β = −5.63 [95% CI: −8.53, −2.72; p-value < 0.01]) (Bashash *et al.* 2017) (see **Figure D10**). Choi *et al.* (2015), however, evaluated cognitive function endpoints in addition to IQ and found no significant associations between concurrent water or urinary fluoride levels and Wide Range Assessment of Visual Motor Ability (WRAVMA) scores, finger tapping test scores, and grooved pegboard test scores, although there were some significant associations based on degree of fluorosis (see **Figure D10**). Another study using construction and memory scores in children 6–11 years old observed significantly lower scores with increasing concurrent child single spot urinary fluoride even after adjusting for age (−0.29 and −0.27 for copy [p-value < 0.001] and immediate recall [p-value < 0.001], respectively [CIs not reported]). Although these children were also exposed to arsenic, the presence of arsenic could not explain the changes as test scores were not significantly associated with urinary arsenic levels (−0.05 and 0.02 for copy and immediate recall, respectively [CIs not reported]) (Rocha-Amador *et al.* 2009) (see **Figure D9**).

Attention-related Disorders Including ADHD and Learning Disabilities in Children

Four studies evaluated attention related disorders or learning disabilities. All four studies found an association between increased fluoride and increased ADHD or learning disability; however, studies varied in the exposure metrics and outcomes measure. Bashash *et al.* (2018) evaluated behaviors associated with ADHD in children ages 6–12 years using the Conners' Rating Scales-Revised (CRS-R) and observed significant associations between maternal urinary fluoride (measured during each trimester) and ADHD-like symptoms, particularly those related to inattention (an increase in 0.5 mg/L of maternal urinary fluoride was significantly associated with a 2.84-point increase [95% CI: 0.84, 4.84; p-value = 0.0054] in the DSM-IV Inattention Index and a 2.54-point increase [95% CI: 0.44, 4.63; p-value = 0.0178] in the Cognitive Problems and Inattention Index). These two scales contributed to the global ADHD Index and the DSM-IV ADHD Total Index, which were also significantly associated with higher levels of prenatal fluoride exposure (an increase of 0.5 mg/L in maternal urinary fluoride was associated with a 2.38-point increase [95% CI: 0.42, 4.34; p-value = 0.0176] in the DSM-IV ADHD Total Index and a 2.47-point increase [95% CI: 0.43, 4.50; p-value = 0.0175] in the ADHD Index) (see **Figure D10**). Significant associations were not observed between maternal urinary fluoride concentrations during pregnancy and child performance on measures of hyperactivity nor were there any significant results in children using the Conners' Continuous Performance Test (CPT-II, 2nd Edition), a computerized test of sustained attention and inhibitory control (Bashash *et al.* 2018). Wang *et al.* (2020a) also used a Conners' Parent Rating Scale (Chinese version) to assess behavioral outcomes in children ages 7–13 years, but only found a significant association between spot urinary fluoride concentrations in children (model adjusted for creatinine) and psychosomatic problems (adjusted OR for T-score > 70 = 1.97 [95% CI: 1.19, 3.27; p-value = 0.009] and adjusted β = 4.01 [95% CI: 2.74, 5.28; p-value < 0.001]). No associations were found between spot urinary fluoride and ADHD index or other behavioral measures.

Barberio *et al.* (2017b) evaluated learning disabilities in children 3–12 years of age, including ADHD, attention deficit disorder (ADD), and dyslexia, as part of the Canadian Health Measures Survey and found a small but significantly increased risk in self-reported (children 12 years of age) or parent- or guardian-reported (children 3–11 years of age) learning disabilities associated with higher spot urinary fluoride levels in children (adjusted OR = 1.02; 95% CI: 1.00, 1.03; p-value < 0.05) (see **Figure D11**); however, significant associations were not observed in analyses using creatinine- or specific gravity-adjusted urinary fluoride (Barberio *et al.* 2017b). Barberio *et al.* (2017b) also reported no associations between single spot urinary fluoride and ADHD in children ages 3 to 12 years. Riddell *et al.* (2019) used the same Canadian Health Measured Survey, but evaluated children 6–17 years old. Riddell *et al.* (2019) found a significantly increased risk for ADHD diagnosis with both tap water fluoride (adjusted OR per 1-mg/L increase = 6.10; 95% CI: 1.60, 22.8; p-value < 0.05) and community water fluoridation status

(adjusted OR = 1.21; 95% CI: 1.03, 1.42; p-value < 0.05). A similar increase in hyperactivity-inattention symptoms score based on the Strengths and Difficulties Questionnaire was observed with both tap water fluoride (adjusted β per 1-mg/L increase = 0.31; 95% CI: 0.04, 0.58; p-value < 0.05) and community fluoridation status (adjusted β = 0.11; 95% CI: 0.02, 0.20; p-value < 0.05). As was observed with Barberio *et al.* (2017b), Riddell *et al.* (2019) did not observe associations between specific-gravity adjusted spot urinary fluoride concentrations and either ADHD diagnosis (adjusted OR per 1-mg/L increase = 0.96; 95% CI: 0.63, 1.46) or hyperactivity-inattention symptoms (adjusted β = 0.31; 95% CI: −0.04, 0.66).

Summary of Key Findings for Low Risk-of-bias Studies of Other Neurodevelopmental and Cognitive Effects in Children

In summation, the high quality studies (i.e., studies with low potential for bias) provide evidence of an association between fluoride exposure and neurodevelopmental and cognitive effects in children other than IQ; however, the body of evidence is limited by heterogeneity in the outcomes evaluated and few comparable studies. Across these outcomes, eight of nine studies reported a significant association between fluoride exposure and a measure neurodevelopment or cognition other than IQ, which provides support to the consistency in evidence based on children's IQ studies of an association between fluoride exposure and adverse effects on cognitive neurodevelopment.

High Risk-of-bias Studies

High risk-of-bias studies (n = 5) also provide some evidence of associations between fluoride exposure and neurodevelopmental or cognitive effects in children other than effects on IQ, but the results are inconsistent and address different outcomes (Li *et al.* 1994 [translated in Li *et al.* 2008b], Shannon *et al.* 1986, Malin and Till 2015, Morgan *et al.* 1998, Mustafa *et al.* 2018).

Risk of Bias for Neurodevelopmental or Cognitive Effect Studies in Children

The confidence in the human body of evidence was based on studies with the lowest potential for bias (i.e., studies that rated probably low or definitely low risk of bias for at least two of the three key risk-of-bias questions and did not have any other risk-of-bias concerns that would indicate serious issues with the studies). Each of the nine low risk-of-bias studies on other neurodevelopmental effects in children had little or no risk-of-bias concerns. Four of the nine studies were rated definitely low or probably low risk of bias for all risk-of-bias questions, and the remaining five studies were rated probably high risk of bias for a single question that was judged to have minimal impact on overall potential bias. None of the nine studies had a rating of definitely high risk of bias for any question. Although the nine low risk-of-bias studies had minimal or no concerns, the five studies with high overall potential for bias (n = 5) had several risk-of-bias concerns related to one or more of the three key risk-of-bias questions (confounding, exposure characterization, and outcome assessment). The key risk-of-bias questions are discussed below. Risk-of-bias ratings for other neurodevelopmental effect studies in children are available in **Figure A3-9** through **Figure A3-12** and **Appendix 4** for the low and high risk-of-bias studies.

Confounding for Other Neurodevelopmental Studies in Children

Low Risk-of-bias Studies

As discussed above, there are nine studies considered to have low risk of bias when assessed across all risk-of-bias domains. Seven of nine low risk-of-bias studies were considered to have low potential for bias due to confounding because the authors addressed potential confounders through study design or analysis. All seven of these studies addressed the three potential confounders considered key for all studies (child's age, child's sex, and socioeconomic status) and also addressed arsenic as a potential co-exposure of concern through study design or analysis. Other potential confounders, including health factors, smoking, and parental characteristics, were also addressed in many of the low risk-of-bias

studies. One of the studies (Bashash *et al.* 2018) examined several potential confounders in sensitivity analyses involving subsets of participants, including HOME scores, child contemporaneous fluoride exposure measured by child urinary fluoride adjusted for specific gravity, and maternal lead and mercury exposures. The authors reported that none of the sensitivity analyses indicated appreciable changes in the fluoride-related association with behaviors related to ADHD, nor did they find evidence of effect modification between sex and maternal urinary fluoride.

Among the nine low risk-of-bias studies, two studies were identified that have potential for bias due to confounding (Rocha-Amador *et al.* 2009, Valdez Jimenez *et al.* 2017). Although both of these studies adjusted for several confounders through analysis or study design, Valdez Jimenez *et al.* (2017) did not address a potential concern for co-exposure to arsenic, and Rocha-Amador *et al.* (2009) does not appear to adjust for SES or address why it would not be a concern in the study population (see **Appendix 4** for further details). Although these two studies have some potential for bias due to confounding, these studies are considered to have low potential for bias overall, as they have low potential for bias for the other two key risk-of-bias questions (exposure characterization and outcome assessment), and no other major concerns for bias were identified. Consistent with the IQ studies, bias due to confounding is not likely a concern for the low risk-of-bias studies.

High Risk-of-bias Studies

The five high risk-of-bias studies in the human body of evidence did not adequately address potential confounders through study design or analysis. The same concerns due to potential confounding noted previously for the high risk-of-bias children's IQ studies were also present in the other neurodevelopmental high risk-of-bias studies including not addressing the three potential confounding variables considered key for all studies (age, sex, SES) and/or not addressing potential co-exposures (e.g., arsenic) in areas of potential concern.

Exposure Characterization in Other Neurodevelopmental Studies in Children

Low Risk-of-bias Studies

There were no risk-of-bias concerns regarding exposure assessment in the low risk-of-bias studies. All of the low risk-of-bias studies had individual exposure data based on urine or water measures with appropriate analyses, and most of the urinary fluoride studies accounted for urinary dilution when appropriate. Although there are concerns related to using urine samples (see **Risk-of-bias Considerations for Human Studies** section for details), the studies that used maternal urine measured urinary fluoride multiple times throughout pregnancy (Bashash *et al.* 2017, Bashash *et al.* 2018, Valdez Jimenez *et al.* 2017). Another study demonstrated correlations between urinary fluoride and fluoride in the drinking water, fluorosis, or estimated dose based on water (Choi *et al.* 2015). Bashash *et al.* (2017) excluded exposure measurement outliers but found that doing so did not change the results in a meaningful way.

High Risk-of-bias Studies

A frequent critical limitation among the high risk-of-bias studies was lack of information regarding exposure or poor exposure characterization. In the high risk-of-bias studies that assessed the association between fluoride exposure and other neurodevelopmental and cognitive effects in children, fluoride exposure assessment was based on dental fluorosis, municipality-level water fluoridation prevalence data, number of years living in an area with fluorinated water, or group-level water samples. See the **Exposure Characterization in IQ Studies** section for further discussion on the limitations of exposure assessments in high risk-of-bias studies.

Outcome Assessment in Other Neurodevelopmental Studies in Children

Low Risk-of-bias Studies

The low risk-of-bias studies have few concerns regarding outcome assessment. Six of the nine studies used appropriate methods for measuring other neurodevelopmental effects in the study population being assessed, and blinding of outcome assessors was either reported or not a concern.

Among the nine low risk-of-bias studies, three studies were identified that have a potential for bias due to outcome assessment. One of the studies (Wang *et al.* 2020a) had potential concern for bias due to lack of information regarding the blinding of outcome assessors. Two of the studies (Riddell *et al.* 2019, Barberio *et al.* 2017b) were based on the same study population in Canada where different questions were asked in Cycles 2 (2009–2011) and 3 (2012–2013) of the Canadian Health Measures Survey (CHMS) to ascertain learning disabilities including ADHD. In Cycle 2, subjects were asked if they had a learning disability diagnosed by a health professional and, if yes, were asked what kind. In Cycle 3, CHMS did not ask what kind of learning disability was diagnosed nor was a reason for the question omission provided. Because no reason was provided for the removal of the question, and because a question on learning disability without the specific diagnosis may be more prone to bias, this change in questioning from Cycles 2 to 3 is a potential concern. Blinding was not considered an issue in these two studies, but the methods for obtaining the information are considered to be less than ideal methods for measuring learning disabilities including ADHD. Although the questionnaire asked about doctor diagnosis of a learning disability, there was no confirmation with medical records. Moreover, these questionnaires were not validated like the Conners' Rating Scales, which would have been a better method for assessing ADHD. Although the outcome assessment methods are less than ideal, there was no direct evidence that they were conducted incorrectly or that the methods would bias the results in any specific direction. Because this was the only concern in these studies, they were considered to have low risk of bias overall.

High Risk-of-bias Studies

Among the studies on other neurodevelopmental effects with high potential for bias, there were several reasons for studies to be considered probably or definitely high risk of bias for outcome assessment. One study (Shannon *et al.* 1986) was considered to have probably high risk of bias based on lack of information regarding blinding of outcome assessors. One study was considered definitely high risk of bias because outcome was assessed based on a parent-completed questionnaire, and the study authors noted that the parents were informed of the study's intent and were requested to provide information on fluoride history. Other studies used outcome assessment methods that were not validated or utilized group-level measurements (i.e., school performance).

Confidence Assessment of Findings on Other Neurodevelopmental Effects in Children

The high quality studies (i.e., studies with low potential for bias) provide evidence of an association between fluoride exposure and other cognitive neurodevelopmental effects, including lower neurobehavioral scores in infants, cognitive effects other than IQ in children, and increased attention-related disorders including ADHD in children; however, there is low confidence in this body of evidence due to limitations in the data set, including the heterogeneity in the outcomes assessed, a limited number of directly comparable studies, and differences in outcome assessment methods even when studies evaluated similar outcomes. Although there are limitations in the body of evidence, the low risk-of-bias studies demonstrate a relationship between higher fluoride exposure and neurodevelopmental effects, even in very young children, which supports the consistency in evidence shown in children's IQ studies of an association between fluoride exposure and adverse effects on cognitive neurodevelopment.

Cognitive Effects in Adults

Low Risk-of-bias Studies

Overview of Studies

Two low risk-of-bias studies evaluated the association between fluoride exposure and cognitive effect in adults (Jacqmin *et al.* 1994, Li *et al.* 2016). These two studies used the same test for cognitive function (i.e., Mini-Mental State or MMS Examination) and used drinking water fluoride levels to assess fluoride exposure. Li *et al.* (2016) also measured urinary fluoride. Both studies were cross-sectional in design. One study was conducted in France (Jacqmin *et al.* 1994) and the other in China (Li *et al.* 2016). Both studies were conducted in older populations (i.e., over 60 or 65 years of age).

Table 8 provides a summary of study characteristics and key findings related fluoride exposure and to cognitive effects in adults for the two low risk-of-bias studies. The purpose of the table is to summarize key findings (independent of whether an effect was found) from each study and is not meant to be a comprehensive summary of all results. For each study, results are summarized for each exposure measure assessed. Results from multiple analyses using the same exposure measure may not all be presented unless conflicting results were reported.

Table 8. Studies on Cognitive Function in Adults[a,b]

Study	Study Design (Location/Subjects) [n]	Exposure Measures and Summary Statistics	Assessment Timing	Outcome and Methods	Neurological Outcome Summary[c]
Jacqmin *et al.* (1994)	Cross-sectional France (Gironde and Dordogne)/elderly adults [3,490]	Drinking water Range: 0.03–2.03 mg	Adults (ages ≥ 65 years)	Cognitive function: MMS Examination	No significant increase in the prevalence of cognitive impairment with increasing fluoride quartiles No statistical adjustment for confounders
Li *et al.* (2016)	Cross-sectional China (Inner Mongolia)/adults [511]	Drinking water daily fluoride intake Mean (SD): 2.23 (2.23) (normal group), 3.62 (6.71) (cognitive impairment group) mg Urine Mean (SD): 1.46 (1.04) (normal group), 2.47 (2.88) (cognitive impairment group) mg/L Fluorosis score Mean (SD): 0.74 (0.98) (normal group), 1.29 (1.01) (cognitive impairment group)	Adults (ages ≥ 60 years)	Cognitive function: MMS Examination	Subjects with cognitive impairment had a significantly higher skeletal fluorosis score and urinary fluoride concentrations; odds of increasing severity of cognitive impairment increased with urinary fluoride concentrations, but were not statistically significant; no significant association with total daily water fluoride intake Adjusted for sex, age, education, marital status (married vs. not married), alcohol consumption (non-drinkers, light drinkers, moderate to heavy drinkers), smoking history (never smoker, ex-smoker, light smoker, heavy smoker), and serum homocysteine levels

[a]Includes low risk-of-bias studies.

[b]Definitions: **GM**: geometric mean; **MMS**: Mini-Mental State.

[c]Associations between cognitive effects in adults and fluoride levels were reported quantitatively, as possible. For studies with multiple analyses and results, the table summarizes key findings and is not a comprehensive summary of all findings. Results also indicate when a study found no association, provided as a qualitative statement of no association.

Summary of Results

Results from two low risk-of-bias studies in adults were not consistent when assessing evidence for a potential association between fluoride exposure and cognitive impairment (based on the MMS Examination) (Jacqmin *et al.* 1994, Li *et al.* 2016). Jacqmin *et al.* (1994) did not find an association between drinking water fluoride and cognitive impairment in populations in France (n = 3,490) and found prevalence rates of cognitive impairment to be the same regardless of fluoride exposure (see **Figure D12**). In contrast, Li *et al.* (2016) did find significantly higher urinary fluoride levels and skeletal fluorosis scores in the cognitively-impaired group compared with the control group in an analysis of 38 cognitively-impaired cases and 38 controls matched for several confounders including age, gender, education, alcohol consumption, and smoking (p-value < 0.05). However, the authors found no significant correlation between cognitive impairment and total daily water fluoride intake (adjusted ORs = 0.94 [95% CI: 0.85, 1.04] and 0.86 [95% CI: 0.69, 1.06] in the moderate and severe cognitive impairment groups, respectively) or urinary fluoride levels (adjusted ORs = 1.12 [95% CI: 0.89, 1.42] and 1.25 [95% CI: 0.87, 1.81] in the moderate and severe cognitive impairment groups, respectively) in subjects from fluorosis-endemic areas of China (n = 511).

High Risk-of-bias Studies

The results from five out of seven high risk-of-bias studies provide evidence of cognitive impairment in adults associated with exposure to fluoride; however, there was heterogeneity in the outcomes assessed, a limited number of directly comparable studies, and some variability in results (e.g., variation in IQ results across studies). Due to the limited number of low risk-of-bias studies identified that assess cognitive impairment in adults, the results from the high risk-of-bias studies are summarized in greater detail below than has been done in this document for the IQ in children and other neurodevelopmental and cognitive effects in children bodies of evidence.

In aluminum factory workers (exposed to gaseous and particular fluoride emissions during the production of aluminum metal), significant decreases in IQ (Duan *et al.* 1995), diminished performance on several neurobehavioral core battery tests (NCTBs) (Guo *et al.* 2001 [translated in Guo *et al.* 2008b]), and impaired psychomotor performance and memory were observed (Yazdi *et al.* 2011). One study conducted on adult subjects with fluorosis (dental and skeletal) from a fluorosis-endemic area compared with healthy subjects from a non-endemic area observed significant differences for some cognitive function tests (i.e., tests of speech fluency, recognition, and working memory) but not others and generally did not observe a significant change in IQ except in the operation scores (Shao 2003). One prospective cohort study evaluated exposure to fluoride in children at age of 5 years, based on whether or not the children resided in areas with community water fluoridation or used fluoride toothpaste or fluoride tablets, and found no clear differences in IQ scores of the subjects at age 38 years (Broadbent *et al.* 2015). One additional study suggested that populations living in areas with higher drinking water fluoride had lower levels of dementia (Still and Kelley 1980); however, the study was not focused on effects of fluoride, but rather if fluoride was able to reduce the risk associated with aluminum by competing with aluminum and reducing the aluminum bioavailability. Therefore, the study was considered inadequate to evaluate the effects of fluoride on dementia (Still and Kelley 1980). A more recent study in Scotland evaluated dementia rates associated with aluminum and fluoride drinking water concentrations and observed a significant increased risk of dementia per standard deviation increase in fluoride (p-value < 0.001) with the risk of dementia more than doubled in the highest quartile of fluoride exposure (56.3 µg/L) compared to the lowest quartile (<44.4 µg/L). The authors also found a significantly increased risk of dementia associated with increased aluminum levels at all quartiles compared with the reference group (p-values < 0.05) but found no statistical interaction between aluminum and fluoride levels in relation with dementia (Russ *et al.* 2019). In addition to studies that

reported on cognitive impairment and exposure to fluoride, two high risk-of-bias studies were identified that reported impaired motor and sensory function (Rotton *et al.* 1982) and a higher prevalence of self-reported headaches, insomnia, and lethargy (Sharma *et al.* 2009) associated with fluoride exposure.

Risk of Bias for Cognitive Effect Studies in Adults

Due to the small number of studies with a low potential for bias and a lack of risk-of-bias issues (see **Figure A3-13** and **Figure A3-14**), the key risk-of-bias domains (confounding, exposure characterization, outcome assessment) are not discussed separately in respective subsections, as was done for the IQ in Children and Other Neurodevelopmental and Cognitive Effects in Children bodies of evidence. The high risk-of-bias studies had concerns across several domains (see **Figure A3-15** and **Figure A3-16**), but there were still relatively few studies. Therefore, the discussion for high risk-of-bias studies is also not separated into subsections by key domain.

Low Risk-of-bias Studies

Both low risk-of-bias studies on cognitive effects in adults had little or no risk-of-bias concerns. One study was rated definitely low or probably low risk of bias for all risk-of-bias questions (Li *et al.* 2016), and the other study was rated probably high risk of bias for a single question that was judged to have minimal impact on overall potential bias (Jacqmin *et al.* 1994). Jacqmin *et al.* (1994) had potential concern for bias due to confounding because smoking was not addressed as a potential confounder, which has potential to impact risk for Alzheimer's disease and rates could vary by parish (the target population consisted of men and women from 75 civil parishes in Southwestern France).

High Risk-of-bias Studies

There were several issues in the seven studies in adults considered to have high potential for bias. Four of the seven studies had potential concern for bias due to lack of information on the comparison groups, or the comparison groups were considered not to be appropriate. All seven studies had potential concern for bias regarding potential confounders not being addressed including possible co-exposures in occupational studies (e.g., aluminum) and smoking. Five of the seven studies had potential concern for bias due to lack of information regarding exposure characterization or poor exposure characterization with the most utilized exposure measure in these studies being a comparison between exposed and unexposed areas. In one case (Broadbent *et al.* 2015), multiple sources of fluoride exposure were assessed separately without properly controlling for the other sources of exposure, which could bias the results (see **Exposure Characterization in IQ Studies** for further details). Four studies also had potential for bias based on limitations in the outcome assessment, which was mainly due to lack of blinding of outcome assessors or lack of sufficient details on how the outcomes were assessed.

Confidence Assessment of Findings on Cognitive Effects in Adults

The body of evidence available to examine the association between exposure to fluoride and cognitive effects in adults is limited to two low risk-of-bias cross-sectional studies. The human body of evidence in adults is considered inadequate to evaluate whether fluoride exposure is associated with cognitive effects due to low confidence in the human data in adults, a limited number of studies, and a lack of evidence of an effect.

Mechanistic Data in Humans

Eight low risk-of-bias studies that evaluated fluoride exposure and mechanistic data in humans were considered potentially relevant to neurological effects. Effects on the thyroid were specifically evaluated because the NRC 2006 report identified this as a possible effect of fluoride (NRC 2006), and changes in thyroid hormones have been identified as a mechanism for neurodevelopmental effects (Haschek and Rousseaux 1991). These included effects on thyroid hormones in children (Kheradpisheh *et al.* 2018b,

Kheradpisheh *et al.* 2018a, Malin *et al.* 2018), adults (Kheradpisheh *et al.* 2018b, Kheradpisheh *et al.* 2018a, Malin *et al.* 2018), or children and adults combined (Barberio *et al.* 2017a). In addition, some studies evaluated self-reported thyroid conditions in children and adults combined (Barberio *et al.* 2017a) and thyroid diseases in adults (Kheradpisheh *et al.* 2018b, Peckham *et al.* 2015) (see **Figure A3-17** and **Figure A3-18**). Although the low risk-of-bias studies provide some evidence of mechanistic effects (primarily changes in thyroid stimulating hormone [TSH] levels in children), the studies were too heterogeneous or limited in number to make any determination on mechanism (see **Figure 7**).

Among the seven low risk-of-bias studies that reported on changes in thyroid hormones, three studies were conducted in children (Zhang *et al.* 2015b, Singh *et al.* 2014, Kumar *et al.* 2018) and reported increases in TSH levels. Zhang *et al.* (2015b) reported significant increases in TSH in children from a fluorosis-endemic area (median fluoride drinking water concentration = 1.40 mg/L; interquartile range = 1.23–1.57 mg/L) compared with a non-fluorosis-endemic area (median fluoride drinking water concentration = 0.63 mg/L; interquartile range = 0.58–0.68 mg/L), while 3,5,3'-triiodothyronine (T_3) or thyroxine (T_4) were not significantly different between the two groups. Similarly, Singh *et al.* (2014) observed significantly higher TSH levels in children without dental fluorosis who lived in a fluorosis-endemic area (fluoride drinking water concentrations of 1.6–5.5 mg/L) compared with children without dental fluorosis who lived in a non-fluorosis-endemic area (fluoride drinking water concentrations of 0.98–1.00 mg/L). When all children (with and without dental fluorosis) in the endemic area were compared to children from the non-endemic area, the TSH levels were higher in children from the fluorosis-endemic area although results did not reach statistical significance ($p = 0.057$). Significant differences in T_4 or T_3 were not observed between groups (Singh *et al.* 2014). Kumar *et al.* (2018) also observed a significant increase in TSH levels in children from a fluorosis endemic area (1.5–5.8 mg/L fluoride) compared with a control area (0.94–1.08 mg/L fluoride). There were also decreases in T_3 and T_4, but results were not statistically significant.

Barberio *et al.* (2017a) evaluated fluoride effects on TSH levels in children and adults combined and found no relationship between fluoride exposure (measures in urine and tap water) and TSH levels. In the one study that evaluated thyroid hormone levels in adults but not children, Kheradpisheh *et al.* (2018b) found a significant increase in TSH associated with higher fluoride concentrations in drinking water in both adults with and without thyroid diseases such as hypothyroidism, hyperthyroidism, thyroid nodules, or thyroid cancer. Significant increases in T_3 were associated with higher fluoride in drinking water in adults without thyroid diseases, but increases in T_3 were not significant in adults with thyroid diseases. A significant association between T_4 and higher fluoride in drinking water was not observed in adults with or without thyroid diseases (Kheradpisheh *et al.* 2018b).

Other than changes in hormone levels, there is limited evidence of fluoride-related mechanistic effects in the three low risk-of-bias studies that evaluated thyroid-related effects. Barberio *et al.* (2017a) found no relationship between fluoride exposure and self-reported thyroid conditions in children and adults (children were older than 12). Kheradpisheh *et al.* (2018b) also found no association between fluoride exposure and hypothyroidism in an adult population in Iran. One study found a significantly higher prevalence of hypothyroidism in areas with higher fluoride concentrations in drinking water (>0.7 mg/L) compared with areas with lower fluoride drinking water concentrations (≤0.7 mg/L) (Peckham *et al.* 2015).

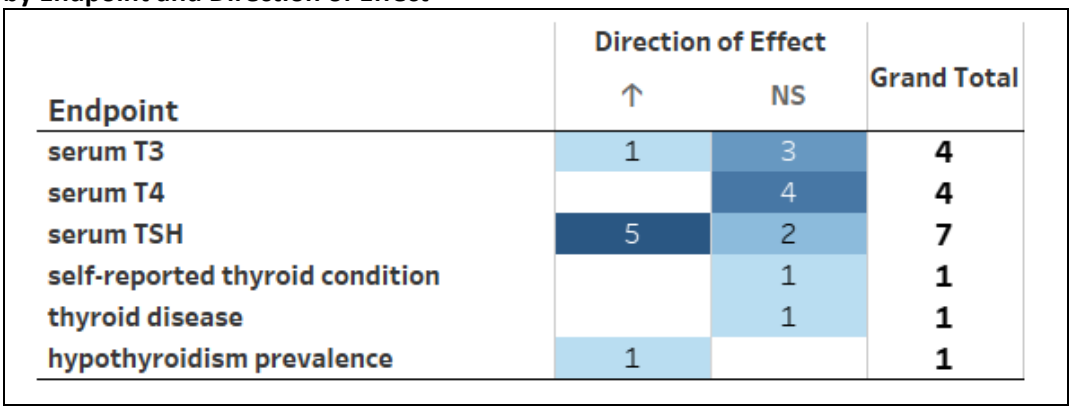
Sixteen high risk-of-bias studies were available that evaluated mechanistic data in humans associated with fluoride exposure, including effects on thyroid hormones in children (n = 9 studies); thyroid hormones in adults (Michael 1996, Yasmin 2013); catecholamines in adults (Michael *et al.* 1996) or in

subjects of unknown ages (Chinoy and Narayana 1992); acetylcholinesterase (AChE) or serotonin levels in children (Singh *et al.* 2013, Lu *et al.* 2019); brain histopathology or biochemistry in aborted fetuses (Du *et al.* 1992 [translated in Du *et al.* 2008], Yu *et al.* 1996 [translated in Yu *et al.* 2008]); and mitochondrial fission/fusion molecules in children (Zhao *et al.* 2019). Similar to the low risk-of-bias studies, the high risk-of-bias studies provide some evidence of mechanistic effects (primarily changes in TSH levels in children); however, the data are insufficient to identify a clear mechanism by which fluoride causes neurodevelopmental or cognitive effects in humans.

Among high risk-of-bias studies (see **Figure A3-19** and **Figure A3-20**), varying results were reported in 11 studies that evaluated fluoride exposure and effects on thyroid hormones, and a few of these studies (Lin *et al.* 1991, Yang *et al.* 1994 [translated in Yang *et al.* 2008], Wang *et al.* 2001) were complicated by high or low iodine in the high fluoride area. When considering fluoride effects on each of the hormones individually, similar to results from low risk-of-bias studies, the most consistent evidence of fluoride-associated effects on a thyroid hormone was reported as changes in TSH levels in children, although there was some variation in the direction of effect. Six of the nine high risk-of-bias studies that evaluated changes in TSH levels in children reported increases in TSH levels with higher fluoride (Lin *et al.* 1991, Susheela *et al.* 2005, Wang *et al.* 2001, Yang *et al.* 1994 [translated in Yang *et al.* 2008], Yao *et al.* 1996, Yasmin *et al.* 2013). Two of the nine high risk-of-bias studies reported decreases in TSH levels in children with higher fluoride (Khandare *et al.* 2017, Khandare *et al.* 2018). One of the nine studies found no significant alterations in TSH levels in children from fluorosis-endemic areas (Hosur *et al.* 2012) (see **Figure 8**).

When considering fluoride-associated effects on TSH, T_3, and T_4 levels together, studies that evaluated changes in all three thyroid hormones reported varying combinations of increases, decreases, or no changes in levels across the three hormones, although among the eight low and high risk-of-bias studies that evaluated the effects of fluoride exposure on TSH, T_3, and T_4 levels and reported increases in TSH levels in children, seven of the eight studies found no alterations in T_3 levels (one study found an increase in T_3), and six of the eight studies found no alterations in T_4 levels (two studies found an increase in T_4). Studies also displayed variation by age in fluoride-associated effects on TSH, T_3, and T_4. Due to the dynamic relationship between the thyroid gland, the pituitary gland, and the production and clearance of TSH, T_3, and T_4, the variations in results are not unexpected and do not eliminate the possibility of a mechanistic link between thyroid effects and neurodevelopmental or cognitive effects; however, the data do not support a clear indication that thyroid effects are a mechanism by which fluoride causes these effects in humans.

Figure 7. Number of Low Risk-of-bias Studies that Evaluated Thyroid Hormones in Children and Adults by Endpoint and Direction of Effect*



Endpoint	Direction of Effect ↑	Direction of Effect NS	Grand Total
serum T3	1	3	4
serum T4		4	4
serum TSH	5	2	7
self-reported thyroid condition		1	1
thyroid disease		1	1
hypothyroidism prevalence	1		1

*Interactive figure and additional study details in Tableau® (https://public.tableau.com/profile/ntp.visuals#!/vizhome/Fluoride_EpiThyroid_UPDATE/Figures6and7). This figure displays study counts for low risk-of-bias studies in both children and adults, as these counts are most relevant to the summary of fluoride-related mechanistic effects in low risk-of-bias studies. Counts for high risk-of bias studies and studies by age (i.e., children, adults, or children/adults combined) can also be accessed in the interactive figure in Tableau®. Study counts are tabulated by significance (unless if study footnotes in Tableau indicate that statistical significance was not tested)—statistically significant increase (↑), statistically significant decrease (↓), or not significant (NS). For example, the "↑" column displays numbers of unique studies with significantly increased results.

*Interactive figure and additional study details in Tableau® (https://public.tableau.com/profile/ntp.visuals#!/vizhome/Fluoride_EpiThyroid_UPDATE/Figures6and7). This figure displays study counts for high risk-of-bias studies in children, as these counts are most relevant to the summary of fluoride-related effects on thyroid hormones in high risk-of-bias studies. Counts for low risk-of bias studies, studies in adults, or all studies combined, can also be accessed in the interactive figure in Tableau®. Study counts are tabulated by significance (unless if study footnotes in Tableau indicate that statistical significance was not tested)—statistically significant increase (↑), statistically significant decrease (↓), or not significant (NS). For example, the "↑" column displays numbers of unique studies with significantly increased results.

In addition to evaluating thyroid hormone levels, a few high risk-of-bias studies evaluated other mechanistic data associated with fluoride exposure; however, the data are insufficient to identify a clear mechanism by which fluoride might cause neurodevelopmental or cognitive effects in humans. Serum epinephrine and norepinephrine were significantly increased in a fluoride-endemic region (not reported whether subjects were children or adults) compared to a non-endemic region (Chinoy and Narayana 1992). Serum adrenaline and noradrenaline were significantly increased in adults in a fluoride-endemic

area (fluoride in the drinking water ranged from 1.0–6.53 ppm) compared to a control area (fluoride in the drinking water ranged from 0.56–0.72 ppm) (Michael *et al.* 1996). Serum AChE was significantly reduced in children from a high fluoride region compared to a lower fluoride region (Singh *et al.* 2013). Serum serotonin was significantly increased in children from Turkey who were drinking water containing 2.5 mg/L of fluoride compared to children drinking bottled water or water containing <0.5 mg/L of fluoride (Lu *et al.* 2019). Aborted fetuses from high fluoride areas in China were found to have histological changes in the brain and significant changes in neurotransmitter levels compared to a control area (Du *et al.* 1992 [translated in Du *et al.* 2008], Yu *et al.* 1996 [translated in Yu *et al.* 2008]).

There are also two more recent low risk-of-bias studies that evaluated polymorphisms in dopamine-related genes; however, a determination on mechanism cannot be made at this time due to the limited number of studies. For children (10–12 years old) with a Val158Met polymorphism in the *COMT* gene (i.e., catechol-O-methyltransferase), which results in slower degradation and greater availability of dopamine within the brain, a stronger association between increasing urinary fluoride levels and decreasing IQ was reported (Zhang *et al.* 2015b). For children (7–12 years old) with a dopamine receptor-2 (DRD2) Taq 1A polymorphism (which is involved in reduced D2 receptor density and availability) and the TT (variant) genotype, a significant inverse relationship between log urine fluoride and IQ was observed; however, this significant relationship was not observed in children with the CC (wild-type) or CT (hybrid) genotypes (Cui *et al.* 2018).

Animal Learning and Memory Data

The NTP provided a review of the experimental animal evidence in the earlier draft monographs (NTP 2020) and agrees with the NASEM review committee comments (NASEM 2020, 2021)(placeholder to cite NTP 2021 Response to NASEM comments) that the experimental animal database is of poor quality, with many studies suffering from major reporting deficiencies. The NTP acknowledges that further efforts to disentangle the potential for motor activity deficits to influence tests of learning and memory in the fluoride literature are warranted. Overall, these general issues and deficiencies with the experimental animal database led to NTP's conclusion that the animal studies are currently *inadequate* to inform the question of an association between fluoride exposures and neurodevelopmental and cognitive effects in humans. Therefore, this systematic review does not include an experimental animal section.

Mechanistic Data in Animals

There are a wide variety of studies in animals that evaluate mechanistic effects potentially related to neurological changes following oral fluoride exposure (see **Appendix 5**); however, the mechanisms underlying fluoride-associated cognitive neurodevelopmental effects are not well characterized and review of the data did not identify a mode of action for fluoride effects on IQ in children. Categories of mechanistic endpoints with the largest amount of available data include changes in biochemical components of the brain or neurons, neurotransmitters, oxidative stress, histopathology, and thyroid function. Limiting the data to studies with at least one exposure at or below 20 ppm fluoride drinking water equivalents (gavage and dietary exposures were back calculated into equivalent drinking water concentrations for comparison) still provided a sufficient number of studies for evaluation of these mechanistic endpoints. This evaluation is provided in **Appendix 5**. Neurotransmitter and biochemical changes in the brain and neurons were considered to be the mechanistic areas with the greatest potential to demonstrate effects of fluoride on the brain of animals in the lower dose range and provide evidence of changes in the brain that may relate to lower IQ in children (see **Appendix 5**). Histological data can be useful in determining whether effects are occurring in the brain at lower fluoride concentrations; however, author descriptions of these effects may be limited thereby making it difficult

to directly link histological changes in the brain to learning and memory effects. Oxidative stress is considered a general mechanistic endpoint that cannot be specifically linked to neurodevelopmental or cognitive effects in humans; however, like histopathology, it may help in identifying changes in the brain occurring at lower concentrations of fluoride. Although any effects in the brain or neurological tissue at lower concentrations of fluoride may support reduced IQ in humans, it may be difficult to distinguish the potential effects of fluoride on learning and memory functions from other neurological or general health outcomes.

In Vitro Data on Neurodevelopmental or Cognitive Effects

Although in vitro data were collected as part of the systematic review process, NTP determined that the information on neurological effects obtained from these studies is too general, and results cannot necessarily be attributed to effects on learning and memory or other cognitive functions at this time. The in vitro data may help support specific mechanisms identified from in vivo mechanistic data; however, as described above, no specific mechanism has been determined for fluoride effects on learning and memory or other neurodevelopmental or cognitive outcomes.

DISCUSSION

This systematic review evaluated the available animal and human literature concerning the association between fluoride exposure and cognitive neurodevelopment. The available data on potential mechanisms to evaluate biological plausibility were also assessed. This review addresses whether exposure to fluoride could present a potential hazard (i.e., has the potential to cause harm at any exposure level). Benefits of fluoride with respect to oral health are not addressed in this review.

This review extended the NTP's previous evaluation of the experimental animal data (NTP 2016). Although the animal data provide some evidence of effects of fluoride on neurodevelopment, they give little insight into the question of whether fluoride influences IQ. This is due to the deficiencies identified in the animal body of evidence. Mechanistic studies in humans provide some evidence of adverse neurological effects of fluoride. However, these studies were too heterogenous and limited in number to make any determination on biological plausibility.

The literature on adults is also limited; therefore, it was determined that there is low confidence in the body of evidence from studies that evaluate fluoride exposure and adult cognition. Compared to the literature in adults, there is a much more extensive literature in children.

The literature in children was separated into studies assessing IQ and studies assessing other cognitive neurodevelopmental outcomes. There is low confidence in the body of evidence from studies that evaluate fluoride exposure and other cognitive neurodevelopmental outcomes in children. Altogether, the results from eight of nine high quality studies (three prospective cohort and five cross-sectional studies from seven different study populations) provide some evidence that fluoride is associated with other cognitive neurodevelopmental outcomes in children. The data also suggest that neurodevelopmental effects occur in very young children. However, the number of studies is limited and there is too much heterogeneity in the outcomes measured and methods used to directly compare studies of any one outcome. Additional studies on outcomes such as attention deficit hyperactivity disorder (ADHD) and other attention-related disorders, where there is some evidence of an effect of fluoride exposure, would be necessary to critically assess the data.

Most of the epidemiological studies (n = 66) assessed the association between fluoride exposure and IQ in children. Although all studies, both high and low quality, were considered, this evaluation focuses on the high quality, low risk-of-bias studies in children for two reasons. First, there are fewer limitations and greater confidence in the results of the high quality studies. Second, there is a relatively large number of high quality studies (n = 19), such that the body of evidence from these studies could be used to evaluate confidence in the association between fluoride exposure and changes in children's IQ.

This review finds, with moderate confidence, that fluoride exposure is consistently associated with lower IQ in children. The inverse association between fluoride exposure and children's IQ was consistent across different study populations, study locations, study quality/risk of bias determinations, study designs, exposure measures, and types of exposure data (group-level and individual-level). There were 19 low risk-of-bias studies that were conducted in 15 study populations, across 5 countries, and evaluating more than 7,000 children. Of these 19 studies, 18 reported that higher fluoride exposure is associated with lower IQ. These include 3 prospective cohort studies and 15 cross-sectional studies (12 of which indicated that exposure likely preceded the outcome). Forty-one of 47 low quality studies in children also found evidence of an inverse relationship between fluoride exposure and IQ.

Many studies in this assessment relied on drinking water fluoride levels (both group-level measures and individual-level measures), rather than measures of total fluoride exposures, to establish exposed versus "unexposed" or reference groups. Although fluoride in water is a major source of exposure [comprising 40 to 70% of total exposure (US EPA 2010)], other sources provide variable amounts that depend on personal preferences and habits. The use of dental products containing fluoride and consuming foods and beverages prepared with fluoridated water can also result in measurable exposures (US EPA 2010). Green *et al.* (2019) suggested that significant exposures occur from black tea consumption. Thus, drinking water fluoride levels may, but usually do not, reflect total fluoride exposures. This could be a potential limitation in studies that rely on water fluoride data to assess fluoride exposure (in particular, earlier studies). However, because water is only part of a person's total exposure to fluoride, this limitation would likely result in an underestimate of exposure to fluoride. Also, this limitation is less of a concern in areas where fluoride in the drinking water is high because drinking water likely contributes a large proportion of the total fluoride intake in those areas as compared to areas where fluoride in the drinking water is lower.

This review found that the quality of exposure assessment has improved over the years. More recent studies by Valdez Jimenez *et al.* (2017), Bashash *et al.* (2017), and Green *et al.* (2019) used individual measures of urinary fluoride, either maternal urine collected prenatally or children's urine, which confirmed the inverse association between total fluoride exposure and children's IQ and other cognitive neurodevelopmental effects. Studies using different types of exposure measures reported similar findings of an association, which strengthens confidence in earlier studies that reported IQ deficits with increasing group-level fluoride exposures. However, there is less certainty in the quantitative estimates of the magnitude of IQ deficits from earlier studies that used group-level exposure measures than the estimates from more recent studies that used individual-level exposure measures.

It is worth noting that there are circumstances where typical children's water consumption considered with water fluoride levels may substantially underestimate total fluoride exposures. One example is bottle fed infants where nutrition is provided by powdered formula that is rehydrated with fluoridated water (Till *et al.* 2020). To decrease an exclusively formula fed infant's exposure to fluoride, for the purpose of reducing risk of dental fluorosis, the Centers for Disease Control and Prevention (CDC) recommends using low fluoride bottled water to mix with infant formula (CDC 2015). A few studies also support the possibility of heightened sensitivities to the detrimental cognitive effects of fluoride exposures in individuals with certain genetic polymorphisms in dopamine receptor D2, or catechol-O-methyltransferase (Cui *et al.* 2018, Zhang *et al.* 2015b), potentially impacting dopamine catabolism and receptor sensitivity. Differential exposures to fluoride and genetic susceptibilities of children to fluoride may represent special situations that would appear to warrant further research.

The following section briefly recaps the strength of the epidemiological evidence for an inverse association between fluoride exposures and cognitive neurodevelopmental deficits. This is followed by a more detailed listing of limitations of the evidence base and limitations of the systematic review, with some suggestions of areas where further research may be most beneficial.

Strengths of the Evidence Base

Strengths in the epidemiological evidence base include:

- Sixty-six studies directly addressing the relationship between high fluoride exposure and deficits in children's IQ or other measures of neurological function.

- Twelve high quality cross-sectional studies with low risk of bias providing evidence that exposure occurred prior to outcome assessment.
- Studies from diverse geographic locations that included data for more than 7,000 children.
- Nineteen high quality studies evaluating the same outcome (i.e., IQ) and nine evaluating other neurodevelopmental outcomes.
- Consistency in the reported responses to fluoride exposure in studies of both low and high quality.
- Consistency in the reported responses to fluoride exposure across different study populations, study designs, and exposure measures.
- Similar findings of studies with group- and individual-level information on exposure and outcomes.
- Wide variety of confounders either addressed by study design or captured across the evidence base, with no consistent patterns that would suggest an alternative explanation.

Limitations of the Evidence Base

Limitations in the epidemiological studies with low risk of bias include:

- Few studies available that assessed the association between fluoride exposure and cognitive function (particularly IQ) in adults and attention-related disorders including ADHD in children and adults.
- Heterogeneity in outcomes assessed for other neurobehavioral outcomes, limiting the assessment of other possible effects in children.
- Studies rarely separated the results by gender or provided information to indicate that gender was not a modifying factor.
- Effects of lower total fluoride exposures on children's IQ remain unclear. More studies at lower exposure levels are needed to fully understand potential effects in ranges typically found in the United States (i.e., <1.5 mg/L in water).
- No studies investigating the association between fluoride exposure and neurodevelopmental or cognitive effects in adults or children have been conducted in the United States.

Limitations in the epidemiological studies with high risk of bias include:

- Many of the original publications were in a non-English language and provided limited details on methodology.
- Studies lacked information regarding exposure and/or had serious limitations in the exposure assessment. Exposure assessment concerns include limited individual exposure information, a lack of information on fluoride sampling methods and timing of the exposure measurements, a lack of quantitation of levels of fluoride in drinking water in a few studies, and a lack of individual-level information on fluorosis in areas reported to be endemic for fluorosis.
- The comparison groups in studies conducted in areas endemic for fluorosis still may have been exposed to high levels of fluoride or levels similar to those used in water fluoridation in the United States. This factor may have limited the ability to detect true effects.

- Studies did not provide sufficient direct information (e.g., participation rates or methods for selection) to evaluate selection bias.
- Failure to address potential confounders was an issue for many studies. Some studies conducted simple statistical analyses without accounting for any potential confounders in the analysis, although many noted similarities between the study populations. In cases where adjustments in analyses were made, often these studies did not account for potential confounders considered critical for that study population and outcome.
- Studies conducted in areas with high, naturally-occurring fluoride levels in drinking water often did not account for potential exposures to arsenic or iodine deficiencies in study subjects in areas where these were likely to occur.
- Studies lacked information on whether the outcome assessors were blind to the exposure group, including studies that examined children in their schools and subjects from high-fluoride communities.

Limitations in the animal and mechanistic evidence base include:

- The overall poor quality of experimental animal studies and the relatively few well-designed and well-performed studies at lower exposure levels (i.e., <20 ppm, which is roughly equivalent to human exposure of <4 ppm).
- Poor understanding of the specific molecular events responsible for fluoride's adverse effects on neurological function.

A key data gap in the human and animal bodies of evidence includes the need for mechanistic insight into fluoride-related neurodevelopmental or cognitive changes.

Limitations of the Systematic Review

There are few limitations of this systematic review. The human body of evidence included a large database of observational studies. Most of the observational studies were cross-sectional; however, 12 of these were considered to provide sufficient evidence that exposure occurred prior to the outcome. In addition, the systematic review covered a wide range of study designs, populations, and measures of fluoride exposure. The systematic review was designed to cover reports on all potential mechanistic data including effects on the thyroid. After review of the studies evaluating thyroid effects, studies that only evaluated goiters and other effects on thyroid size were not considered in this review. This is not considered a limitation because changes in thyroid size are not functional changes to the thyroid that could specifically indicate a mechanism for thyroid involvement in neurodevelopment. In addition, review of the mechanistic data was limited to in vivo studies with at least one concentration below 20 ppm. This is not considered a limitation for the systematic review because the mechanistic body of evidence was used to evaluate biological plausibility for the effects observed in humans; therefore, data were limited to concentrations that would be more reflective of human exposures. The decision to not more closely evaluate the in vitro data is not considered a limitation because there were sufficient in vivo data, and no key events were identified where in vitro data would provide additional insight.

Following the recommendation of the NASEM committee in its review of the September 16, 2020, draft monograph, the experimental animal section has been removed and is not included in this monograph. Although the deficiencies identified in the animal body of evidence support this removal (see **Animal Learning and Memory Data** for further explanation), the NTP acknowledges that the absence of the

experimental animal data is a limitation of this systematic review. For the purpose of this review, the NTP considers the experimental animal data to be *inadequate* to inform whether fluoride exposure is associated with cognitive effects (including cognitive neurodevelopmental effects) in humans.

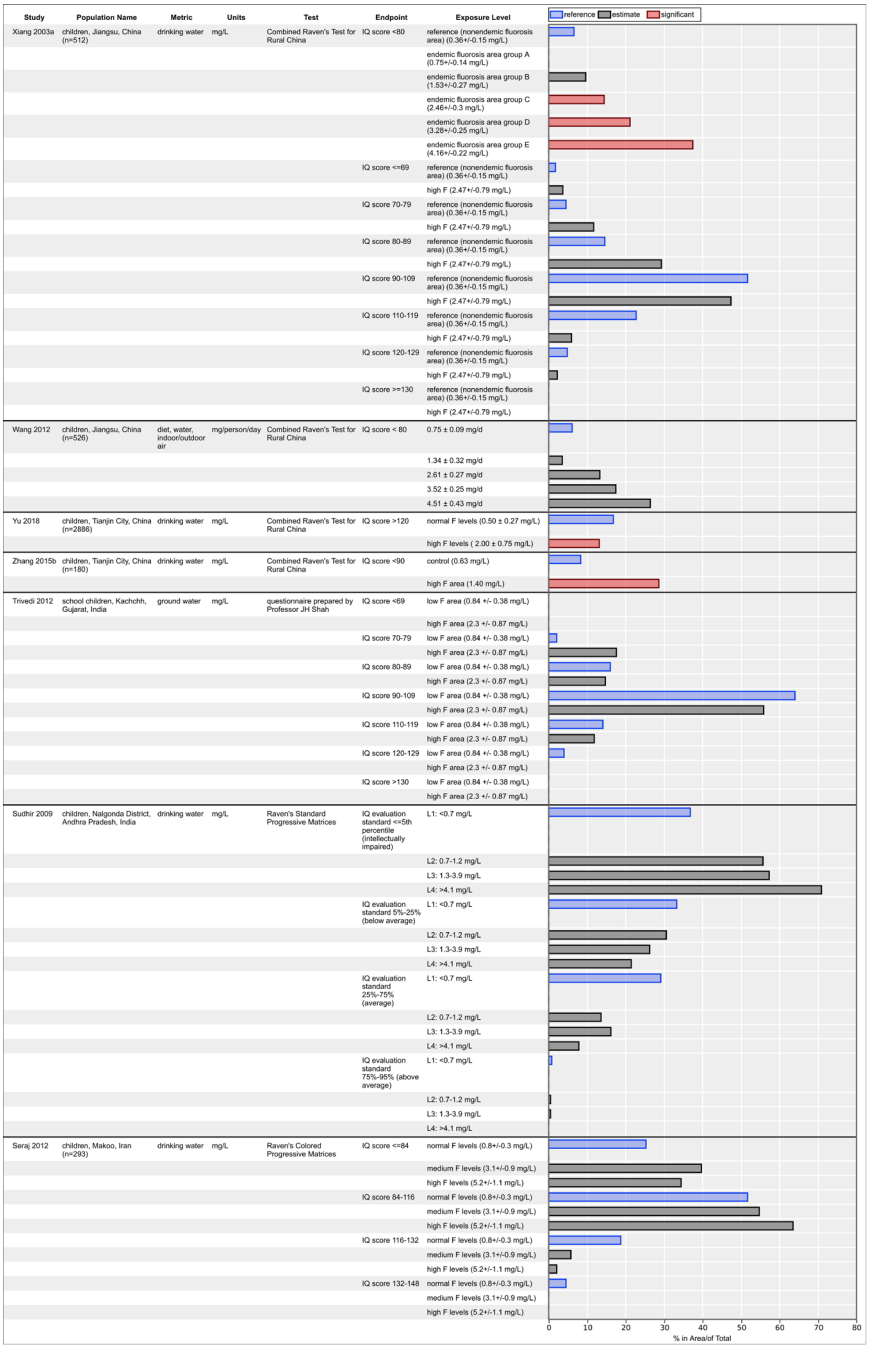
DATA FIGURES

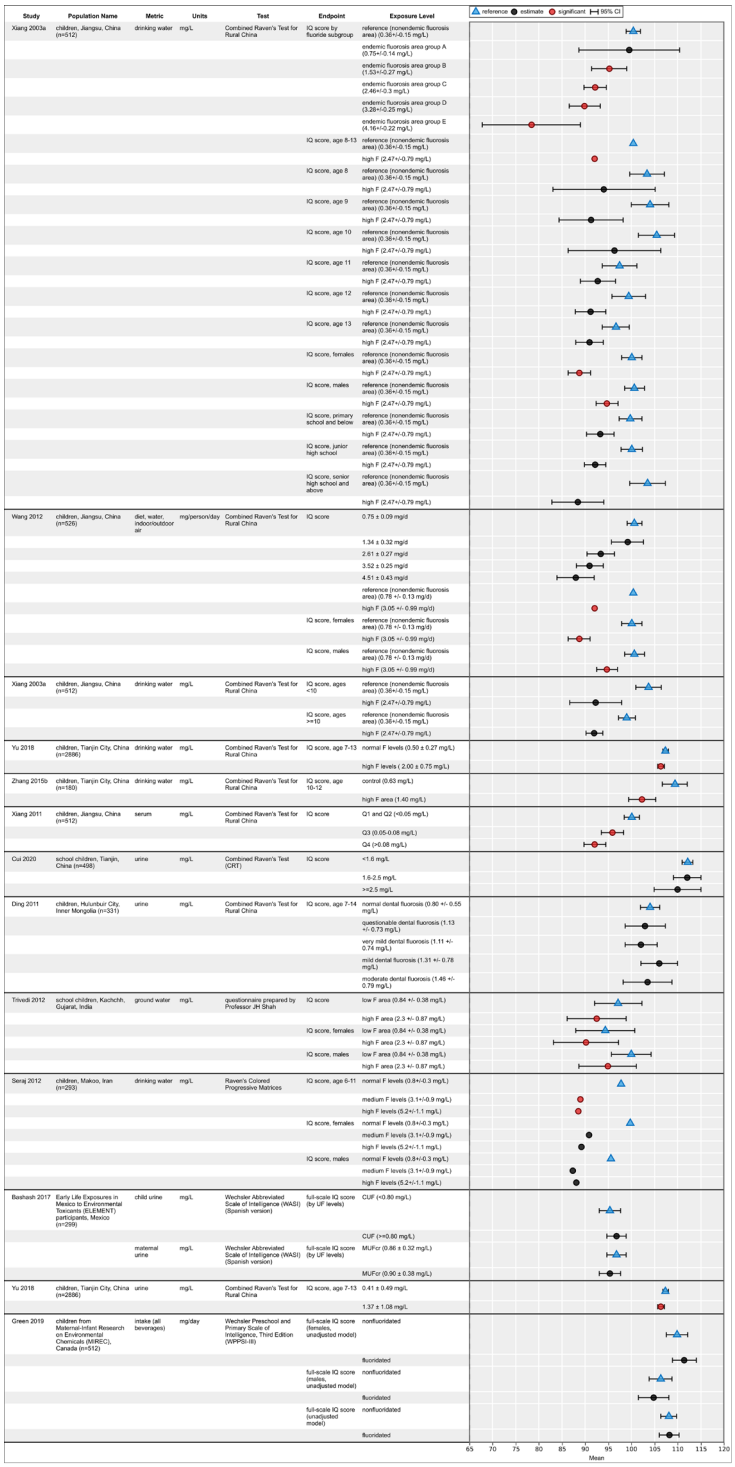
Neurodevelopmental or Cognitive Effects and Outcomes

Figure D1. IQ Distribution in Children by Fluoride Exposure (low risk-of-bias studies; presented as % in area or % of total group)



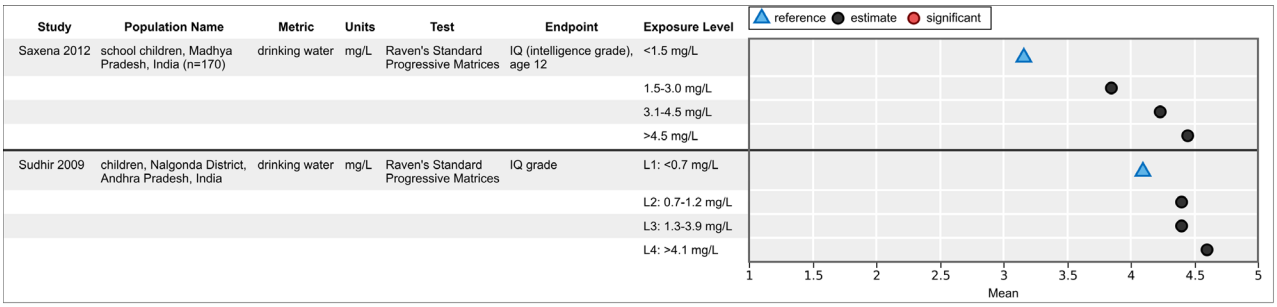
Interactive figure and additional study details in HAWC here. "F" represents fluoride. Differences in intelligence between the reference group and treatment groups were statistically significant although significance was not reported separately for each score level.

Figure D2. Mean IQ in Children by Fluoride Exposure (low risk-of-bias studies)



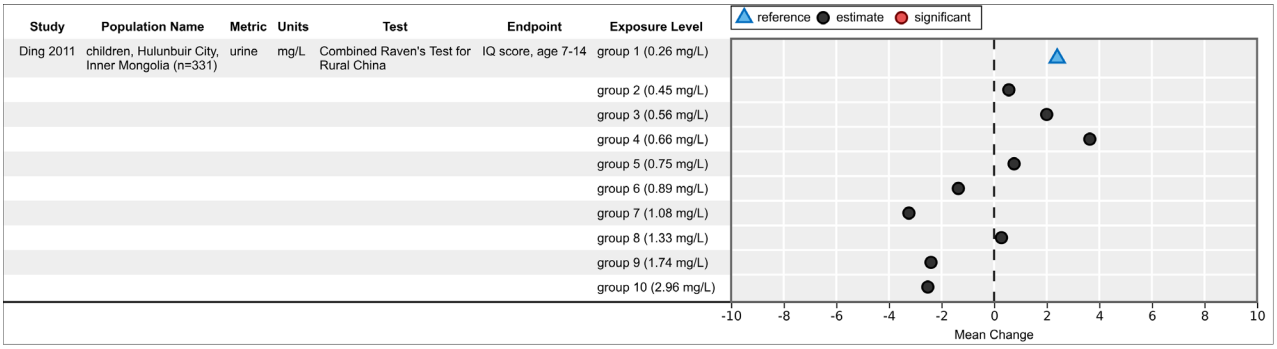
Interactive figure and additional study details in HAWC here. "F" represents fluoride. Three additional publications based on subsample of the larger Yu *et al.* (2018) cohort were identified (Zhao *et al.* 2019, Zhou *et al.* 2019, Zhao *et al.* 2020); however, results from these studies are not presented here. The main study by Yu *et al.* (2018) is considered a better representation of the IQ results. For all studies, SDs are available and can be viewed in HAWC by clicking the data points within the plot area; however, 95% CIs could not be calculated for Seraj *et al.* (2012) because Ns are not available for exposure groups.

Figure D3. Intelligence Grade in Children by Fluoride Exposure (low risk-of-bias studies; presented as mean)



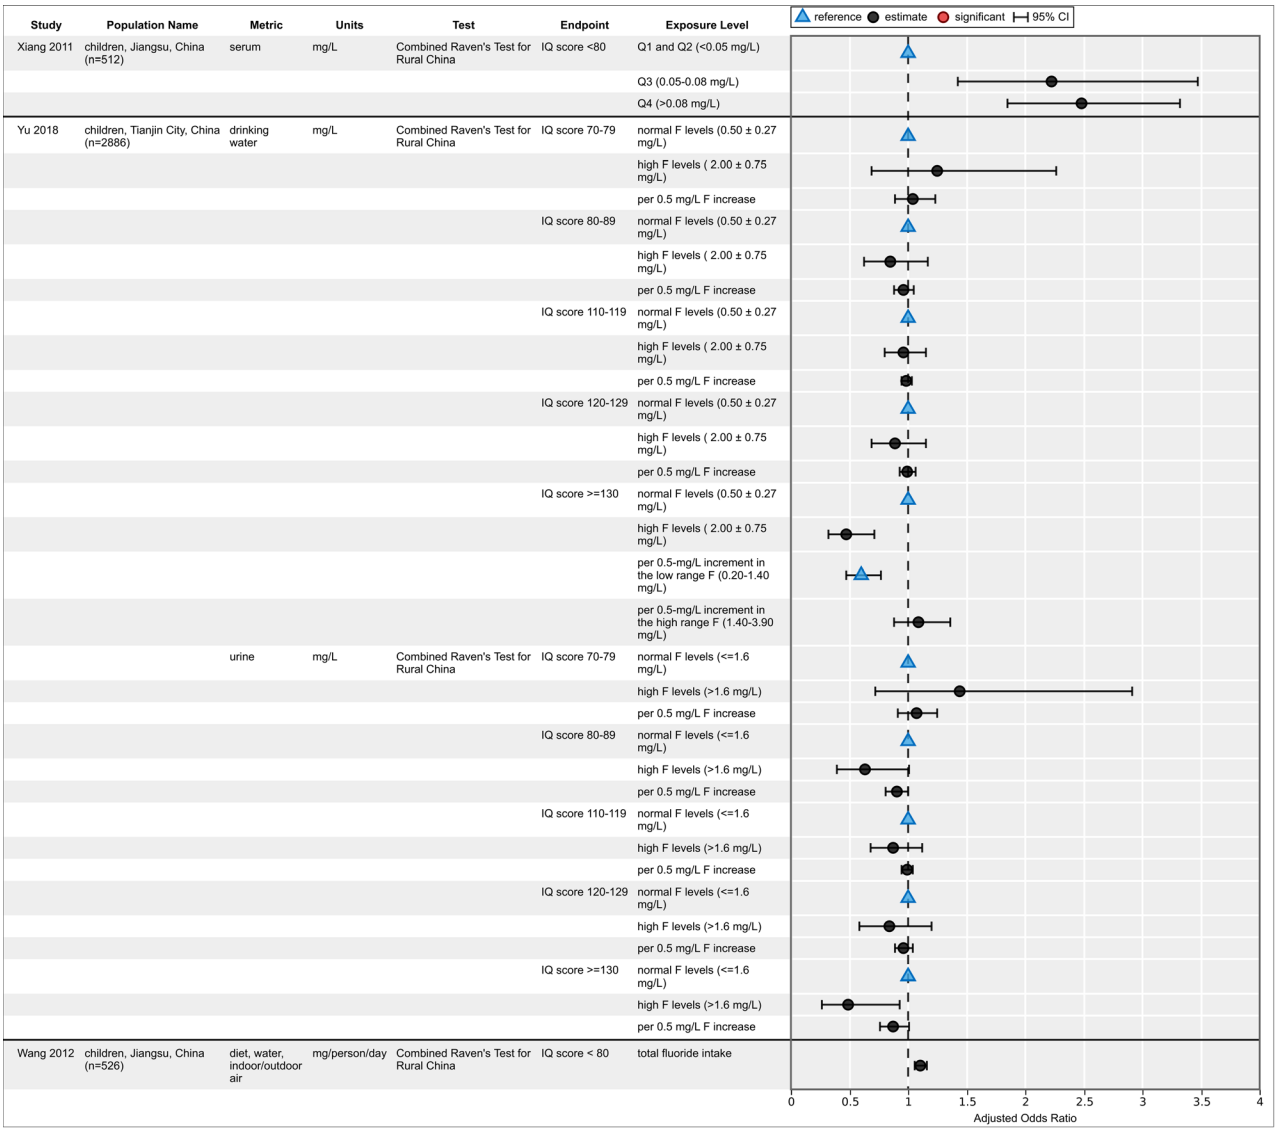
Interactive figure and additional study details in HAWC here. For Saxena *et al.* (2012), children's intelligence was measured using the Raven's Standard Progressive Matrices. Children's scores were converted to percentile and specific grades were allotted based on the percentiles. Grades ranged from intellectually superior (Grade I) to intellectually impaired (Grade V). Results for Soto-Barreras *et al.* (2019) are not presented here. Outcomes in the study were presented as levels of fluoride exposure associated with each intelligence grade. Results reported were not significant.

Figure D4. Mean Change in IQ in Children by Fluoride Exposure (low risk-of-bias studies)



Interactive figure and additional study details in HAWC here. For Ding *et al.* (2011), SDs are available and can be viewed in HAWC by clicking the data points within the plot area; however, 95% CIs could not be calculated because Ns for each exposure group are not available.

Figure D5. IQ Score in Children by Fluoride Exposure (low risk-of-bias studies; presented as adjusted OR)

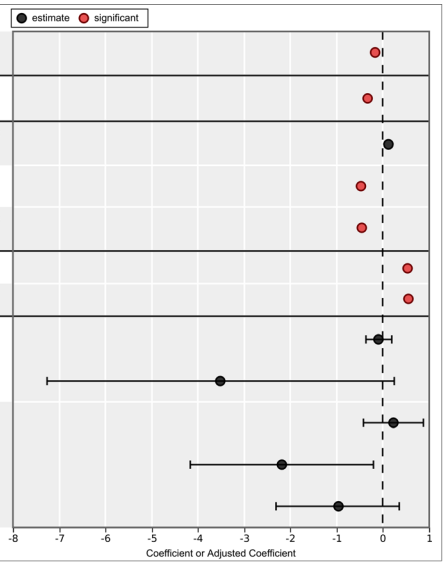


Study	Population Name	Metric	Units	Test	Endpoint	Exposure Level
Xiang 2011	children, Jiangsu, China (n=512)	serum	mg/L	Combined Raven's Test for Rural China	IQ score <80	Q1 and Q2 (<0.05 mg/L)
						Q3 (0.05-0.08 mg/L)
						Q4 (>0.08 mg/L)
Yu 2018	children, Tianjin City, China (n=2886)	drinking water	mg/L	Combined Raven's Test for Rural China	IQ score 70-79	normal F levels (0.50 ± 0.27 mg/L)
						high F levels (2.00 ± 0.75 mg/L)
						per 0.5 mg/L F increase
					IQ score 80-89	normal F levels (0.50 ± 0.27 mg/L)
						high F levels (2.00 ± 0.75 mg/L)
						per 0.5 mg/L F increase
					IQ score 110-119	normal F levels (0.50 ± 0.27 mg/L)
						high F levels (2.00 ± 0.75 mg/L)
						per 0.5 mg/L F increase
					IQ score 120-129	normal F levels (0.50 ± 0.27 mg/L)
						high F levels (2.00 ± 0.75 mg/L)
						per 0.5 mg/L F increase
					IQ score >=130	normal F levels (0.50 ± 0.27 mg/L)
						high F levels (2.00 ± 0.75 mg/L)
						per 0.5-mg/L increment in the low range F (0.20-1.40 mg/L)
						per 0.5-mg/L increment in the high range F (1.40-3.90 mg/L)
		urine	mg/L	Combined Raven's Test for Rural China	IQ score 70-79	normal F levels (<=1.6 mg/L)
						high F levels (>1.6 mg/L)
						per 0.5 mg/L F increase
					IQ score 80-89	normal F levels (<=1.6 mg/L)
						high F levels (>1.6 mg/L)
						per 0.5 mg/L F increase
					IQ score 110-119	normal F levels (<=1.6 mg/L)
						high F levels (>1.6 mg/L)
						per 0.5 mg/L F increase
					IQ score 120-129	normal F levels (<=1.6 mg/L)
						high F levels (>1.6 mg/L)
						per 0.5 mg/L F increase
					IQ score >=130	normal F levels (<=1.6 mg/L)
						high F levels (>1.6 mg/L)
						per 0.5 mg/L F increase
Wang 2012	children, Jiangsu, China (n=526)	diet, water, indoor/outdoor air	mg/person/day	Combined Raven's Test for Rural China	IQ score < 80	total fluoride intake

Interactive figure and additional study details in HAWC here. For Xiang *et al.* (2011), there was a significant linear trend across different levels of serum fluoride for IQ score < 80 ($p < 0.001$). For Yu *et al.* (2018), significance levels by IQ score were not reported.

Figure D6. Correlations between IQ Score and Fluoride Exposure in Children (low risk-of-bias studies; presented as coefficient)

Study	Population Name	Metric	Units	Test	Endpoint	Exposure Level	Stat Description
Xiang 2003a	children, Jiangsu, China (n=512)	urine	mg/L	Combined Raven's Test for Rural China	IQ score	continuous F measure	Pearson's correlation coefficient adjusted for creatinine
Wang 2012	children, Jiangsu, China (n=526)	diet, water, indoor/outdoor air	mg/person/day	Combined Raven's Test for Rural China	IQ score	total fluoride intake	correlation coefficient
Zhang 2015b	children, Tianjin City, China (n=180)	drinking water	mg/L	Combined Raven's Test for Rural China	IQ score, age 10-12	continuous F measure	partial correlation coefficient adjusted for age and gender
		serum	mg/L	Combined Raven's Test for Rural China	IQ score, age 10-12	continuous F measure	partial correlation coefficient adjusted for age and gender
		urine	mg/L	Combined Raven's Test for Rural China	IQ score, age 10-12	continuous F measure	partial correlation coefficient adjusted for age and gender
Saxena 2012	school children, Madhya Pradesh, India (n=170)	drinking water	mg/L	Raven's Standard Progressive Matrices	IQ (intelligence grade), age 12	continuous F measure	regression coefficient (R)
		urine	ppm	Raven's Standard Progressive Matrices	IQ (intelligence grade), age 12	continuous F measure	regression coefficient (R)
Yu 2018	children, Tianjin City, China (n=2886)	drinking water	mg/L	Combined Raven's Test for Rural China	change in IQ score (unadjusted model)	per 0.5-mg/L increment in the low range F (0.20-3.40 mg/L)	unadjusted beta
						per 0.5-mg/L increment in the high range F (3.40–3.90 mg/L)	unadjusted beta
		urine	mg/L	Combined Raven's Test for Rural China	change in IQ score (unadjusted model)	per 0.5-mg/L increment in the low range F (0.01-1.60 mg/L)	unadjusted beta
						per 0.5-mg/L increment in the medium range F (1.60-2.50 mg/L)	unadjusted beta
						per 0.5-mg/L increment in the high range F (2.50-5.54 mg/L)	unadjusted beta



Interactive figure and additional study details in HAWC here. "F" represents fluoride. For Saxena *et al.* (2012), a significant relationship between water fluoride level and intelligence grade was observed. Increasing intelligence grades reflected increasing levels of impairment (reduced intelligence) in children. Zhao *et al.* (2020) and Zhou *et al.* (2019) also had correlations, but these were based on a subsample of the Yu *et al.* (2018) study (which presented betas and provided a better representation of the IQ data).

Figure D7. Correlations between IQ Score and Fluoride Exposure in Children (low risk-of-bias studies; presented as adjusted beta)—(a) China; (b) all other areas

(a)

Study	Population Name	Metric	Units	Test	Endpoint	Comparison Set	Exposure Level
Choi 2015	first-grade children, China (n=51)	drinking water	mg/L	Wechsler Intelligence Scale for Children-IV	digit span backward test score	continuous exposure_water	log10 F

							continuous formula intake-adjusted MUF

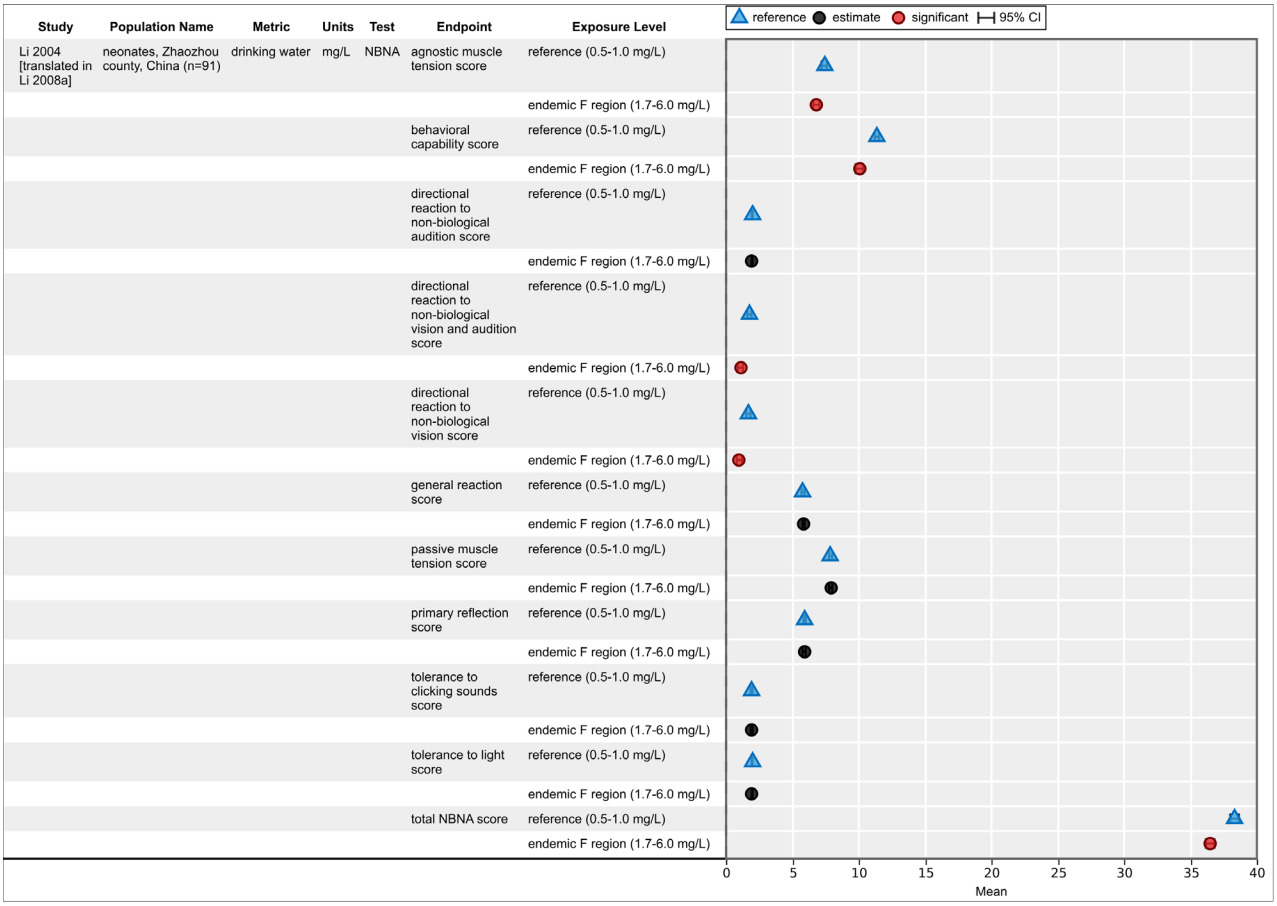
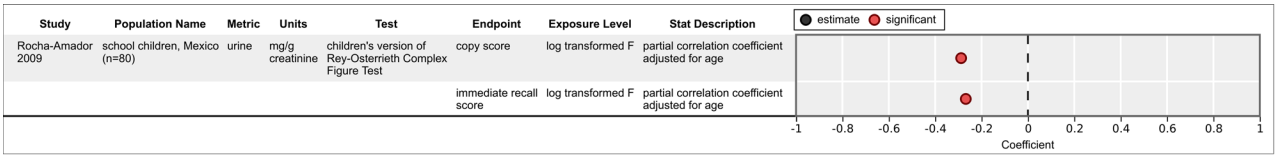
Interactive figure and additional study details in HAWC here for part (a) and here for part (b). "F" represents fluoride. For Yu *et al.* (2018), authors note an obvious decrease in the IQ score at water fluoride exposure levels between 3.40 mg/L and 3.90 mg/L and a similar adverse effect on IQ scores at urinary fluoride exposure levels from 1.60 mg/L to 2.50 mg/L, and so the changes in IQ score are indicated as significant; however, significance levels by change in IQ score were not reported.

Figure D8. Mean Motor/Sensory Scores in Children by Fluoride Exposure (low risk-of-bias studies)



Interactive figure and additional study details in HAWC here. "F" represents fluoride. 95% CIs are small and are within figure symbols and may be difficult to see. Values for SDs and 95% CIs can be viewed in HAWC by clicking the data points within the plot area.

Figure D9. Correlations between Other Neurological Effects and Fluoride Exposure in Children (low risk-of-bias studies; presented as coefficient)



Interactive figure and additional study details in HAWC here. "F" represents fluoride.

Figure D10. Correlations between Other Neurological Effects and Fluoride Exposure in Children (low risk-of-bias studies; presented as adjusted beta)

							moderate/severe fluorosis (2.66 mg/L)
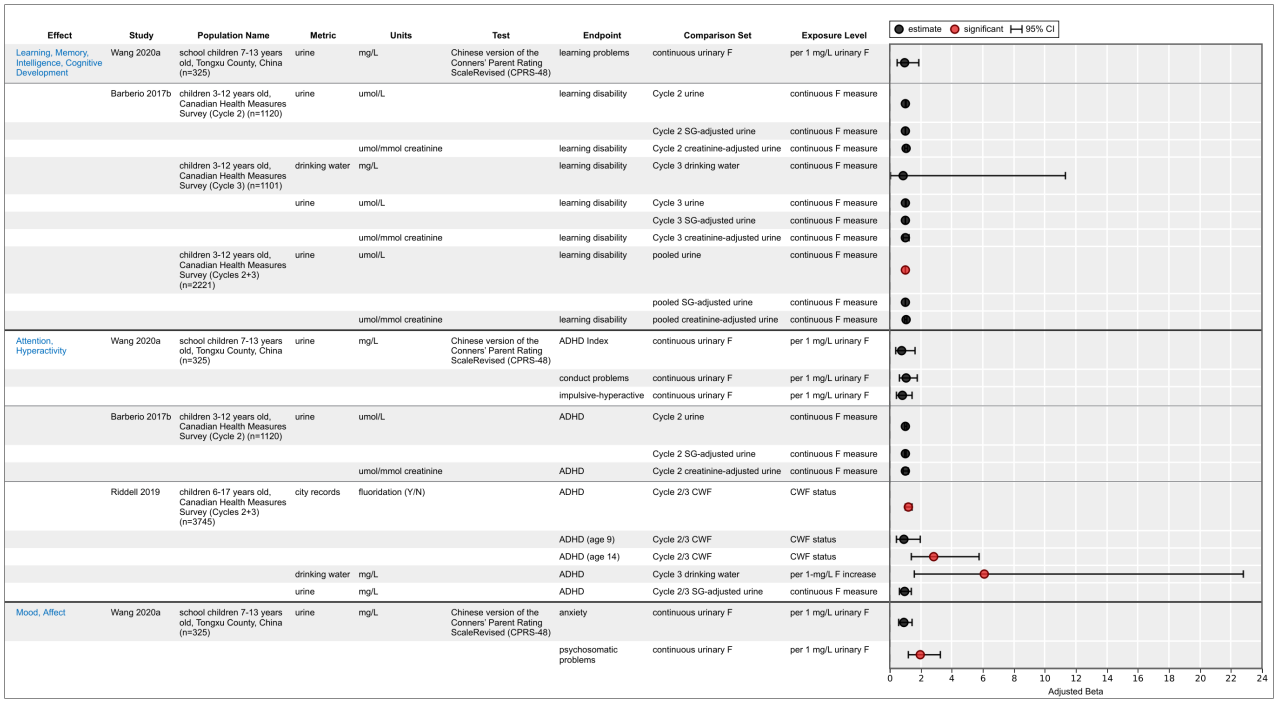
			urine	mg/L	WRAVMA	drawing test score	log10 F

Interactive figure and additional study details in HAWC here. "F" represents fluoride. Bashash *et al.* (2018) observed significant associations between maternal urinary fluoride and ADHD-like symptoms related to inattention (an increase in 0.5 mg/L of maternal urinary fluoride was associated with a 2.84-point increase in the DSM-IV Inattention Index and a 2.54-point increase in Cognitive Problems and Inattention Index). These two scales contributed to the global ADHD Index and the DSM-IV ADHD Total Index shown here.

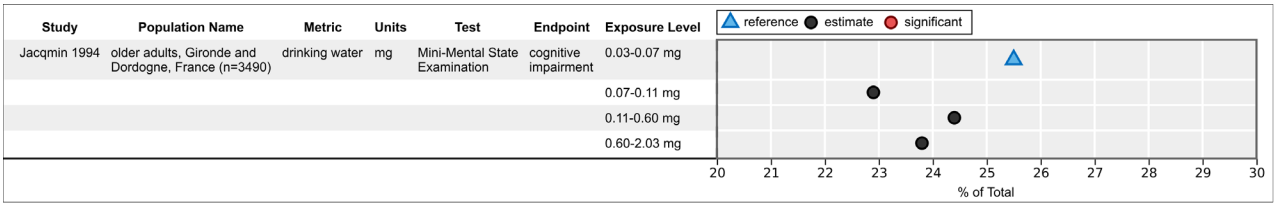
Figure D11. Correlations between Other Neurological Effects and Fluoride Exposure in Children (low risk-of-bias studies; presented as adjusted OR)



Effect	Study	Population Name	Metric	Units	Test	Endpoint	Comparison Set	Exposure Level
Learning, Memory, Intelligence, Cognitive Development	Wang 2020a	school children 7-13 years old, Tongxu County, China (n=325)	urine	mg/L	Chinese version of the Conners' Parent Rating ScaleRevised (CPRS-48)	learning problems	continuous urinary F	per 1 mg/L urinary F
	Barberio 2017b	children 3-12 years old, Canadian Health Measures Survey (Cycle 2) (n=1120)	urine	umol/L		learning disability	Cycle 2 urine	continuous F measure
							Cycle 2 SG-adjusted urine	continuous F measure
				umol/mmol creatinine		learning disability	Cycle 2 creatinine-adjusted urine	continuous F measure
		children 3-12 years old, Canadian Health Measures Survey (Cycle 3) (n=1101)	drinking water	mg/L		learning disability	Cycle 3 drinking water	continuous F measure
			urine	umol/L		learning disability	Cycle 3 urine	continuous F measure
							Cycle 3 SG-adjusted urine	continuous F measure
				umol/mmol creatinine		learning disability	Cycle 3 creatinine-adjusted urine	continuous F measure
		children 3-12 years old, Canadian Health Measures Survey (Cycles 2+3) (n=2221)	urine	umol/L		learning disability	pooled urine	continuous F measure
							pooled SG-adjusted urine	continuous F measure
				umol/mmol creatinine		learning disability	pooled creatinine-adjusted urine	continuous F measure
Attention, Hyperactivity	Wang 2020a	school children 7-13 years old, Tongxu County, China (n=325)	urine	mg/L	Chinese version of the Conners' Parent Rating ScaleRevised (CPRS-48)	ADHD Index	continuous urinary F	per 1 mg/L urinary F
						conduct problems	continuous urinary F	per 1 mg/L urinary F
						impulsive-hyperactive	continuous urinary F	per 1 mg/L urinary F
	Barberio 2017b	children 3-12 years old, Canadian Health Measures Survey (Cycle 2) (n=1120)	urine	umol/L		ADHD	Cycle 2 urine	continuous F measure
							Cycle 2 SG-adjusted urine	continuous F measure
				umol/mmol creatinine		ADHD	Cycle 2 creatinine-adjusted urine	continuous F measure
	Riddell 2019	children 6-17 years old, Canadian Health Measures Survey (Cycles 2+3) (n=3745)	city records	fluoridation (Y/N)		ADHD	Cycle 2/3 CWF	CWF status
						ADHD (age 9)	Cycle 2/3 CWF	CWF status
						ADHD (age 14)	Cycle 2/3 CWF	CWF status
			drinking water	mg/L		ADHD	Cycle 3 drinking water	per 1-mg/L F increase
			urine	mg/L		ADHD	Cycle 2/3 SG-adjusted urine	continuous F measure
Mood, Affect	Wang 2020a	school children 7-13 years old, Tongxu County, China (n=325)	urine	mg/L	Chinese version of the Conners' Parent Rating ScaleRevised (CPRS-48)	anxiety	continuous urinary F	per 1 mg/L urinary F
						psychosomatic problems	continuous urinary F	per 1 mg/L urinary F

Interactive figure and additional study details in HAWC here. "F" represents fluoride. Drinking water results for Barberio *et al.* (2017b) have a large confidence interval and are not completely visible in the figure. 95% CIs are 0.068–11.33 and can be viewed in HAWC by clicking the OR within the plot area.

Figure D12. Cognitive Impairment in Adults by Fluoride Exposure (low risk-of-bias studies; presented as % of total group)



Study	Population Name	Metric	Units	Test	Endpoint	Exposure Level
Jacqmin 1994	older adults, Gironde and Dordogne, France (n=3490)	drinking water	mg	Mini-Mental State Examination	cognitive impairment	0.03-0.07 mg
						0.07-0.11 mg
						0.11-0.60 mg
						0.60-2.03 mg

Interactive figure and additional study details in HAWC here. Results from Li *et al.* (2016) suggested that fluoride exposure may be a risk factor for cognitive impairment in elderly subjects; however, results from the study were not conducive to presentation in this visualization.

Note: the roles of individual contractors differed: [a] indicates monograph development; [b] indicates review of data, results, and analyses; [c] indicates database and HAWC support; [d] indicates literature screening, [e] indicates data extraction, [f] indicates risk-of-bias assessment, [g] indicates meta-analysis

Peer Reviewers

The peer reviewers were outside experts selected for their experience with fluoride, developmental neurobehavioral toxicity, and systematic review procedures. Peer reviewers were screened for conflict of interest prior to their service and did not report any conflicts of interest. Service as a peer reviewer does not necessarily indicate that the reviewer endorses the final document.

Protocol Reviewers

June 2017	**Evaluation protocol finalized:** Review protocol finalized for use and posting
May 2019	**Revised protocol:** Revised review protocol posted
September 2020	**Revised protocol:** Revised review protocol posted

APPENDICES

Appendix 1. Literature Search Strategy

The strategy for this search is broad for the consideration of neurodevelopmental or cognitive endpoints and comprehensive for fluoride as an exposure or treatment in order to ensure inclusion of relevant papers. The search terms for PubMed are provided below. The specific search strategies for other databases are available in the protocol (https://ntp.niehs.nih.gov/go/785076).

Appendix 2. Detailed Literature Search Results and List of Included Studies

Detailed Literature Search Results

Literature Search Results Counts and Title and Abstract Screening

The electronic database searches retrieved 25,522 unique references in total (20,883 references during the initial search conducted in December 2016, 3,733 references during the literature search updates [including the final updated search conducted for the primary epidemiology studies on May 1, 2020], and 906 references from the supplemental Chinese database searches); 15 additional references were identified by technical advisors or from reviewing reference lists in published reviews and included studies. As a result of title and abstract screening, 1,036 references were moved to full-text review, and 24,501 references were excluded (11,478 by manual screening for not satisfying the PECO criteria and 13,023 based on the SWIFT algorithm).

Full-text Review

Among the 1,036 references that underwent full-text review, 497 references were excluded during the full-text review with reasons for exclusion documented at this stage; 337 references were excluded for not satisfying the PECO criteria; and 160 references from the May 2020 searches (main literature search update and supplemental Chinese database searches) were excluded for not including information that would materially advance the human, animal in vivo, or mechanistic findings (see the **Literature Search** section for a description of the methodology). These screening results are outlined in a study selection diagram that reports numbers of studies excluded for each reason at the full text review stage (see **Figure 2**) [using reporting practices outlined in Moher *et al.* (2009)]. After full-text review, 539 studies were considered relevant with primary neurological outcomes, secondary neurological outcomes, and/or outcomes related to thyroid function. A few studies assessed data for more than one evidence stream (human, non-human mammal, and/or in vitro), and several human and animal studies assessed more than one type of outcome (e.g., primary and secondary outcomes). The number of included studies is summarized below. There are:

- 159 human studies (78 primary only; 13 secondary only; 5 primary and secondary; 6 primary and thyroid; 2 secondary and thyroid; and 55 thyroid only);
- 339 non-human mammal studies (7 primary only; 186 secondary only; 67 primary and secondary; 6 primary, secondary, and thyroid; 4 secondary and thyroid; and 69 thyroid only); and,
- 60 in vitro/mechanistic studies (48 neurological and 12 thyroid).

One publication contained human, experimental non-human mammal, and in vitro data. Three publications contained both human and experimental non-human mammal data. Fourteen publications contained data relevant to both experimental non-human mammal studies and in vitro studies.

List of Included Studies

Studies in Humans

As described in **Figure 2**, 159 human studies were included; however, full data extraction was only conducted on studies with neurological outcomes or thyroid hormone data. Data extraction was completed using HAWC. Data were extracted from a subset of included studies in humans (n = 116) and are available in HAWC based on outcome. The following lists of references are organized as studies that are available in HAWC followed by studies that are not available in HAWC. Specifically, data for primary neurodevelopmental or cognitive outcomes (learning, memory, and intelligence) and secondary neurobehavioral outcomes (anxiety, aggression, motor activity, or biochemical changes), as well as thyroid hormone level data, were extracted from included human studies and are available in HAWC. Data for included studies identified through the 2020 literature search update were only extracted for primary neurodevelopmental or cognitive outcomes; a subset of these studies (n = 5) also included secondary neurobehavioral outcomes and/or thyroid hormone level data that were not extracted because those data would not materially advance the human or mechanistic findings. Included human studies that only evaluated other thyroid-related effects such as goiters or thyroid size (n = 43) were not extracted and are not available in HAWC. The list below presents the 159 human studies that were included in the review. An overview of the screening results is outlined in the study selection diagram (**Figure 2**) that reports numbers of included studies as well as numbers of studies excluded for each reason at the full text review stage.

Studies in Non-human Animals

As described in **Figure 2**, 339 non-human mammal studies were included; however, full data extraction was only conducted on studies with primary neurological outcomes and/or secondary functional neurological outcomes (e.g., motor activity). Data extraction was completed using HAWC. Data were extracted from a subset of included studies in animals (n = 123) and are available in HAWC based on outcome. The following lists of references are organized as studies that are available in HAWC followed by studies that are not available in HAWC. Specifically, all primary outcomes and functional neurological secondary outcomes (e.g., motor activity) were extracted from animal studies and are available in HAWC, including studies from the NTP (2016) assessment. Studies are also available in HAWC that evaluated mechanistic effects related to oral fluoride exposure at or below 20 ppm fluoride drinking water equivalents for categories of mechanistic endpoints with the largest amount of available data (i.e., biochemistry of the brain or neurons, neurotransmission, oxidative stress, and histopathology [n = 70]); however, these mechanistic data were generally not extracted. Several animal studies assessed primary neurological outcomes and/or functional neurological secondary outcomes and mechanistic effects in the four mechanistic categories listed above (n = 56). In total, 140 animal studies are available in HAWC (70 with primary neurological outcomes and/or secondary functional neurological outcomes without relevant mechanistic data; 15 with relevant mechanistic data only; and 55 with primary/or secondary functional neurological outcomes with relevant mechanistic data). Studies that evaluated other mechanistic endpoints, as well as studies that only assessed mechanistic effects at fluoride levels above 20 ppm fluoride drinking water equivalents, are not available in HAWC (n = 199). The list below presents the 339 non-human animal studies that were included in the review. An overview of the screening results is outlined in the study selection diagram (**Figure 2**) that reports numbers of included studies as well as numbers of studies excluded for each reason at the full text review stage.

In Vitro Experimental Studies

As described in **Figure 2**, 60 in vitro experimental studies were included; however, data extraction was not conducted on in vitro studies. Therefore, in vitro experimental studies are not available in HAWC with the exception of in vitro studies that also reported in vivo non-human animal data that meet the relevant criteria for being made available in HAWC. The following lists of references are organized as studies that are available in HAWC (n = 6) followed by studies that are not available in HAWC (n = 54).

Appendix 4. Details for Low Risk-of-bias Studies

IQ studies

Bashash *et al.* (2017)

Study Details:

- ***Study design*:** Prospective cohort
- ***Population*:** Early Life Exposures in Mexico to Environmental Toxicants (ELEMENT) participants (pregnant mothers and their children aged 4 or 6–12 years).
- ***Study area:*** Mexico City, Mexico
- ***Sample size:*** 299 mother–child pairs, of whom 211 had data for the IQ analyses.
- ***Data relevant to the review:*** Adjusted and unadjusted associations between IQ scores and maternal or child's urinary fluoride concentrations.
- ***Reported association with fluoride exposure:*** Yes: Significant association between maternal urinary fluoride and IQ score (adjusted β = −2.50; 95% CI: −4.12, −0.59). No significant associations with children's urinary fluoride.

Risk of Bias:

- **Author contacts:**
  - Authors were not contacted for additional information because it was not necessary.
- ***Population selection:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Study participants were selected from two different cohorts from three hospitals in Mexico City that serve low-to-moderate income populations. One cohort was from an observational study of prenatal lead exposure and neurodevelopment outcomes and the other was from a randomized trial of the effect of calcium on maternal blood lead levels. The authors state that participants had no history of psychiatric disorders, high-risk pregnancies, gestational diabetes, illegal drug use, or continuous prescription drugs, but they do not include any information on smoking habits. Study populations appear to be similar, but there may be some differences because subjects were selected from two different cohorts that were recruited from slightly different time periods.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the exposure groups were similar despite the subjects coming from different original study populations where different methods were used for recruitment.
- ***Confounding:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Data were collected via questionnaire on maternal age, education, marital status at first prenatal visit, birth order, birth weight, gestational age at delivery, maternal smoking, maternal IQ, and HOME scores. All models were adjusted for gestational age at birth, child's sex, birth weight, birth order, child's age at testing, maternal marital status, smoking history, age at delivery, maternal IQ, education, and cohort, with additional testing for children's urinary fluoride, mercury, lead, and calcium. Sensitivity analyses additionally adjusted for HOME score. Confounders not considered included BMI, iodine deficiency, arsenic, and maternal mental health and

nutrition. Arsenic is assumed not to be a potential co-exposure in this population as the study authors did not discuss it as an issue but did discuss other co-exposures. Arsenic is included in the water quality control program in Mexico City and is not considered a concern in this population.

- *Potentially important study-specific confounders:* All key confounders were addressed.
  - *Direction/magnitude of effect*: Not applicable.
- *Basis for rating:* Probably low risk of bias based on direct evidence that key confounders including other potential co-exposures were addressed and indirect evidence that the methods used to collect the information were valid and reliable and that arsenic is not likely to be an issue in this study population.

- ***Attrition:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Although there was a large amount of attrition, the study authors clearly describe all reasons for attrition and also provide characteristics to compare those participants included to those excluded. There were some slight differences between those included and those excluded, but there is nothing to indicate that the attrition would potentially bias the results.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that exclusion of subjects from analyses was adequately addressed, and reasons were documented when subjects were removed from the study or excluded from analyses.
- ***Exposure:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Urinary fluoride concentrations were determined in spot urine samples (2nd morning void) collected from mothers (during at least one trimester) and children ages 6–12 years. Fluoride content was measured using ion-selective electrode-based assays. QC methods were described including between laboratory correlations. All samples were measured in duplicate. Extreme outliers were excluded. Urinary dilution was addressed by using creatinine-adjusted levels.
    - *Direction/magnitude of effect*: Not applicable.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that exposure was consistently assessed using well-established methods that directly measured exposure.
- ***Outcome:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Outcome was assessed using the McCarthy Scales of Children's Abilities (MSCA) in 4-year-old children (translated into Spanish) and the Wechsler Abbreviated Scale of Intelligence (WASI) in 6–12-year-olds. The WASI is a well-established test and the validity of both tests is well documented by the authors. Inter-examiner reliability was evaluated and reported with a correlation of 0.99 (++ for methods). The study report stated that psychologists were blind to the children's fluoride exposure (++ for blinding). Overall rating for methods and blinding = ++.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that the outcome was blindly assessed using instruments that were valid and reliable in the study population.
- ***Selective Reporting:***
  - *Rating:* Definitely low risk of bias (++)

- *Summary:* All outcomes outlined in the abstract, introduction, and methods are reported in sufficient detail.
- *Basis for rating:* Definitely low risk of bias based on direct evidence that all measured outcomes were reported.

- ***Other potential threats:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:*
    - *Statistical analyses:* Statistical analyses used were appropriate for the study. Statistical tests of bivariate associations [using Chi-square tests for categorical variables and analysis of variance (ANOVA)] were used to compare the means of the outcomes or exposure within groups based on the distribution of each covariate. Generalized additive models (GAMs) were used to estimate the adjusted association between fluoride exposure and measures of children's intelligence. Residual diagnostics were used to examine model assumptions and identify any potentially influential observations. Results are reported as adjusted effects and 95% CIs. In sensitivity analyses, regression models accounted for clustering at the cohort level by using cohort as a fixed effect in the models. Although using cohort as a random effect would be more appropriate, using individual-level exposure data and accounting for numerous potential confounders in the models likely captured the cohort effect. Additional models with cohort as a random effect were also subsequently made available via personal communication with the study authors and showed similar results to the main model.
    - *Other potential concerns:* None identified.
  - *Basis for rating:* Definitely low risk if bias based on direct evidence that the statistical analyses were appropriate and there were no other potential threats to risk of bias identified.
- ***Basis for classification as low risk-of-bias study overall:*** Definitely or probably low risk-of-bias ratings in confounding, exposure, and outcome. Study strengths include individual exposure measurements, outcome blindly assessed, and the prospective cohort study design.

Choi *et al.* (2015)

Study Details:

- ***Study design*:** Cross-sectional
- ***Population*:** First grade children (ages 6–8 years)
- ***Study area:*** Mianning County in southern Sichuan, China
- ***Sample size:*** 51 first grade children
- ***Data relevant to the review:*** Associations between IQ (digit span for auditory span and working memory and block design for visual organization and reasoning components of WISC-IV only) with continuous urine or drinking water fluoride levels. Study also had information based on dental fluorosis score.
- ***Reported association with fluoride exposure:*** Yes: Compared to the normal/questionable dental fluorosis, the moderate/severe dental fluorosis group was associated with significantly lower total (adjusted β = −4.28; 95% CI: −8.22, −0.33) and backward (adjusted β = −2.13; 95% CI: −4.24,

−0.02) digit span scores. Linear correlations between total digit span and fluoride in urine (adjusted β = −1.67; 95% CI: −5.46, 2.12) and in drinking water (adjusted β = −1.39; 95% CI: −6.76, 3.98) were observed but not significant. Other outcomes not significantly associated with fluoride exposure.

Risk of Bias:

- **Author contacts:**
  - Authors were not contacted for additional information because it was not necessary.
- ***Population selection:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Subjects were selected during the same time frame using the same methods. Fifty-one first-grade children residing in Mianning County in southern Sichuan, China were included in this pilot study. It is not specified if the 51 children represented all the first-grade children from this area or if some refused to participate. Children who did not speak Chinese, were not students at the Primary School of Sunshui Village in Mianning County, or those with chronic or acute disease that might affect neurobehavioral function tests were excluded. Demographic characteristics are presented in Table 1 of the study, which indicates that subjects were similar. Potential confounders are adjusted for in the statistical analyses.
  - *Basis for Rating:* Definitely low risk of bias based on direct evidence that the exposure groups were similar and were recruited within the same time frame using the same methods with no evidence of differences in participation/response rates.
- ***Confounding:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* The parents or guardians completed a questionnaire on demographic and personal characteristics of the children (sex, age at testing, parity, illnesses before age 3, and past medical history) and caretakers (age, parity, education and occupational histories, residential history, and household income). A 20-µL capillary blood sample was collected at the school by a Mianning County Center for Disease Control (CDC) health practitioner and tested for possible iron deficiency which could be used as a covariate of neurodevelopmental performance. Confounders that were not assessed include: maternal BMI, parental mental health, maternal smoking status, maternal reproductive factors, parental IQ, and HOME score. However, the study authors noted that confounding bias appeared to be limited due to the minimal diversity in the social characteristics of the subjects. The study authors indicated that CDC records documented that levels of other contaminants including arsenic and lead were very low in the area. Iodine differences were not specifically addressed, but there is no indication from the information provided that this might be a concern.
  - *Potentially important study-specific confounders:* All key confounders were considered in this study.
    - *Direction/magnitude of effect*: Not applicable.
  - *Basis for rating:* Probably low risk of bias because there is direct evidence that the key confounders are taken into account and indirect evidence that co-exposure to arsenic is likely not an issue in this area and that methods used for collecting the information were valid and reliable.

- ***Attrition:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* The majority of results were reported for the 51 children stated to be included in the pilot study. In Table 5 of the study, the N for each dental fluorosis category only totals 43, but the text indicates 8 children did not have a Dean Index because permanent teeth had not erupted.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that exclusion of subjects from analyses was adequately addressed, and reasons were documented when subjects were removed from the study or excluded from analyses.
- ***Exposure:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* The study used three different measurements of fluoride exposure: well water fluoride concentrations from the residence during pregnancy and onwards, fluoride concentrations from children's first morning urine samples, and degree of children's dental fluorosis. Fluoride concentrations in community well water were measured and recorded by Mianning County CDC; specific methods were not reported, but they likely used standard methods as they were conducted by the CDC and were likely the same as those used to measure the fluoride in urine. Migration of subjects was noted to be limited. Well water fluoride concentrations of the mother's residence during pregnancy and onward were used to characterize a child's lifetime exposure. To provide a measure of the accumulated body burden, each child was given a 330-mL (11.2-oz) bottle of Robust© distilled water (free from fluoride and other contaminants) to drink the night before the clinical examinations, after emptying the bladder and before bedtime. The first urine sample the following morning was collected at home, and the fluoride concentration was determined on a 5-mL sample using an ion-specific electrode at the Mianning CDC. There is no indication that urinary fluoride levels accounted for dilution nor was it clear that the method of administering water to the children and collection methods sufficiently controlled for differences in dilution. One of the investigators, a dentist, performed a blinded dental examination on each child's permanent teeth to rate the degree of dental fluorosis using the Dean Index. The Dean Index is a commonly used index in epidemiological studies and remains the gold standard in the dentistry armamentarium. The Index has the following classifications: normal, questionable, very mild, mild, moderate, and severe. Quality control (QC) procedures are not reported but were likely appropriate.
    - *Direction/magnitude of effect***:** Current levels were used to assess lifetime exposure. This is likely to be a non-differential exposure misclassification and direction of bias is unknown. Because subject migration appears to be limited, it is likely that the current fluoride levels are adequate reflections of past exposure. Dental fluorosis would be an indicator that exposure occurred in the past and there was a fair correlation between degree of dental fluorosis and current urine and water fluoride levels, with both increasing with increasing levels of dental fluorosis.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that exposure was consistently assessed using well-established methods that directly measure exposure.

- ***Outcome:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* The study authors adopted culture-independent tests considered feasible for children aged 6 to 8 years. The Wide Range Assessment of Memory and Learning (WRAML) was used for the assessment of memory and learning. Three subtests were also used. The Finger Windows subtest assesses sequential visual memory. The Design Memory subtest assesses the ability to reproduce designs from memory following a brief exposure. The Visual Learning subtest assesses the ability to learn the locations of pictured objects over repeated exposures. The Wechsler Intelligence Scale for Children-Revised (WISC-IV) included digit span for auditory span and working memory and block design for visual organization and reasoning. The grooved pegboard test assesses manual dexterity. The tests used have been validated on a western population. Although there is no information provided to indicate that they were validated on the study population, the study authors indicated that the tests were culture-independent (+ for methods). Blinding of the outcome assessors or steps to minimize potential bias was not reported. However, it is unlikely that the assessors had knowledge of the individual exposure as children all came from the same area, and water and urine levels were tested at the CDC. (+ for blinding). Overall = +.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that all outcomes were assessed blindly using instruments that were valid and reliable in the study population.
- ***Selective Reporting:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* All outcomes outlined in the abstract, introduction, and methods are reported in sufficient details.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that all measured outcomes were reported.
- ***Other potential threats:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:*
    - *Statistical analyses:* Statistical analyses were appropriate. Multiple regression models evaluate the associations between exposure indicators and test scores after adjusting for potential confounders. Specific regression models are not described or refenced, just stated to be “standard regression analysis with confounder adjustment.” The distributions of fluoride concentrations in urine and water were skewed and were log10-transformed to approximate a Gaussian distribution (test not specified). Results are reported as adjusted effects and 95% CIs. There is no evidence that residual diagnostics were used to examine model assumptions; however, the impact on the effect estimates is expected to be minimal.
    - *Other potential concerns:* It should be noted that this study was a pilot study and, therefore, had a relatively small sample size (i.e., 51 children).
  - *Basis for rating:* Probably low risk if bias based on indirect evidence that the statistical analyses were appropriate and there were no other potential threats to risk of bias identified.

- ***Basis for classification as low risk-of-bias study overall: Probably low risk-of-bias ratings in the*** confounding, exposure, and outcome risk-of-bias domains. Study strengths include individual fluoride measurements with blinding at outcome assessment likely. All key confounders and many other confounders were taken into account in the study design or analysis.

Cui *et al.* (2018)

Study Details:

- ***Study design*:** Cross-sectional
- ***Population*:** School children aged 7–12 years from four schools in two districts in China with different fluoride levels
- ***Study area:*** Jinghai and Dagang in Tianjin City, China
- ***Sample size:*** 323 school children
- ***Data relevant to the review:*** IQ scores by urine fluoride levels.
- ***Reported association with fluoride exposure:*** Yes: Significant correlation between IQ score and urinary fluoride (adjusted β = −2.47; 95% CI: −4.93, −0.01).

Risk of Bias:

- **Author contacts:**
  - Authors were contacted in June 2019 to obtain additional information for risk-of-bias evaluation.
- ***Population selection:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Four schools were selected from the same district in China. The schools were selected based on levels of fluoride in the local drinking water and the degree of school cooperation. No details were provided on the number of schools in given areas or the difficulty in getting school cooperation. It was noted that the residents in the four areas had similar living habits, economic situations, and educational standards. Although authors do not provide the specific data to support this, fluoride levels and IQ scores were provided by different subject characteristics. The areas were classified as historically endemic fluorosis and non-fluorosis. Cluster sampling was used to select the grades in each school according to previously set child ages, and classroom was randomly selected with all students within a selected classroom included. Reasons for exclusion do not appear to be related to exposure or outcome.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the exposure groups were similar and recruited within the same time frame using the same methods, with no evidence of differences in participation/response rates.
- ***Confounding:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* The measurements of all covariates were obtained by structured questionnaires that were completed by children with the help of their parents. Confounders that were assessed include: child's gender, child's ethnicity, child's age, child's BMI, birth (normal vs abnormal), mother's age at delivery, mother's education, income per family member, mother's smoking/alcohol during pregnancy, family member smoking, environmental noise, iodine region (non-endemic vs iodine-excess-

endemic area), factory within 30 m of residence, iodine salt, diet supplements, seafood/pickled food/tea consumption, surface water consumption, physical activity, stress, anger, anxiety/depression, trauma, having a cold 5 times a year, thyroid disease in relatives, mental retardation in relatives, and cancer in relatives. Covariates not considered include parity, maternal and paternal IQ, and quantity and quality of caregiving environment (e.g., HOME score). The authors report that there are no other environmentally toxic substances that may affect intelligence, such as high arsenic or iodine deficiency according to the Tianjin Centers for Disease Prevention and Control.

- *Potentially important study-specific confounders:* All key confounders were considered in this study.
  - *Direction/magnitude of effect*: Not applicable.
- *Basis for rating:* Probably low risk of bias because there is indirect evidence that the key confounders are considered, methods for collecting the information are valid and reliable, and co-exposure to arsenic is likely not an issue in this area.

- ***Attrition:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Of the 400 children enrolled, 35 were excluded because they did not have informed consent signed by a guardian or they moved out of the area. Forty-two children were excluded because they did not have a DRD2 genotyping measurement. It is unclear if these children were from the same schools or if they were evenly distributed throughout the study area. It was also unclear if the excluded subjects were similar to those included in the study. In the study, some analyses had fewer than the 323 subjects, but this seems reasonable given the subgroups that were being evaluated.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that exclusion of subjects from analyses was adequately addressed, and reasons were documented when subjects were removed from the study or excluded from analyses.
- ***Exposure:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Although children were selected based on area fluoride levels, fluoride in the urine was used in the analysis. Urine was collected from each child the morning of enrollment and analyzed within a week. Fluoride levels were measured using an ion-selective electrode according to the China standard. A brief description of the method was provided, but no QC methods were reported. The study authors did not account for urinary dilution in the spot samples.
    - *Direction/magnitude of effect*: Not accounting for dilution could cause there to be some exposure misclassification. The direction and magnitude would depend on where the differences occurred.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that exposure was consistently assessed using acceptable methods that provide individual levels of exposure.
- ***Outcome:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* IQ was measured by professionals using the Combined Raven's Test-The Rural in China method, which is the appropriate test for the study population (++ for methods). Blinding or other methods to reduce bias were not reported. Although it is

unlikely that the outcome assessor would have knowledge of the child's urine fluoride levels, there is potential that they would know if the child was from an endemic or non-endemic area if the IQ tests were conducted at the child's school, and there was no information provided on how the IQ tests were administered. Correspondence with the study author noted the cross-sectional nature of the study with outcome and exposure assessed at the same time making the outcome assessors blind to the exposure. However, there is still potential for knowledge of the area (+ for blinding).

- *Basis for rating:* Probably low risk of bias based on indirect evidence that the outcome was blindly assessed using instruments that were valid and reliable in the study population.

- ***Selective Reporting:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* All outcomes in the abstract, introduction, and methods are reported in sufficient details.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that all measured outcomes were reported.
- ***Other potential threats:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:*
    - *Statistical analyses:* Statistical analyses were appropriate. Multiple linear regression models were applied to evaluate the relationship between urine fluoride levels and IQ scores, accounting for numerous potential confounders. The urinary fluoride levels were log-transformed due to a skewed distribution. Residual diagnostics were used to examine model assumptions. Model robustness was tested through bootstrap, sensitivity analysis after excluding potential outliers, and cross-validation techniques. Results are reported as adjusted effects and 95% CIs. The analysis did not account for clustering at the school level or at the grade level (students were from four schools in grades selected via a clustered sampling method). There is no evidence that the sampling strategy was otherwise accounted for via sampling weights. The impact of these factors on the effect estimates is expected to be minimal given the use of individual-level data and adjustment for several potential confounders.
    - *Other potential concerns:* None identified.
  - *Basis for rating:* Probably low risk if bias based on indirect evidence that the statistical analyses were appropriate and there were no other potential threats to risk of bias identified.
- ***Basis for classification as low risk-of-bias study overall:*** Probably low risk-of-bias ratings in confounding, exposure, and outcome. Study strengths include individual exposure measurements but is limited by the cross-sectional study design and lack of accounting for urine dilution. All key confounders were accounted for in the study design or analysis.

Cui *et al.* (2020)

Study Details:

- ***Study design*:** Cross-sectional
- ***Population*:** School children aged 7–12 years
- ***Study area:*** Tianjin City, China (one randomly selected school from each district based on iodine levels in the water), presumably was an expansion of the Cui *et al.* (2018)
- ***Sample size:*** 498 school children
- ***Data relevant to the review:*** IQ scores by urine fluoride levels.
- ***Reported association with fluoride exposure:*** Yes: A 2-point decrease in IQ was observed in the highest urinary fluoride group compared to the lowest urinary fluoride group (i.e., 110.00 in ≥2.5-mg/L group versus 112.16 in <1.6-mg/L group); however, the results did not achieve statistical significance based on a one-way ANOVA comparing the three different urinary fluoride categories only.

Risk of Bias:

- **Author contacts:**
  - Authors were not contacted for the 2020 publication. Authors were contacted in June 2019 for additional information on the Cui *et al.* (2018) publication. Information obtained from that correspondence may have been used for additional information in the 2020 publication.
- ***Population selection:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Subjects were recruited from 2014 to 2018. One school was selected from each district where water concentrations of water iodine were <10, 10–100, 100–150, 150–300 and >300 µg/L. In each school, classes were randomly sampled for the appropriate age group of 7–12 years old. A table of subject characteristics was provided by IQ. A total of 620 children were recruited, and 122 children who did not have complete information or enough blood sample were excluded. Reasons for exclusion do not appear to be related to exposure or outcome. The characteristics of the 498 included children are presented.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the exposure groups were similar and were recruited within the same time frame using the same methods, with no evidence of differences in participation/response rates.
- ***Confounding:***
  - *Rating:* Probably high risk of bias (-)
  - *Summary:* It was noted by the study authors that there were no other environmental poisons except water fluoride. Other studies also conducted in this area of China noted specifically that arsenic was not a concern. Iodine was addressed as that was one of the main points of the study. Twenty-one factors (provided in Table 1 of the study) were selected as confounders, and a homemade questionnaire of unspecified validity was used for obtaining the information. It was noted that child age, stress, and anger were significantly associated with IQ although it is unclear if these varied by fluoride level. However, Cui *et al.* (2018) indicates that stress and anger were not significantly

associated with fluoride, and it is assumed that results would be similar for this study even though more children were included in the current study.

- *Potentially important study-specific confounders:* Age (children 7–12 years old)
  - *Direction/magnitude of effect*: Age is a potential confounder for IQ, even in the narrow age range evaluated in this study. The direction of effects may depend on the number of children in each age group within the different urinary fluoride categories; however, these data were not provided. In general, there were fewer subjects ≤ 9 years of age (i.e., 111) compared to > 9 years of age (i.e., 387) with a significantly higher IQ in the ≤9-year-old age group. Therefore, if exposure were higher in the older subjects, this could bias away from the null.
- *Basis for rating:* Probably high risk of bias because there is indirect evidence that age was not addressed as a confounder and it may be related to both IQ and exposure.

- ***Attrition:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Of the 620 (20%) children recruited, 122 were excluded due to incomplete information or inadequate blood sample. No information was provided to indicate if there were similarities or differences in the children included versus the children excluded, but exclusion is unlikely to be related to either outcome or exposure.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that exclusion of subjects from analyses was adequately addressed, and reasons were documented when subjects were removed from the study or excluded from analyses.
- ***Exposure:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Children's morning urine was collected with a clean polyethylene tube and fluoride was measured using a fluoride ion-selective electrode following Chinese standard WS/T 89-2015. A brief description was provided, but no QC methods were reported. The study authors do not account for urinary dilution in the spot samples.
    - *Direction/magnitude of effect*: Not accounting for dilution could cause there to be some exposure misclassification. The direction and magnitude would depend on where the differences occurred.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that exposure was consistently assessed using acceptable methods that provide individual levels of exposure.
- ***Outcome:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* IQ was measured using the Combined Raven's Test, which is an appropriate test for the study population (++ for methods). Blinding was not mentioned; however, the outcome assessors would not likely have knowledge of the child's urinary fluoride. Subjects appear to have been recruited based on iodine levels and it is, therefore, unlikely that there would be any knowledge of potential fluoride exposure. Correspondence with the study authors for the Cui *et al.* (2018) study also indicated that the outcome assessors would have been blind.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the outcome was blindly assessed using instruments that were valid and reliable in the study population.

- ***Selective Reporting:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* All outcomes in the abstract, introduction, and methods are reported in sufficient details.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that all measured outcomes were reported.
- ***Other potential threats:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:*
    - *Statistical analyses:* One-way ANOVA was used to make comparisons between mean IQ by urinary fluoride levels. Consideration of heterogeneity of variances was not reported. There is no adjustment for potential confounders or for clustering of children at the school level. There is no evidence that the sampling strategy was otherwise accounted for (i.e., via sampling weights. The impact of these factors on the effect estimates is expected to be minimal given the use of individual-level data. The primary focus of the study was to evaluate associations between IQ and thyroid hormone or dopamine levels (not between IQ and fluoride levels). It should also be noted that more advanced analyses used for thyroid hormone- and dopamine-IQ associations still lacked adjustment for school and accounting for clustering of children from the same school.
    - *Other potential concerns:* None identified.
  - *Basis for rating:* Probably low risk if bias based on indirect evidence that the statistical analyses were appropriate and there were no other potential threats to risk of bias identified.
- ***Basis for classification as low risk-of-bias study overall:*** Probably low risk-of-bias ratings in exposure and outcome. Study strengths include individual exposure measurements, but the study is limited by the cross-sectional study design, lack of accounting for urine dilution, and by not addressing age as a potential confounder.

Ding *et al.* (2011)

Study Details:

- ***Study design*:** Cross-sectional
- ***Population*:** Elementary school children aged 7–14 years old
- ***Study area:*** Hulunbuir City, Inner Mongolia, China
- ***Sample size:*** 331 school children
- ***Data relevant to the review:*** IQ mean difference based on 10 categories of urine fluoride.
- ***Reported association with fluoride exposure:*** Yes: Significant association between urinary fluoride and IQ score (each 1 mg/L increase in urinary fluoride was associated with a lower IQ score of 0.59 points; 95% CI: −1.09, −0.08).

Risk of Bias:

- **Author contacts:**
  - Authors were not contacted for additional information because it was not necessary.

- ***Population selection:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* The study randomly selected 340 7–14-year-olds from four nearby elementary schools in Hulunbuir. Authors stated that the four elementary schools appeared to be very similar in teaching quality. The study authors noted that they followed the principles of matching social and natural factors like economic situation, educational standards, and geological environments as much as possible; however, how this was done is unclear and no table of study subject characteristics by group was provided.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the exposure groups were similar and were recruited within the same time frame using the same methods, with no evidence of differences in participation/response rates.
- ***Confounding:***
  - *Rating:* Probably high risk of bias (-)
  - *Summary:* It was noted that none of the four sites had other potential neurotoxins including arsenic in their drinking water. Although they did not provide the specifics, they did provide a reference. In addition, iodine deficiency was noted as not being issue in any of the four areas. Age was the only confounder adjusted in the model. Although dental fluorosis severity by % female was reported, not enough data were provided to determine if it was a confounder that should have been considered in the regression. The study authors note that future studies will include covariates such as parents' educational attainment, mother's age at delivery, and household income.
  - *Potentially important study-specific confounders:* Gender
    - *Direction/magnitude of effect***:** There is not enough information to determine if there is an effect from gender. There were some differences in dental fluorosis level by gender, but it is unclear how this might impact the results or if the distribution of gender differed by age.
  - *Basis for rating:* Probably high risk of bias based on indirect evidence that there were differences in gender that were not considered in the study design or analyses.
- ***Attrition:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Data were relatively complete (i.e., <5% loss). Of the 340 subjects selected for inclusion, 5 were excluded because they lived in the area for less than a year with an additional 4 not consenting to participate.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that exclusion of subjects from analysis was adequately addressed, and reasons were documented when subjects were removed from the study or excluded from analyses.
- ***Exposure:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Spot urine samples were collected and measured using China CDC standards. All samples were analyzed twice using a fluoride ion-selective electrode. Recovery rates were specified as 95–105% with an LOD of 0.05 mg/L. Water samples were collected from small-scale central water supply systems and tube wells with handy pumps and were processed using standard methods similar to the urine samples. Quality assurance validation was reported. A blind professional examiner evaluated the children for dental

fluorosis using the Dean's Index. All urine and water samples were above the LOD. Urine levels were the primary exposure measure used in the analysis. The study authors did not account for urinary dilution in the spot samples. The mean urine fluoride concentration was correlated with the dental fluorosis levels.

- *Direction/magnitude of effect*: Spot urine samples that did not account for dilution could have exposure misclassification. The misclassification is likely non-differential and potential direction of bias is unknown.

- *Basis for rating:* Probably low risk of bias based on indirect evidence that exposure was consistently assessed using well-established methods that directly measure exposure.

- ***Outcome:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* IQ was determined using the Combined Raven's Test-The Rural in China (CRT-RC3) (++ for methods). Although blinding was not reported, it is unlikely that the IQ assessors had knowledge of the children's urine levels or even of the water levels from the four sites as these were sent to a separate lab for testing (+ for blinding). Overall rating for methods and blinding = +.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the outcome was blindly assessed using instruments that were valid and reliable in the study population.
- ***Selective Reporting:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* All outcomes outlined in the abstract, introduction, and methods are reported in sufficient details.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that all measured outcomes were reported.
- ***Other potential threats:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:*
    - *Statistical analyses:* Statistical analyses were reasonable (ANOVA and multiple linear regression), but consideration of homogeneity of variance was not reported. The NASEM committee review (NASEM 2021) pointed out a potential concern for the lack of accounting for clustering at the school-level because children were selected from four elementary schools. However, as pointed out in the ***Selection*** domain, the authors stated that they followed the principles of matching social and natural factors like economic situation, educational standards, and geological environments to the extent possible and that the four elementary schools appeared to be very similar in teaching quality. There is no evidence that the sampling strategy was otherwise accounted for (I.e., via sampling weights). The impact of these factors on the effect estimates is expected to be minimal given the use of individual-level data and adjustment for age as a potential confounder.
    - *Other potential concerns:* None identified.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the statistical analyses were appropriate and that there were no other potential threats to risk of bias.

- ***Basis for classification as low risk-of-bias study overall:*** Probably low risk-of-bias ratings in exposure and outcome. Study strengths include individual exposure measurements, but the study is limited by the cross-sectional study design, lack of accounting for urine dilution, and by not addressing gender as a potential confounder.

Green *et al.* (2019)

Study Details:

- ***Study design*:** Prospective cohort
- ***Population*:** Maternal-Infant Research on Environmental Chemicals (MIREC) participants (pregnant mothers and their children aged 3–4 years)
- ***Study area:*** 10 cities, Canada
- ***Sample size:*** 512 mother−child pairs (238 from non-fluoridated areas, 162 from fluoridated areas; 264 females, 248 males)
- ***Data relevant to the review:*** Adjusted linear regression models evaluating associations between IQ in both genders together and separate, with maternal urinary fluoride across all three trimesters, or with estimated maternal fluoride intake.
- ***Reported association with fluoride exposure:*** Yes: Significantly lower full-scale IQ per 1-mg/L increase in maternal urinary fluoride in boys (adjusted β = −4.49), but not girls (adjusted β = 2.40) and not in both genders combined (adjusted β = −1.95); significantly lower full-scale IQ per 1-mg increases in maternal intake in both genders combined (adjusted β = −3.66 [no sex interaction]); significantly lower full-scale IQ per 1-mg/L increase in drinking water fluoride in both genders combined (adjusted β = −5.29 [no sex interaction]).

Risk of Bias:

- **Author contacts:**
  - Authors were contacted in June 2019 for additional information for the risk if bias evaluation.
- ***Population selection:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Pregnant women were recruited from the same population, during the same timeframe, and using the same methods as the MIREC program. Methods were reported in detail.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that the exposed groups were similar and were recruited with the same methods during the same time frame.
- ***Confounding:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* The study considered several possible covariates including maternal age, pre-pregnancy BMI, marriage status, birth country, race, maternal education, employment, income, HOME score, smoking during pregnancy, secondhand smoke in the home, alcohol consumption during pregnancy, parity, child's gender, child's age at testing, gestational age, birth weight, time of void, and time since last void. The study also conducted secondary analyses to test for lead, mercury, arsenic, and PFOA. There is no indication of any other potential co-exposures in this study population. Iodine deficiency

or excess could not be assessed but is not expected to differentially occur. The study was not able to assess parental IQ or mental health disorders. Methods used to obtain the information included questionnaires and laboratory tests.

- *Potentially important study-specific confounders:* All key confounders were addressed.
  - *Direction/magnitude of effect:* Not applicable.
- *Basis for rating:* Probably low risk of bias based on indirect evidence that the methods used to collect the information were valid and reliable and direct evidence that key confounders including potential co-exposures were addressed.

- ***Attrition:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Of the 610 recruited children, 601 (98.5%) completed testing. Of the 601 mother-child pairs, 512 (85.2%) had all three maternal urine samples and complete covariate data, and 400 (66.6%) had data available to estimate fluoride intake.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that exclusion of subjects from analyses was adequately addressed, and reasons were documented when subjects were removed from the study or excluded from analyses.
- ***Exposure:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Spot urine samples from all three trimesters of pregnancy were evaluated using appropriate methods, and results were adjusted for creatinine and specific gravity. Fluoride intake was estimated based on fluoride water levels and information on consumption of tap water and other water-based beverages (e.g., tea, coffee) was obtained via questionnaire.
    - *Direction/magnitude of effect***:** There is not any specific direction or magnitude of bias expected. Urinary fluoride levels are reflective of a recent exposure. Having measurements from all three trimesters of pregnancy provides a better representation of actual exposure than a single measurement although the potential for missed high exposure is possible. However, the possibility of the occurrence of missed high exposure would be similar in all females and would be non-differential. For the fluoride intake, exposure was based on the fluoride levels in the water at the residence. If women worked outside the home and the majority of intake occurred from areas outside the home (and were different from levels in the home), there is potential to bias toward the null.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that exposure was consistently assessed using well-established methods that directly measured exposure.
- ***Outcome:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* The Wechsler Preschool and Primary Scale of Intelligence was normalized for ages 2.5–<4.0 and child sex using the U.S population-based norms. Blinding was not reported, but it is unlikely that the outcome assessors had knowledge of the maternal fluoride level or were aware if the city had fluoridated water.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the outcome was blindly assessed using instruments that were valid and reliable in the study population.

- ***Selective Reporting:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* All outcomes were reported.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that all measured outcomes were reported.
- ***Other potential threats:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:*
    - *Statistical analyses:* Multivariate linear regression analyses were used to evaluate the associations between maternal urinary fluoride and fluoride intake and children's IQ scores. Regression diagnostics were used to test assumptions for linearity, normality, and homogeneity. There were no potential influential observations (based on Cook's distance). Sensitivity analyses showed that the effects of maternal urinary fluoride (MUF), fluoride intake, and water fluoride were robust to the exclusion of two very low IQ scores in males (<70). City was accounted for as a covariate in the regression models published. Additional models with city as a random effect were also subsequently made publicly available and showed similar results to the main model.
    - *Other potential concerns:* None identified.
  - *Basis for rating:* Definitely low risk if bias based on direct evidence that the statistical analyses were appropriate and there were no other potential threats to risk of bias identified.
- ***Basis for classification as low risk-of-bias study overall:*** Probably low risk-of-bias ratings in confounding, exposure, and outcome. Study strengths include individual exposure measurements, prospective cohort design, and addressing potential key confounders.

Rocha-Amador *et al.* (2007)

Study Details:

- ***Study design*:** Cross-sectional
- ***Population*:** Children aged 6–10 years
- ***Study area:*** Moctezuma (low fluoride, low arsenic) and Salitral (high fluoride, high arsenic) of San Luis Potosí State and 5 de Febrero (high fluoride, high arsenic) of Durango State, Mexico
- ***Sample size:*** 132 children
- ***Data relevant to the review:*** Associations between full-scale IQ, performance IQ, verbal IQ and child's urine or water fluoride levels.
- ***Reported association with fluoride exposure:*** Yes: Significant associations between fluoride and IQ scores (full-scale IQ adjusted βs of –10.2 [water] and −16.9 [urine]; CIs not reported); arsenic also present, but the effect was smaller (full-scale IQ adjusted βs of –6.15 [water] and –5.72 [urine]; CIs not reported).

Risk of Bias:

- **Author contacts:**
  - Authors were not contacted for additional information because it was not necessary.
- ***Population selection:***

- *Rating:* Probably low risk of bias (+)
- *Summary:* All children in 1st through 3rd grades in three rural areas in Mexico (n = 480) were screened for study eligibility including age, time at residence, and address. Authors report that the three selected communities were similar in population and general demographic characteristics. Children who had lived in the area since birth and were 6–10 years old were eligible to participate (n = 308). Of the 308 children, 155 were randomly selected and the response rate was 85%, but participation was not reported by area. It was noted, however, that no significant differences in age, gender, or time of residence were observed between participants and non-participants. Timeframe for selection was not mentioned but appears to be similar. Sociodemographic characteristics of subjects was provided in Table 1 of the study. There was a significant difference in SES and transferrin saturation, but these were taken into account in the analysis.
- *Basis for rating:* Probably low risk of bias based on indirect evidence that the populations were similar and differences were noted and addressed in the analysis.

- ***Confounding:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* The study design or analysis accounted for child's age, sex, SES, transferrin saturation, weight, height, blood lead levels, and mother's education. Arsenic levels were highly correlated with fluoride levels; however, arsenic and fluoride were evaluated alone, and arsenic was found to have less of an effect on IQ than fluoride. This provides evidence that arsenic has been addressed as a co-exposure and cannot explain the association between fluoride exposure and decreased IQ. Smoking was not addressed and methods for measuring many of the confounders were not reported.
  - *Potentially important study-specific confounders:* Arsenic
    - *Direction/magnitude of effect*: The presence of arsenic in this study, which also demonstrated an association, would bias the effect away from the null. Although arsenic may contribute to some of the magnitude of the observed effect of fluoride (the exact impact of arsenic on the magnitude cannot be assessed), the presence of arsenic does not fully explain the observed association between fluoride and IQ. The presence of arsenic may affect the magnitude of the association between IQ and fluoride, but it has no impact on the direction of the effect.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the methods used to collect the information were valid and reliable and direct evidence that key confounders were addressed.
- ***Attrition:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Of 155 children randomly selected for study participation, 85% responded to enroll. According to the authors, there were no significant differences in age, gender, or time of residence between responders and non-responders. However, no data are provided to support this, and no breakdown of responders/non-responders by region is provided. Data were provided for the 132 children agreeing to participate.

- *Basis for rating:* Probably low risk of bias based on indirect evidence that exclusion of subjects from analyses was adequately addressed, and reasons were documented when subjects were removed from the study or excluded from analyses.

- ***Exposure:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Urine samples were collected on the same day as psychological evaluations and were analyzed for fluoride according to NIOSH Method 8308 (Fluoride in Urine). For QC, a reference standard was also used (NIST SRM 2671a). Urine samples were also analyzed for arsenic by using the Atomic Absorption Spectrophotometer with hydride system and used a reference standard for QC. Levels were adjusted for urinary creatinine levels to account for dilution in the spot samples. Tap water samples were collected from each child's home on the day of biological monitoring. Fluoride was measured with a sensitive, specific ion electrode. Detailed methods are provided including internal quality controls. It was noted that in the high fluoride group it was common to drink bottled water low in fluoride and to only use the tap water for cooking; therefore, urine was considered the most appropriate measure of exposure. Only children who had lived at the same residence since birth were included.
    - *Direction/magnitude of effect***:** Not applicable.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that exposure was consistently assessed using well-established methods that directly measured exposure.
- ***Outcome:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Neuropsychological profiles were assessed through the WISC-RM (revised for Mexico). This is a well-established test appropriately adjusted for the study population. However, no additional validation is provided (+ for methods). The study report stated that the test assessors were masked to both arsenic and fluoride water levels (++ for blinding). Overall rating for methods and blinding = +.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the outcome was blindly assessed using instruments that were valid and reliable in the study population.
- ***Selective Reporting:***
  - *Rating:* Probably high risk of bias (-)
  - *Summary:* It was reported that an interaction between fluoride and arsenic was measured, but it was only noted in the discussion that the study design precluded testing statistical interaction between fluoride and arsenic. This provides indirect evidence of selective reporting.
  - *Basis for rating:* Probably high risk of bias based on indirect evidence that there was selective reporting.
- ***Other potential threats:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:*
  - *Statistical analyses:*
    - *Statistical analyses:* Statistical analyses used were appropriate for the study. Multivariate linear analyses were used to evaluate the associations between fluoride in water and urine and children's IQ scores Exposures were natural

log-transformed, but rationale was not provided. Regression diagnostics were not used to test model assumptions for linearity, normality, and homogeneity. The analyses did not account for clustering at the community level. The three selected communities were similar in population and general demographic characteristics. Although the analysis used individual-level exposures rather than area-level exposures, if the exposure levels within a certain area are highly correlated (which might be expected), then the results might still be biased. However, the overall impact on the effect estimates is expected to be minimal given the use of individual-level data and adjustment for multiple potential confounders.

        - *Other potential concerns:* None identified.
    - *Basis for rating:* Probably low risk if bias based on indirect evidence that the statistical analyses were appropriate and there were no other potential threats to risk of bias identified.
- ***Basis for classification as low risk-of-bias study overall:*** Definitely or probably low risk-of-bias ratings in confounding, exposure, and outcome. Study strengths include individual exposure measurements and outcomes blindly assessed, but it is limited by the cross-sectional study design and not being able to completely rule out the influence of arsenic in the results.

Saxena *et al.* (2012)

Study Details:

- ***Study design*:** Cross-sectional
- ***Population*:** Children aged 12 years
- ***Study area:*** Madhya Pradesh, India
- ***Sample size:*** 170 children
- ***Data relevant to the review:*** Mean IQ grade (not standard scores; higher IQ grades are associated with lower intelligence) by water fluoride quartiles, continuous water fluoride, or continuous urinary fluoride.
- ***Reported association with fluoride exposure:*** Yes: Significant correlations between IQ score and water (r = 0.534) and urinary (r = 0.542) fluoride levels. Significant increase in mean IQ grade (i.e., increase in proportion of children with intellectual impairment) with increasing water fluoride quartile.

Risk of Bias:

- **Author contacts:**
    - Authors were contacted in August of 2017 to obtain additional information for risk-of-bias evaluation.
- ***Population selection:***
    - *Rating:* Probably low risk of bias (+)
    - *Summary:* There was indirect evidence that subjects were similar and were recruited using the same methods during the same time frame. The study participants were selected from a stratified cluster of geographic areas based on fluoride concentration in groundwater. According to the authors, the selected villages were similar in population and demographic characteristics. Data are provided to show the breakdown in SES,

parental education, height/age, and weight/height and no significant differences were noted. Participation was stated to be voluntary, but participation rates were not provided. It is unclear if the 170 subjects were selected with 100% participation or if the 170 subjects were all that were asked to participate, but it appears that all subjects participated. Timing of the recruitment was not provided but is assumed to occur during the same time frame.

- *Basis for rating:* Probably low risk of bias based on indirect evidence that subjects were similar and recruited using the same methods during the same time frame.

- ***Confounding:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* There was indirect evidence that key confounders including potential co-exposures were addressed using reasonable methods. A questionnaire, completed with the assistance of parents, was used to collect information on child characteristics (age, sex, height, weight), residential history, medical history (including illness affecting nervous system and head trauma), educational level of the head of the family (in years), and SES of the family. The SES was recorded according to the Pareek and Trivedi classification. The nutritional status of the children was calculated using the Waterlow's classification, which defines two groups for malnutrition using height for age ratio (chronic condition) and weight for height ratio (acute condition). Within both groups, it categorizes the malnutrition as normal, mildly impaired, moderately impaired, or severely impaired. Urinary lead and arsenic were analyzed using the atomic absorption spectrophotometer. Urinary iodine was measured using the Dunn method. Authors do not report which covariates were included in the multivariate regression models; however, there was no difference in reported demographic characteristics. All subjects were the same age, and there was no difference in iodine, lead, or arsenic between the groups. Mean urinary arsenic levels did increase with increasing fluoride even though there was no significant difference by group.
  - *Potentially important study-specific confounders:* All key confounders were considered in this study.
    - *Direction/magnitude of effect***:** Not applicable.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the methods used to collect the information were valid and reliable and that key confounders including potential co-exposures were addressed.
- ***Attrition:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Results were provided for all 170 children stated to be included in the study.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence of no attrition.
- ***Exposure:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* A sample of 200 mL of drinking water was collected at each child's home. The fluoride levels were analyzed by a fluoride ion-selective electrode. Each subject was also asked to collect a sample of their first morning urine. The fluoride content in the urine was determined using a fluoride ion-selective electrode. QA/QC and LOD were not reported and urinary dilution was not assessed. Although only current levels were measured, children who had changed water source since birth were excluded.

        - *Direction/magnitude of effect*: Spot urine samples that did not account for dilution could have exposure misclassification. The misclassification is likely non-differential and not likely to bias in any specific direction. Children who had changed water since birth were excluded, but it was not specifically noted that the fluoride in the water source was stable over the years.
    - *Basis for rating:* Probably low risk of bias based on indirect evidence that exposure was consistently assessed using well-established methods that directly measured exposure.
- ***Outcome:***
    - *Rating:* Probably low risk of bias (+)
    - *Summary:* Intelligence is assessed using the Raven's Standard Progressive Matrices and categorized into five grade levels. Although it was not noted that the test was validated to the study population, the test is visual and would be applicable to most populations (+ for methods). There is no mention of blinding by test administrators or evaluators and the exposure groups come from different geographic areas. It was also not reported who measured the levels of fluoride from the home or urine samples. Correspondence with the study authors indicated that the outcome assessors were blind to the children's fluoride status (++ for blinding). Overall rating for methods and blinding = +.
    - *Basis for rating:* Probably low risk of bias based on indirect evidence that the outcome was blindly assessed using instruments that were valid and reliable in the study population.
- ***Selective Reporting:***
    - *Rating:* Definitely low risk of bias (++)
    - *Summary:* All outcomes outlined in the abstract, introduction, and methods are reported in sufficient detail.
    - *Basis for rating:* Definitely low risk of bias based on direct evidence that all measured outcomes were reported.
- ***Other potential threats:***
    - *Rating:* Probably low risk of bias (+)
    - *Summary:*
        - *Statistical analyses:* One way analysis of variance (ANOVA), simple linear regression, and multiple linear regression were used to compare mean intelligence grades by water fluoride levels and to assess the association between grades and urinary fluoride. Consideration of heterogeneity of variance (for ANOVA) was not reported. Regression diagnostics were not used to test model assumptions for linearity, normality, and homogeneity. Given the ordinal nature of the intelligence grade variable (score from 1 to 5), ordinal logistic regression would have been a more appropriate method. There was no adjustment for area-level clustering in multivariate analyses (although subjects were selected via stratified cluster sampling from two areas). Although the analysis used individual-level exposures rather than area-level exposures, if the exposure levels within a certain area are highly correlated (which might be expected), then the results might still be biased. However, the overall impact on the effect estimates is expected to be minimal given the use of individual-level data and adjustment for potential confounders.
        - *Other potential concerns:* None identified.

  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the statistical analyses were appropriate, and there were no other potential threats to risk of bias identified.
- ***Basis for classification as low risk-of-bias study overall:*** Probably low risk-of-bias ratings in confounding, exposure, and outcome. Study strengths include individual exposure measurements and the addressing of potential key confounders, but it was limited by the cross-sectional study design and lack of addressing dilution in the urine samples.

Seraj *et al.* (2012)

Study Details:

- ***Study design*:** Cross-sectional
- ***Population*:** Children aged 6–11 years
- ***Study area:*** five villages, Makoo, Iran
- ***Sample size:*** 293 children
- ***Data relevant to the review:*** IQ (mean and distribution) assessed by Raven's Colored Progressive Matrices and presented by fluoride area; beta was also provided for water fluoride.
- ***Reported association with fluoride exposure:*** Yes: Significant association between water fluoride and IQ score (adjusted β = −3.865; CIs not reported); significantly higher IQ score in normal area (97.77 ± 18.91) compared with medium (89.03 ± 12.99) and high (88.58 ± 16.01) areas.

Risk of Bias:

- **Author contacts:**
  - Authors were not contacted for additional information because it was not necessary.
- ***Population selection:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Subjects were selected from five villages in Makoo. The villages were stated to all be rural with similar general demographic and geographic characteristics and were comparable in terms of SES and parental occupations. Children were 6–11 years old. Age, gender, and education were taken into account in the analysis. No other characteristics were provided or discussed. Participation rates were not reported. There is indirect evidence that the populations were similar, and some possible differences were addressed.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that subjects were similar and recruited using the same methods during the same time frame.
- ***Confounding:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Age, gender, dental fluorosis intensity, and educational levels (child's and parents') were evaluated as potential confounders. Other potential confounders such as smoking were not discussed. Information was obtained from a detailed questionnaire. Lead was measured, but only found in low levels in the drinking water throughout the study regions. Iodine in the water was also stated to be measured and residents were receiving iodine-enriched salt. Arsenic was not addressed, but there is no evidence that

arsenic levels would vary across villages in this area. Based on water quality maps, co-exposure to arsenic is likely not a major concern in this area.

- *Potentially important study-specific confounders:* Arsenic.
  - *Direction/magnitude of effect*: Conceptually, if there were differential amounts of arsenic in the different villages, co-exposure to arsenic could bias the results with the direction of the bias dependent on where the arsenic was present; however, arsenic is not expected to be a major concern in this study area based on water quality maps.
- *Basis for rating:* Probably low risk of bias based on indirect evidence that the methods used to collect the information were valid and that key confounders including potential co-exposures were addressed or were not likely to be an issue in the study area.

- ***Attrition:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Attrition was low if it occurred. It was noted that 293 out of 314 children living in the villages were recruited. It is not clear if 21 children were excluded based on exclusion criteria or if they refused to participate; however, this accounts for less than 10% of the population and results were available for all 293 subjects.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that exclusion of subjects from analyses was adequately addressed, and reasons were documented when subjects were removed from the study or excluded from analyses.
- ***Exposure:***
  - *Rating:* Probably high risk of bias (-)
  - *Summary:* Exposure was primarily based on area of residence. Fluoride in the groundwater was analyzed by the SPADNS (Sulfophenylazo dihydroxynaphthalene-disulfonate) method, utilizing 4000 UV-Vis spectrophotometer in the environmental health engineering laboratory of the Public Health School of Tehran University of Medical Sciences. Specific details were not provided on methods of collection, samples locations, or if these locations represented the primary sources of drinking water for the subjects. Villages were categorized into normal (0.5–1 ppm), moderate (3.1±0.9 ppm), and high (5.2±1.1 ppm) fluoride based on the mean fluoride content of all seasons presumably for the stated 12-year time period. Subjects were stated to be long-life residents of the village. Dental fluorosis was also measured and increased in severity with fluoride levels; however, all areas had some degree of dental fluorosis. Although authors used an average fluoride level in varying seasons over presumably 12 years, they used a less-established method without reporting reliability or validity, nor did they provide data to indicate that the mean was truly representative of the fluoride levels over time and throughout the village. Although dental fluorosis severity increased with increasing fluoride levels, the data could also indicate potential exposure misclassification.
    - *Direction/magnitude of effect*: The presence of dental fluorosis in all groups indicates that there may have been different exposure in some children at a younger age. Although there were only about 20 children in the “normal” fluoride group with very mild to mild dental fluorosis, this could bias the results toward the null because those children may have experienced a higher level of

fluoride at some point. The other two fluoride groups were exposed to fluoride levels that likely exceeded those in the "normal" fluoride group.

- *Basis for rating:* Probably high risk of bias based on indirect evidence that exposure was assessed using insensitive methods.

- ***Outcome:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Intelligence was evaluated using the Raven's Color Progressive Matrices. This is a well-established method. Although the study authors did not provide data to indicate that the methods were valid in this study population, the test is designed to be culturally diverse. (+ for methods). The study report stated that test administrators were blinded. (++ for blinding). Overall rating for methods and blinding = +.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that outcomes were blindly assessed using instruments that were valid and reliable in the study population.
- ***Selective Reporting:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* All outcomes outlined in the abstract, introduction, and methods were reported. However, because they did not report the method for obtaining the betas in Table 4 of the study, it is not clear if these were adjusted or unadjusted betas.
  - *Basis for rating:* Probably low risk of bias based on direct evidence that all the study's measured outcomes were reported, but the results were not sufficiently reported.
- ***Other potential threats:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:*
    - *Statistical analyses:* Statistical methods for comparisons of IQ level by exposure groups were reasonable (ANOVA, post hoc test and Kruskal-Wallis test), but consideration of heterogeneity of variance was not reported. Clustering at the village levels was not accounted for in multivariate analyses which used area-level water fluoride levels. Because the exposure levels within a certain area are highly correlated (which might be expected), the results are likely to be biased. There was adjustment for some potential individual-level confounders, and the children were from five rural areas with similar general demographic and geographic characteristics and were comparable in terms of SES and parental occupations. These factors are expected to mitigate some of the impact of lack of accounting for clustering, and the overall impact on the effect estimates is expected to be minimal.
    - *Other potential concerns:* None identified.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the statistical analyses were appropriate and there were no other potential threats to risk of bias identified.
- ***Basis for classification as low risk-of-bias study overall:*** Probably low risk-of-bias ratings in confounding and outcome. Study strengths include addressing potential key confounders, but it was limited by the cross-sectional study design and the group-level exposure data.

Soto-Barreras *et al.* (2019)

Study Details:

- ***Study design*:** Cross-sectional
- ***Population*:** Children aged 9–10 years
- ***Study area:*** Chihuahua, Mexico
- ***Sample size:*** 161 children
- ***Data relevant to the review:*** Water fluoride, urinary fluoride, exposure dose, and dental fluorosis index by IQ grade.
- ***Reported association with fluoride exposure:*** No: Results were not presented to evaluate an association between fluoride exposure and IQ, but rather to compare fluoride levels within IQ grades. For this reason, the results for this study are not comparable to other studies that evaluated IQ scores by fluoride exposure levels. No significant differences in measured fluoride levels across IQ grades were observed.

Risk of Bias:

- **Author contacts:**
  - Authors were not contacted for additional information because it was not necessary.
- ***Population selection:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Subjects were selected using a multistage cluster sampling. During the first stage, 13 public elementary schools were randomly selected from a pool of 73 using a cluster sample design. Secondly, only fourth grade students were included. Authors stated that they wanted to keep the same grade level, but they were not specific as to why fourth graders were selected as opposed to any other grade. Lastly, only children whose parents or guardians attended and responded to the survey were included. There is no information provided on how the 13 schools selected may be similar or different from the 60 schools not selected. There is no information provided on the number of children in the fourth grade to know participant rates. It was only noted that 245 children were examined, but 161 were included after the exclusion rules were applied. Inclusion and exclusion criteria are presented. Reasons for exclusion do not appear to be related to exposure or outcome. Characteristics of participants and non-participants are not compared; however, characteristics of the 161 included children were provided and any differences were taken into account in the analysis.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the exposed groups were similar and were recruited using similar methods during the same time frame.
- ***Confounding:***
  - *Rating:* Probably high risk of bias (-)
  - *Summary:* No confounders were considered when evaluating fluoride associations with intelligence; they were only applied when evaluating fluoride levels and dental caries. Based on Table 4 of the study, there was no significant association between IQ grade and child's age, sex, parental education, or SES status. No other information was reported or considered. There is no information on potential co-exposures. Based on

water quality maps, the arsenic prediction indicates a greater than 50% probability of exceeding the WHO guidelines for arsenic of 10 µg/L in areas of Chihuahua, Mexico.

- *Potentially important study-specific confounders:* Arsenic.
  - *Direction/magnitude of effect*: The direction and magnitude of effects is unknown. There is potential for arsenic to occur in the study area, but it is not known how it relates to fluoride exposure. If they occur together in the water, it will bias away from the null; however, if they occurred in different areas, there is potential to bias toward the null.
- *Basis for rating:* Probably high risk of bias based on indirect evidence that there is potential for exposure to arsenic that was not sufficiently addressed.

- ***Attrition:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* A total of 161 of 245 children were included in the study. Exclusion criteria are presented and are unrelated to outcome or exposure. For the 161 children, there are no missing outcome data.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that exclusion of subjects from analyses was adequately addressed, and reasons were documented when subjects were removed from the study or excluded from analyses.
- ***Exposure:***
  - *Rating:* Probably low risk of bias (+);Probably high risk of bias (-)
  - *Summary:* **Urinary Fluoride (probably low risk of bias):** First morning void urine samples were collected based on NIOSH methods. Water samples were also stated to be collected, but it does not appear that methods followed any particular standard, and there is no indication that subjects were provided with collection containers. Analysis was based on a calibration curve using fluoride ion selective electrode. QC methods were mentioned. Based on results, there were values below detection limits, but LODs or % below LOD were not reported.

    Daily fluoride exposure (probably high risk of bias): Daily fluoride exposure was based on the water fluoride level, drinking water consumption (based on parental report of how many glasses of water consumed), and body weight.
    - *Direction/magnitude of effect*: Spot urine samples that did not account for dilution could have exposure misclassification. The misclassification is likely non-differential and is not likely to bias in any specific direction. Daily exposure was based partially on parental report of water consumption. The direction and magnitude of effect is unknown.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that exposure was consistently assessed using well-established methods that directly measured exposure. The daily fluoride exposure is probably high risk of bias because there is indirect evidence that the exposure was assessed using methods of unknown validity.
- ***Outcome:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Intellectual ability was evaluated using Raven's Colored Progressive Matrices by an independent examiner. Some details were provided, but it was not stated that the tests were assessed blind; however, there is no indication that subjects were from high fluoride areas and the assessor would not have knowledge of the urine or water fluoride

levels. Results for children were converted into a percentile according to age (details not provided) and overall scores were assigned an intellectual grade of I to V as described in the report.
    - *Basis for rating:* Probably low risk of bias based on indirect evidence that the outcome was blindly assessed using instruments that were valid and reliable in the study population.
- ***Selective Reporting:***
    - *Rating:* Definitely low risk of bias (++)
    - *Summary:* All outcomes outlined in the abstract, introduction, and methods were reported in sufficient detail.
    - *Basis for rating:* Definitely low risk of bias based on direct evidence that all measured outcomes were reported.
- ***Other potential threats:***
    - *Rating:* Probably low risk of bias (+)
    - *Summary:*
        - *Statistical analyses:* The Kolmogorov-Smirnov test was used to determine variable distribution. The Kruskal Wallis test was used to compare exposure levels between IQ grades with a Dunn's post hoc test. Multivariate logistic regression was used the estimate the association between presence of dental caries and various risk factors. Fluoride levels in drinking water and urine and fluoride exposure dose are compared across intellectual grades. Children were from 13 schools selected via stratified cluster sample design. There was no adjustment for clustering at the school level or for the sampling design. Although the analysis used individual-level exposures rather than area-level exposures, if the exposure levels within a certain school are highly correlated (which might be expected), then the results might still be biased. The large number of clusters (13 schools) makes clustering less of a concern and the impact on the effect estimates is expected to be minimal.
        - *Other potential concerns:* None identified.
    - *Basis for rating:* Probably low risk if bias based on indirect evidence that the statistical analyses were appropriate and there were no other potential threats to risk of bias identified.
- ***Basis for classification as low risk-of-bias study overall:*** Probably low risk-of-bias ratings in exposure and outcome. Study strengths include individual exposure measurements and outcomes blindly assessed, but is limited by the cross-sectional study design, lack of accounting for urine dilution, and by not addressing potential exposures to arsenic in the study area. Although the study is considered to have low potential for bias overall, the focus of the study was to evaluate the relationship between fluoride exposure and lower rates of dental caries. In terms of evaluating an association between fluoride exposure and IQ scores, the study is limited by the way that the data were reported.

Sudhir *et al.* (2009)

Study Details:

- ***Study design*:** Cross-sectional

- ***Population*:** Children aged 13–15 years
- ***Study area:*** Nalgonda district (Andhra Pradesh), India
- ***Sample size:*** 1,000 children
- ***Data relevant to the review:*** Mean IQ grade (not standard scores) or IQ distribution by water fluoride strata (<0.7, 0.7-1.2, 1.3-4.0, and >4.0 ppm).
- ***Reported association with fluoride exposure:*** Yes: Significant increase in mean and distributions of IQ grades (i.e., increase in proportion of children with intellectual impairment) with increasing drinking water fluoride levels.

Risk of Bias:

- **Author contacts:**
  - Authors were contacted in September of 2017 for additional information related to risk-of-bias evaluation, but no response was received.
- ***Population selection:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Children were selected from the same general population during the same time frame and were then broken down into nearly equal exposure groups. A cross-sectional study was conducted among 13–15-year-old school children of Nalgonda district, Andhra Pradesh between August and October 2006. Data were collected from the school children who were life-long residents of Nalgonda district, Andhra Pradesh and who consumed drinking water from the same source during the first 10 years of life. A stratified random sampling technique was used. The entire geographical area of Nalgonda district was divided into four strata based on different levels of naturally occurring fluoride in the drinking water supply. Children were randomly selected from schools in the different strata. It was noted that the 1,000 selected children were equally divided among all four strata, however, each group did not have 250 children (but instead 243−267 in each group). Participation rates are not reported. Exclusion criteria included: children who had a history of brain disease and head injuries, children whose intelligence had been affected by congenital or acquired disease, children who had migrated or were not permanent residents, children with orthodontic brackets, and children with severe extrinsic stains on their teeth. Age and gender data are presented in Table 1 of the study, but this information is not presented by the different fluoride groups.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that subjects were similar and were recruited using the same methods during the same time frame.
- ***Confounding:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Data were collected using a self-administered questionnaire and clinical examination. The self-administered questionnaire requested information on demographic data (appears to cover age and sex), permanent residential address, staple food consumed, liquids routinely consumed, and aids used for oral hygiene maintenance (fluoridated or nonfluoridated). SES was measured using the Kakkar socio-economic status scale (KSESS) with eight closed-ended questions related to parental education, family income, father's occupation, and other factors. All children were asked to fill out the form, and the answers obtained were scored using Kakkar socio-economic status

scoring keys. Based on this scoring, children were divided into three groups—lower class, middle class, or upper class. Age, sex, and SES were not found to be significantly associated with IQ. Other confounders including smoking were not addressed. Co-exposures such as arsenic and lead were not addressed; however, there is no indication that lead is a co-exposure in this population and arsenic is not likely a major concern in this area based on water quality maps.

- *Potentially important study-specific confounders:* Key confounders age, gender, and measures of SES were similar between exposure groups; however, arsenic was not taken into account. Arsenic often occurs in the drinking water along with fluoride in some Indian populations; however, based on water quality maps, this does not appear to be an issue in the Nalgonda district of Andhra Pradesh. Iodine deficiencies are not mentioned.
    - *Direction/magnitude of effect***:** Conceptually, the presence of arsenic would potentially bias away from the null if present with fluoride. Deficiencies in iodine would bias away from the null if present in areas of high fluoride, but toward the null if present in areas of non-high fluoride. Neither of these were considered issues in this study for reasons noted above.
- *Basis for rating:* Probably low risk of bias based on indirect evidence that the key confounders are considered, co-exposure to arsenic is likely not an issue in this area, and methods used for collecting the information were valid and reliable.

- ***Attrition:***
    - *Rating:* Definitely low risk of bias (++)
    - *Summary:* Results were available for the 1,000 children selected to participate.
    - *Basis for rating:* Definitely low risk of bias based on direct evidence of no attrition.
- ***Exposure:***
    - *Rating:* Probably low risk of bias (+)
    - *Summary:* Children were placed into one of four strata based on the level of fluoride in drinking water. Collection of water samples was done in the districts. The placement into strata was based on fluoride levels obtained from documented records of District Rural Water Works Department. Once the children were assigned to strata, it was confirmed that the fluoride level of their drinking water was within the strata assigned. This was done using the methodology followed in National Oral Health Survey and Fluoride Mapping 2002–2003. During the initial visits to the schools, the children were interviewed regarding their history of residence and source of drinking water from birth to 10 years. The first child meeting criteria was given a bottle for water collection and the next child was only given a bottle for collection if the water source was different than that of a previous child. Children were asked to collect the sample of water from the source that was used in the initial 10 years of their life and was collected the next day. It was not reported if all bottles were returned. The water samples collected were subjected to water fluoride analysis using an ion-specific electrode, Orion 720A fluoride meter at District Water Works, Nalgonda to confirm the fluoride levels in the water before commencement of clinical examination. LOD and QA/QC details were not reported.
        - *Direction/magnitude of effect***:** There is some potential for exposure misclassification based on recall of the children on the source of water used in

their first 10 years of life. The misclassification is likely non-differential and not likely to bias in any specific direction. Children who had changed water since birth were excluded, but it was not specifically noted that the fluoride in the water source was stable over the years.

- *Basis for rating:* Probably low risk of bias based on indirect evidence that exposure was consistently assessed using well-established methods that directly measured exposure.

- ***Outcome:***
  - *Rating:* Probably high risk of bias (NR)
  - *Summary:* The Raven's standard progressive matrices (1992 edition) was used to assess IQ. This Raven's test is a standard test and although there is no information provided to indicate that the methods were reliable and valid in the study population, this test was created to be culturally fair (+ for methods). Blinding or other methods to reduce potential bias were not reported (NR for blinding). No response was received to an e-mail request for clarification in September 2017. Overall rating for methods and blinding = NR.
  - *Basis for rating:* Probably high risk of bias based on indirect evidence that the outcome was not assessed blind and could bias the results.
- ***Selective Reporting:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* All outcomes outlined in the abstract, introduction, and methods are reported in sufficient detail.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that all measured outcomes were reported.
- ***Other potential threats:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:*
    - *Statistical analyses:* Chi-square test and Spearman rank correlation were used to assess the association between four different fluoride levels and IQ grades. Area-level exposures were used. Clustering of children within the four areas was not accounted for in the analysis; however, because multiple villages were included in each fluoride exposure level, clustering is less of a concern and the impact on the effect estimates is expected to be minimal.
    - *Other potential concerns:* None identified.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the statistical analyses were appropriate and there were no other potential threats to risk of bias identified.
- ***Basis for classification as low risk-of-bias study overall:*** Probably low risk-of-bias ratings in confounding and exposure. Study strengths include verification of exposure measurements and the addressing of potential key confounders, but it was limited by the cross-sectional study design and lack of information on blinding during outcome assessment.

Till *et al.* (2020)

Study Details:

- ***Study design*:** Prospective cohort
- ***Population*:** MIREC participants (pregnant mothers and their children aged 3–4 years)
- ***Study area:*** 10 cities, Canada
- ***Sample size:*** 398 mother−child pairs (247 from non-fluoridated areas, 151 from fluoridated areas; 200 breastfed as infants, 198 formula-fed as infants)
- ***Data relevant to the review:*** Adjusted linear regression models evaluating associations between IQ with water fluoride concentration (with or without adjusting for maternal urine) in formula-fed or breast-fed infants or by fluoride intake from formula.
- ***Reported association with fluoride exposure:*** Yes: Significantly lower performance IQ with water fluoride by breastfeeding status (adjusted βs = −9.26 formula-fed, −6.19 breastfed) and fluoride intake from formula (adjusted β = −8.76); significantly lower full-scale IQ with water fluoride in formula-fed (adjusted β = −4.40); no significant changes in full-scale IQ for water fluoride in breastfed children or fluoride intake from formula-fed children; no significant changes in verbal IQ scores with fluoride exposure.

Risk of Bias:

- **Author contacts:**
  - Authors were not contacted for additional information because it was not necessary.
- ***Population selection:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Pregnant women were recruited between 2008 and 2011 by the MIREC program from 10 cities across Canada. Inclusion and exclusion criteria were provided. Additional details were stated to be available in Arbuckle *et al.* (2013). A total of 610 children were recruited to participate in the developmental follow-up with 601 children completing all testing. The demographic characteristics of women included in the current analyses (n = 398) were not substantially different from the original MIREC cohort (N = 1945) or the subset without complete water fluoride and covariate data (n = 203). A table of characteristics of the study population is provided. Approximately half of the children lived in nonfluoridated cities and half lived in fluoridated cities.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that the exposed groups were similar and were recruited with the same methods during the same time frame.
- ***Confounding:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Covariates were selected a priori that have been associated with fluoride, breast feeding, and children's intellectual ability. Final covariates included child's sex and age at testing, maternal education, maternal race, second-hand smoke in the home, and HOME score. City was considered but was excluded from the models. Confounders that were not assessed include: parental mental health, iodine deficiency/excess, parental IQ, and co-exposure to arsenic and lead. Co-exposure to arsenic is less likely an issue in this Canadian population because the population mainly received water from municipal water supplies that monitor for lead and arsenic, and the lack of information

is not considered to appreciably bias the results. In addition, a previous study on this population (Green *et al.* 2019) conducted sensitivity analyses on co-exposures to lead and arsenic. Results from these sensitivity analyses support that co-exposures to lead and arsenic are not likely a major concern in this study population.

- *Potentially important study-specific confounders:* All key confounders were considered in this study.
  - *Direction/magnitude of effect*: Not applicable.
- *Basis for rating:* Probably low risk of bias based on direct evidence that key confounders were addressed and indirect evidence that the methods used to collect the information were valid and reliable and co-exposures were not an issue.

- ***Attrition:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Of 610 children, 601 (98.5%) in the MIREC developmental study who were ages 3–4 years completed the neurodevelopment testing. Of the 601 children who completed the neurodevelopmental testing, 591 (99%) completed the infant feeding questionnaire and 398 (67.3%) reported drinking tap water. It was noted that the demographic characteristics were not substantially different from the original MIREC cohort or the 203 subjects without complete water fluoride or covariate data.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that exclusion of subjects from analyses was adequately addressed, and reasons were documented when subjects were removed from the study or excluded from analyses.
- ***Exposure:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Information on breastfeeding was obtained via questionnaire at 30–48 months. Fluoride concentration in the drinking water was assessed by daily or monthly reports provided by water treatment plants. Water reports were first linked with mothers' postal codes and the daily or weekly amounts were averaged over the first 6 months of each child's life. Additional details can be found in Till *et al.* (2018). Maternal urinary exposure was used to assess fetal fluoride exposure. Procedures can be found in Green *et al.* (2019).
    - *Direction/magnitude of effect*: There is not any specific direction or magnitude of bias expected. Urinary fluoride levels are reflective of recent exposure. The possibility of the exposure misclassification would be similar in all subjects and would be non-differential. For the fluoride intake from formula, exposure was based on the fluoride levels in the water at the residence and the proportion of time that the infant was not exclusively breastfed. This exposure misclassification would also be non-differential.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that exposure was consistently assessed using well-established methods that directly measured exposure.
- ***Outcome:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Intelligence was tested using the Wechsler Preschool and Primary Scale of Intelligence III. This is appropriate for both the study population and age group. This is considered a gold standard test. It was not reported whether the evaluators were blind to the child's fluoride exposure status during the assessment. Although it is unlikely that

the assessors had knowledge of the specific drinking water levels or maternal urine levels, there is potential that the outcome assessors had knowledge of the city the child lived in and if the city was fluoridated or non-fluoridated. Correspondence with the study authors on the outcome assessment for Green *et al.* (2019) indicated that it was unlikely that the testers had knowledge of the city's fluoridation. The same is assumed here. Specific measurements included were identified.

- *Basis for rating:* Probably low risk of bias based on indirect evidence that the outcome was blindly assessed using instruments that were valid and reliable in the study population.

- ***Selective Reporting:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* All outcomes outlined in the abstract, introduction, and methods were reported in sufficient details.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that all measured outcomes were reported.
- ***Other potential threats:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:*
    - *Statistical analyses:* Regression diagnostics were used to test assumptions for linearity, normality, and homogeneity. There were two potential influential observations (based on Cook's distance), and sensitivity analyses re-estimated the models without these two variables. Effect modification by breastfeeding status was evaluated. Interestingly, all regression coefficients were divided by 2 to represent change in IQ per 0.5-mg/L change in fluoride. One concern is posed by the lack of accounting for city in the regression models, ideally as a random effect. The authors explored including city as a covariate in the models; however, city was not included either because it was strongly multi-collinear with water fluoride concentration (VIF > 20) (model 1, with water fluoride concentration) or because fluoride intake from formula is a function of water fluoride concentration (assessed at the city level) and was therefore deemed redundant (model 2). However, the models use city-level water fluoride concentrations—and, in sensitivity analyses, adjust for maternal urinary fluoride—which warrants exploration of city as a random effect rather than a fixed effect (as would be the case by having it included as a covariate). Even including individual-level maternal urinary fluoride might not fully account for lack of a city effect, given that the subjects were from six different cities, with half of them fully on fluoridated water. Hence, even individual-level exposures are likely to be correlated at the city level. Based on a previous analysis (Green *et al.* 2019), it is unlikely that exclusion of city from models (as a fixed or random effect) would significantly impact the effect estimates.
    - *Other potential concerns:* None identified.
  - *Basis for rating:* Probably low risk if bias based on indirect evidence that the statistical analyses were appropriate and there were no other potential threats to risk of bias identified.

- ***Basis for classification as low risk-of-bias study overall:*** Probably low risk-of-bias ratings in confounding, exposure, and outcome. Study strengths include individual exposure measurements, prospective cohort design, and the addressing of potential key confounders.

Trivedi *et al.* (2012)

Study Details:

- ***Study design*:** Cross-sectional
- ***Population*:** Children aged 12−13 years
- ***Study area:*** Kachchh, Gujarat, India
- ***Sample size:*** 84 children
- ***Data relevant to the review:*** Mean IQ scores and distribution by low and high fluoride villages.
- ***Reported association with fluoride exposure:*** Yes: Significantly lower mean IQ score in the high fluoride villages (92.53 ± 3.13) compared to the low fluoride villages (97.17 ± 2.54) in boys and girls combined (and by gender).

Risk of Bias:

- **Author contacts:**
  - Authors were contacted in September of 2017 to obtain additional information for risk-of-bias evaluation.
- ***Population selection:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* There is insufficient information provided on the sampling methods to determine if the populations were similar. Although it was noted that samples were obtained for groundwater quality from March to May of 2011, there is no indication that the children were selected at the same time or during a similar time frame. Correspondence with the author indicates that children were selected within a week of the water collection based on random selection of a school in the village. Study participants were selected from six different villages of the Mundra region of Gujarat, India. Subjects were grouped into high and low villages based on the level of fluoride in the drinking water of those villages. The number of subjects per village were not reported, but it was noted that there were 50 children in the low fluoride group and 34 children in the high fluoride group. It is not clear if the differences in numbers were based on different participation rates or if there were fewer children in the high fluoride villages. Recruitment methods including any exclusion criteria and participation rates were not provided. SES was stated to be low and equal based on questionnaire information, but the results were not provided. It should also be noted that only regular students (having attendance more than 80%) of standard 6^{th} and 7^{th} grades were selected, but it was not noted if attendance varied by village. Correspondence with the study author indicated that there was an average of 20 students per class with an average of 40 students per village. It appears that keeping the requirement for 80% attendance was a limiting factor that caused different numbers of children by area; however, this was applied similarly to both groups.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that subjects were similar and recruited using the same methods during the same time frame.

- ***Confounding:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Children were stated to be students of the 6th and 7th standard grades. Age was not addressed, but the children would all be of similar age based on the grades included. Results were reported for males and females separately as well as combined. SES and iodine consumption were stated to be analyzed via a questionnaire and were standardized on the basis of the 2011 census of India. Although it was noted in the abstract that the SES was equal (no data provided), the study report did not mention the iodine results. Although the study authors did not address arsenic or lead, they did provide physicochemical analyses for the water samples from the six different villages. While the authors did not specifically analyze lead or arsenic in the water samples, these physicochemical analyses suggest that differential lead or arsenic exposure were unlikely. Moreover, based on water quality maps, arsenic is not expected to be a major concern in this study area. Based on the information from the water quality maps and the physiochemical analysis of the water provided, there is indirect evidence that neither arsenic nor lead were a concern in this study population.
  - *Potentially important study-specific confounders:* Key confounders age, gender, and measures of SES were similar between exposure groups; however, arsenic was not taken into account. Arsenic often occurs in the drinking water along with fluoride in some Indian populations; however, based on water quality maps, arsenic does not appear to be an issue in the study area.
    - *Direction/magnitude of effect***:** Conceptually, the presence of arsenic would potentially bias away from the null if present with fluoride or toward the null if present in the reference group; however, for reasons noted above, arsenic is not considered a concern in this study population.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the methods used to collect the information were valid and reliable, that potential co-exposures were not an issue, and that key confounders were addressed.
- ***Attrition:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Results were provided for 84 children, but the methods do not indicate how many children were initially selected to participate nor were any exclusion criteria provided. It was noted in the results that 84 children had their groundwater and urine tested, but it was not noted if analyses were restricted to these children or if exposures were assessed in all the children who had IQ measurements. Correspondence with the study author indicated that the main reason for exclusion was a <80% attendance rate, with fluoride and IQ measured on all 84 children who met the criteria.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence of no attrition.
- ***Exposure:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Children in villages were grouped based on fluoride levels that were assessed in groundwater (low F villages versus high F villages). The average concentration of these levels was considered to be the levels in the drinking water with confirmation using urinary fluoride levels. The groundwater samples were selected to cover major parts of the taluka and represent overall groundwater quality. Ten samples were

obtained from each village. Fluoride was measured in the groundwater using ion exchange chromatography. Although urine levels were also significantly higher in the high fluoride village, no information was provided on how or when the urinary samples were obtained or how they were measured. However, correspondence with the study author indicated that the groundwater and urine fluoride levels were available for all 84 children indicating that the urine measures were available for the children that had IQ measures. The urine samples were stated to be collected at the same time that the second water sample was collected.

        - *Direction/magnitude of effect*: Fluoride levels were measured in both the drinking water and urine. Although there is some variability in the measurements, there is no overlap between the two groups and the urine and drinking water levels in the children support each other. Any potential exposure misclassification would be non-differential and direction and magnitude are unknown.
    - *Basis for rating:* Probably low risk of bias based on indirect evidence that exposure was consistently assessed using well-established methods that directly measured exposure.
- ***Outcome:***
    - *Rating:* Probably low risk of bias (+)
    - *Summary:* Outcome methods were only noted to be reported in Trivedi *et al.* (2007), which was scored as follows: IQ was measured in the children of both areas using a questionnaire prepared by Professor JH Shah, copyrighted by Akash Manomapan Kendra, Ahmedabad, India, and standardized on the Gujarati population with 97% reliability rate in relation to the Stanford-Binet Intelligence Scale (+ for methods). Blinding or other methods to reduce bias are not reported, but correspondence with the study author indicated that the teachers were blind to the status of fluoride. The teachers administered the tests in the presence of a research fellow. It is not completely clear who scored the tests, but it is assumed the teachers. (+ for blinding). Overall rating for methods and blinding = +.
    - *Basis for rating:* Probably low risk of bias based on indirect evidence that the outcomes were blindly assessed using instruments that were valid and reliable in the study population.
- ***Selective Reporting:***
    - *Rating:* Definitely low risk of bias (++)
    - *Summary:* All outcomes outlined in the abstract, introduction, and methods are reported in sufficient detail.
    - *Basis for rating:* Definitely low risk of bias based on direct evidence that all measured outcomes were reported.
- ***Other potential threats:***
    - *Rating:* Probably high risk of bias (-)
    - *Summary:*
        - *Statistical analyses:* Mean IQ scores in low and high fluoride villages were compared using a t-test. Consideration of heterogeneity of variances was not reported. Results are reported as means and standard errors of the means, with p-values for significant differences. Area-level exposures were used. There was no accounting for clustering of children within the villages, and comparative

analyses did not account for potential confounders. Urinary fluoride was not considered in the comparative analyses. The lack of individual exposure levels and the lack of accounting for clustering are likely to bias the standard error of the difference in mean IQ levels between the high and low fluoride villages and make the differences appear stronger than they actually are.

- *Basis for rating:* Probably high risk of bias based on indirect evidence that the statistical analyses did not account for clustering, and this lack of accounting could bias the association. There were no other potential threats to risk of bias identified.

- ***Basis for classification as low risk-of-bias study overall:*** Probably low risk-of-bias ratings in confounding, exposure, and outcome. Study strengths include individual exposure measurements and the addressing of potential key confounders, but the study was limited by the cross-sectional study design. Another limitation of the study was lack of accounting for clustering, which may bias the standard error of the differences making the effect appear stronger than it actually is; however, this does not change the nearly 5-point difference in IQ score between the two villages.

Wang *et al.* (2012)

Study Details:

- ***Study design*:** Cross-sectional
- ***Population*:** Children aged 8–13 years (possibly the same study population as Xiang *et al.* (2003a))
- ***Study area:*** Wamiao and Xinhuai villages located in Sihong County, Jiangsu Providence, China
- ***Sample size:*** 526 school children
- ***Data relevant to the review:*** Mean IQ and % low IQ (< 80) by total fluoride intake.
- ***Reported association with fluoride exposure:*** Yes: Significantly lower mean IQ in the endemic versus non-endemic regions, as reported in Xiang *et al.* (2003a); when high exposure group was broken into 4 exposure groups based on fluoride intake, a dose-dependent decrease in IQ and increase in % with low IQ observed; significant correlation between total fluoride intake and IQ ($r = -0.332$); for IQ<80, adjusted OR of total fluoride intake was 1.106 (95% CI: 1.052, 1.163).

Risk of Bias:

- **Author contacts:**
  - Authors were not contacted for additional information because it was not necessary.
- ***Population selection:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* The study appears to be the same study population as Xiang *et al.* (2003a) and Xiang *et al.* (2011); however, the study does not cite these studies as providing additional information and numbers of children differ; therefore, it may be a separate analysis on the same villages. The years of testing were not provided so it cannot be determined if study subjects are the same. Two villages, Wamiao and Xinhuai, located 64 km apart in Sihong County, Jiangsu Province were selected for the study. Wamiao is a village in a region with severe endemic fluorosis and Xinhuai is a village in a non-endemic fluorosis region. Neither village has fluoride pollution from coal or industrial sources. Villages were stated to be similar in terms of annual per capita income,

transportation, education, medical conditions, the natural environment, and lifestyle. All primary students ages 8–13 years currently in school in either village were surveyed with exclusions noted. Of 243 children from Wamiao, 236 (97.12%) were included, and of 305 children from Xinhuai, 290 (95.08%) were included. No table of subject characteristics was provided.

- *Basis for rating:* Probably low risk of bias based on indirect evidence that the exposure groups were similar and were recruited using the same methods within the same time frame, with direct evidence that there was no difference in participation/response rates.

- ***Confounding:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Logistic regression of low IQ rate and total fluoride intake adjusted for age and sex. Both villages had hand-pumped well water for drinking water, but the authors do not mention if arsenic was also present in the drinking water. However, a publication by Xiang *et al. (*2013) on this study area indicates that Xinhuai (the low fluoride area) had significantly higher arsenic levels compared to Wamiao (the endemic fluorosis area), which would bias toward the null. Areas were stated to be similar in annual per capita income, transportation, education, medical conditions, the natural environment, and lifestyle; however, no details were provided. This study did not address other co-exposures, but other studies on populations in these villages (Xiang *et al.* 2011, Xiang *et al.* 2003a) indicate that iodine and lead are not concerns.
  - *Potentially important study-specific confounders:* Arsenic often occurs in the drinking water along with fluoride in some Chinese populations; however, based on information provided in Xiang *et al.* (2013), arsenic concentrations were higher in the low fluoride area compared to the high fluoride area. Because there were significant effects on IQ observed in the high fluoride areas, the impact of co-exposure to arsenic is less of a concern. The presence of arsenic in the control village may cause an underestimation of the effect of fluoride, and despite this potential impact, there was still a significant association between fluoride exposure and IQ.
    - *Direction/magnitude of effect***:** Presence of arsenic in this study population would potentially bias toward the null.
  - *Basis for rating:* Probably low of risk bias because there is indirect evidence that the key confounders are take into account, methods used for collecting the information were valid and reliable, and co-exposures to arsenic and lead and iodine deficiency are not attributing to the effect observed in this area. The potential bias toward the null combined with the reporting of an effect increases confidence that there is an effect.

- ***Attrition:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Data are reported for all 526 children noted to be included in the study. There is a slight discrepancy in the reported total number of children from the high-fluoride village and the number of participants from the high-fluoride village between this paper (236 participated of 243 total children) and the 2003 and 2011 publications on the same study population (222 of 238). This discrepancy is not explained but is not expected to appreciably bias the results.

- *Basis for rating:* Probably low risk of bias based on indirect evidence that exclusion of subjects from analyses was adequately addressed, and reasons were documented when subjects were removed from the study or excluded from analyses.

- ***Exposure:***
  - *Rating:* Probably low risk of bias (+); Probably high risk of bias (-)
  - *Summary:* **Water fluoride (+ probably low risk of bias):** Exposure was based on drinking water levels and fluoride intake. Residents in the Wamiao village were divided into five groups based on fluoride levels in the drinking water. Clean, dry polyethylene bottles were used to collect 50 mL of drinking water from each student's household and fluoride content was measured.

    Total fluoride intake (- probably high risk of bias): Six families from each of the five Wamiao groups were randomly selected as dietary survey households. Intakes of various foods by each person at each meal and intakes of unboiled water, boiled water, and tea were surveyed for four consecutive days. Methods for food collection were described. Five representative households from each village were selected based on geographic location, population distribution, housing structure, and other conditions. Indoor air samples were collected once daily for five consecutive days; outdoor air was sampled at two points once daily for five days. Methods for determining fluoride content in samples were noted to follow specific guidelines. Calculation of total fluoride intake was stated to follow Appendix A of the People's Republic of China Health Industry Standard with some details provided. Although it is assumed the method is valid, it was not detailed how each fluoride determination was made for each subject, and it appears that total fluoride intake was determined based on data from select subjects and not all subjects.
    - *Direction/magnitude of effect***:** There is potential for exposure misclassification based on calculating fluoride intake based on measurements from a few select subjects rather than all subjects. The direction and magnitude of effect cannot be assessed based on the information provided.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that exposure was consistently assessed using well-established methods that directly measured exposure. The intake is probably high risk of bias because there is indirect evidence that the exposure was assessed using methods of unknown validity.

- ***Outcome:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* IQ of each child was measured with the Combined Raven's Test for Rural China (CRT-RC) (++ for methods). The test was stated to be administered to the children independently in a school classroom under the supervision of three exam proctors. Testing methods, testing language, and testing conditions were all in strict accordance with the CRT-RC guidebook. Major testing personnel received necessary training by the Psychology Department of East China Normal University. The children undergoing IQ testing and the test scorers were kept double-blinded throughout the testing process. (++ for blinding). Overall rating= ++.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that the outcome was blindly assessed using instruments that were valid and reliable in the study population.

- ***Selective Reporting:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* All outcomes outlined in the abstract, introduction, and methods are reported in sufficient detail.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that all measured outcomes were reported.
- ***Other potential threats:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:*
    - *Statistical analyses:* Logistic regression analysis was used to determine the odds of having low IQ with increasing fluoride intake. Analyses and methods are not well described. There is no mention of what tests were used for the mean IQ comparison by village; however, statistical software (SPSS) was used, suggesting appropriate tests were applied. Simple linear regression analyses were conducted to evaluate associations between total fluoride intake and children's IQ or low IQ rate. There is no evidence that regression diagnostics were used to test model assumptions for linearity, normality, and homogeneity. Clustering at the village level was not accounted for in the analyses. The overall impact of these factors on effect estimates is expected to be minimal given the use of individual-level data and adjustment for potential confounders.
    - *Other potential concerns:* None identified.
  - *Basis for rating:* Probably low risk if bias based on indirect evidence that the statistical analyses were appropriate and there were no other potential threats to risk of bias identified.
- ***Basis for classification as low risk-of-bias study overall:*** Definitely or probably low risk-of-bias ratings in confounding, exposure, and outcome. Study strengths include individual exposure measurements with blinding at outcome assessment but is limited by the cross-sectional study design and not using individual measurements to calculate fluoride intake. All key confounders were accounted for in the study design or analysis, but there is potential for the presence of arsenic to bias toward the null.

Wang *et al.* (2020b)

Study Details:

- ***Study design*:** Cross-sectional
- ***Population*:** School children aged 7–13 years
- ***Study area:*** Tianjin City, China (possibly a subset of the children from Yu *et al.* (2018))
- ***Sample size:*** 571 school children
- ***Data relevant to the review:*** IQ scores by urine and water fluoride levels.
- ***Reported association with fluoride exposure:*** Yes: Significant associations between IQ score and water fluoride (adjusted β = −1.587 per 1-mg/L increase) and urinary fluoride (adjusted β = −1.214 per 1-mg/L increase) in boys and girls combined based on both quartiles and continuous measures. No significant modification effect of gender.

Risk of Bias:

- **Author contacts:**
  - Authors were not contacted for additional information because it was not necessary.
- ***Population selection:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Subjects were from a cross-sectional study conducted in 2015, but no citation was provided on this cohort (presumably the Yu *et al.* (2018) cohort). It was noted that the subjects in that cohort were from districts with historically high or normal fluoride levels. Subjects for this study were selected by using a stratified and multistage random sampling approach. Brief description was provided. The study area consisted of three historically high fluoride areas and four nonendemic areas. A flow diagram was provided for inclusion and exclusion, but this detail was given for all children and not by area. Therefore, it cannot be determined if the participation differed by area. However, there was a 93% recruitment rate, and the 13 excluded due to missing data are not likely excluded due to exposure. Detailed characteristics of the study population are provided. Exclusion criteria included: "children who had congenital or acquired diseases affecting intelligence, or a history of cerebral trauma and neurological disorders, or those with a positive screening test history (like hepatitis B virus infection, Treponema palladium infection and Down's syndrome) and adverse exposures (smoking and drinking) during maternal pregnancy, prior diagnosis of thyroid disease, and children who had had missing values of significant factors (2.2%) were also excluded."
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that the exposed groups were recruited using similar methods during the same time frame and that any differences between the exposed groups were accounted for in the statistical analyses.
- ***Confounding:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Study authors noted that the study areas are not exposed to other neurotoxins such as lead, arsenic, or mercury nor were they iodine-deficient. Final models included child's age, child's gender, child's BMI, maternal and paternal education, household income, and low birth weight. Other potential confounders that were considered is unclear as they only noted that the confounders were selected based on current literature. Reasons for exclusion included history of disease affecting intelligence, history of trauma or neurological disorders, positive screening test history, or exposures such as smoking or drinking during pregnancy. Information was obtained by questionnaire or measurements. Variables such as parental BMI, behavioral and mental health disorders, IQ, and quantity and quality of the caregiving environment were not addressed.
  - *Potentially important study-specific confounders:* All key confounders were considered in this study.
    - *Direction/magnitude of effect***:** Not applicable.
  - *Basis for rating:* Probably low risk of bias because there is direct evidence that the key confounders are taken into account, indirect evidence that the methods for collecting the information were valid and reliable, and co-exposure to arsenic is not an issue in this area.

- ***Attrition:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* A detailed chart of the recruitment process is presented. The study had a 93% recruitment rate and only 2.2% of subjects with missing data for certain covariates were excluded.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that exclusion of subjects from analyses was adequately addressed, and reasons were documented when subjects were removed from the study or excluded from analyses.
- ***Exposure:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Children provided spot urine samples, presumably at the time of examination. Water samples were randomly collected from public water supplies in each village. Fluoride concentrations were analyzed using fluoride ion-selective electrode according to the national standardized method in China. There is no indication if the urine samples accounted for dilution.
    - *Direction/magnitude of effect***:** Not accounting for dilution could cause there to be some exposure misclassification. The direction and magnitude would depend on where the differences occurred.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that exposure was consistently assessed using acceptable methods that provide individual levels of exposure.
- ***Outcome:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Assessments of IQ scores were conducted by graduate students at the School of Public Health, Tongji Medical College at the Huazhong University of Science and Technology. Each team member was assigned a single task, meaning that only one person would have conducted the IQ tests. A Combined Raven's Test for Rural China was used. Therefore, the test was appropriate for the study population (++ for method). It was note that the examiner was trained and blind to the exposure (++ for blinding). Overall = ++
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that the outcome was blindly assessed using instruments that were valid and reliable in the study population.
- ***Selective Reporting:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* All outcomes in the abstract, introduction, and methods are reported in sufficient details.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that all measured outcomes were reported.
- ***Other potential threats:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:*
    - *Statistical analyses:* Logistic and multivariate regression models accounting for potential confounders were used. Results are presented as betas or ORs and 95% CIs. Regression diagnostics were conducted for all models, including

examination of multicollinearity, heteroscedasticity, and influential observations. Mediation and interaction analyses were appropriate. There is no evidence that the stratified and multistage random sampling approach for subject selection was accounted for in the analyses by using sampling weights or accounting for clustering using random effect models; however, selected villages are similar in population and general demographic characteristics. Given the use of individual-level data and adjustment for potential confounders, the impact on the regression coefficients is likely to be minimal.
        - *Other potential concerns:* None identified.
    - *Basis for rating:* Probably low risk of bias based on indirect evidence that the statistical analyses were appropriate and no other potential threats to risk of bias were identified.
- ***Basis for classification as low risk-of-bias study overall:*** Definitely or probably low risk-of-bias ratings in confounding, exposure, and outcome. Study strengths include individual exposure measurements but is limited by the cross-sectional study design and lack of accounting for urine dilution. All key confounders were considered in the study design or analysis.

Xiang *et al.* (2003a)

Study Details:

- ***Study design*:** Cross-sectional
- ***Population*:** Children aged 8–13 years
- ***Study area:*** Wamiao and Xinhuai villages located in Sihong County, Jiangsu Providence, China
- ***Sample size:*** 512 school children
- ***Data relevant to the review:*** Comparison of IQ (mean and distribution) between Wamiao County (a severe endemic fluorosis area) and Xinhuai County (non-endemic fluorosis area); additional breakdown of the Wamiao area into 5 water fluoride exposure groups.
- ***Reported association with fluoride exposure:*** Yes: Significantly lower IQ scores observed with water fluoride levels of 1.53 mg/L or higher. Percent of subjects with IQ scores below 80 was significantly increased at water fluoride levels of 2.46 mg/L or higher. Significant inverse correlation between IQ and urinary fluoride (Pearson correlation coefficient −0.164). Mean IQ scores for children in the non-endemic region (100.41 ± 13.21) were significantly higher than the endemic region (92.02 ± 13.00).

Risk of Bias:

- **Author contacts:**
    - Authors were not contacted for additional information because it was not necessary.
- ***Population selection:***
    - *Rating:* Probably low risk of bias (+)
    - *Summary:* Two villages, Wamiao and Xinhuai, located 64 km apart in Sihong County, Jiangsu Province were selected for this study, which was conducted between September and December 2002. Wamiao is located in a severe fluorosis endemic area, and Xinhuai is located in a non-endemic fluorosis area. Neither village has fluoride pollution from burning coal or other industrial sources. All eligible children in each village were included; children who had been absent from either village for 2 years or longer or who had a history of brain disease or head injury were excluded. In Wamiao, 93% of the

children (222 out of 238) were included for the study; in Xinhuai, 95% were included (290 out of 305). The children in Wamiao were divided into five subgroups according to the level of fluoride in their drinking water: <1.0 mg/L (group A), 1.0–1.9 mg/L (group B), 2.0–2.9 mg/L (group C), 3.0–3.9 mg/L (group D), and >3.9 mg/L (group E). Children in Xinhuai (0.18–0.76 mg F/L in the drinking water) served as a control group (group F). Demographic characteristics are not presented, and statistical analyses are not adjusted, but mean IQ scores are stratified by child's age, child's gender, family income, and parental education.

- *Basis for rating:* Probably low risk of bias based on indirect evidence that the exposure groups were similar and were recruited using the same methods within the same time frame, with direct evidence that there was no difference in participation/response rates.

- ***Confounding:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Although information was stated to be collected on personal characteristics, medical history, education levels of the children and parents, family SES, and lifestyle, only child's gender, child's age, family income, and parental education were addressed. Other potential co-exposures, such as arsenic, were not addressed. A separate publication in 2003 [(Xiang *et al.* 2003b), letter to the editor], indicated that blood lead levels were not significantly different between the two areas. Although arsenic was not addressed specifically in this publication, Xiang *et al.* (2013) measured both fluoride and arsenic in the Wamiao and Xinhuai areas. Xinhuai (the low fluoride area) had significantly higher arsenic levels compared to Wamiao (the endemic fluorosis area). This is likely to bias toward the null; however, the study observed a significantly lower IQ score in the endemic fluorosis area. Iodine was tested in a subset of the children and found not to be significantly different between the two groups.
  - *Potentially important study-specific confounders:* Arsenic often occurs in the drinking water along with fluoride in some Chinese populations; however, based on information provided in Xiang *et al.* (2013), arsenic concentrations were higher in the low fluoride area compared to the high fluoride area. Because there were significant effects on IQ observed in the high fluoride areas, the impact of co-exposure to arsenic is less of a concern. The presence of arsenic in the control village may cause an underestimation of the effect of fluoride, and despite this potential impact, there was still a significant association between fluoride exposure and IQ.
    - *Direction/magnitude of effect***:** Presence of arsenic in this study population would potentially bias towards the null.
  - *Basis for rating:* Probably low risk of bias because there is indirect evidence that the key confounders are taken into account, methods used for collecting the information were valid and reliable, and co-exposures to arsenic and lead and iodine deficiency are not attributing to the effect observed in this area. The potential bias toward the null combined with the reporting of an effect increases confidence that there is an effect.

- ***Attrition:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Data are complete. IQ results were reported for all 512 children included in the study (222 in the endemic area and 290 in the nonendemic area).

- *Basis for rating:* Definitely low risk of bias based on direct evidence that there was no attrition.

- ***Exposure:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Exposure was based on drinking water and urinary levels of fluoride. The two study areas were selected to reflect a severe endemic area and a nonendemic area. Drinking water was collected from wells and early-morning spot urine samples were collected from a randomly-selected subsample of children. Both water and urine samples were measured using fluoride ion-selective electrode, but no quality control was discussed. Both absolute and creatinine-adjusted urine results were reported.
    - *Direction/magnitude of effect***:** There is potential for exposure misclassification because only current levels were assessed. Migration of subjects in or out of the area was not assessed, but the study authors noted that, if the children had been absent from the village for 2 or more years, they were excluded. Misclassification would likely be non-differential, which could bias the results in either direction.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that exposure was consistently assessed using well-established methods that directly measured exposure.
- ***Outcome:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* The IQ of each child was measured with the Combined Raven's Test for Rural China (CRT-RC) (++ for methods). The test was stated to be administered to the children independently in a school classroom, in a double-blind manner, under the supervision of an examiner and two assistants, and in accordance with the directions of the CRT-RC manual regarding test administration conditions, instructions to be given, and test environment. (++ for blinding). Overall rating= ++
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that the outcome was blindly assessed using instruments that were valid and reliable in the study population.
- ***Selective Reporting:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* All outcomes outlined in the abstract, introduction, and methods are reported in sufficient detail.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that all measured outcomes were reported.
- ***Other potential threats:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:*
    - *Statistical analyses:* There is no mention of the tests conducted, but data were stated to be analyzed using SAS suggesting appropriate tests were applied. Results provided in the tables indicate that t-tests comparing IQ values between the villages (overall and by gender) were conducted, but it was not reported that heterogeneity of variance was assessed. In addition, correlations between IQ and age, family income, and parents' education level were tested with Pearson's correlation. There is no evidence that a test for trend was conducted

to evaluate the stated "significant inverse concentration-response relationship between the fluoride level in drinking water and the IQ of children."

- A potential concern raised by the NASEM (2020) peer review was the lack of accounting for relationships in exposure between persons from the same village. Given only two villages were included and the analyses consisted of village-level comparisons (no use of individual-level covariate data), it is likely that the standard error of the difference in mean IQ between fluoride in water exposure groups will be biased, making differences appear stronger than they actually are. Without controlling for village effects and given the large differences in fluoride concentrations and IQ levels between villages, the apparent dose-response relationship could be due to a village effect in addition to a fluoride effect. However, the dose-response relationship is apparent within the "exposed" village, diminishing the concern for a village-only effect and likely minimizing the impact on the effect estimates.
- *Other potential concerns:* None identified.

- *Basis for rating:* Probably low risk of bias based on indirect evidence that statistical analyses were appropriate and that there were no other threats to risk of bias.

- ***Basis for classification as low risk-of-bias study overall:*** Definitely or probably low risk-of-bias ratings in confounding, exposure, and outcome. Study strengths include individual exposure measurements and outcomes blindly assessed but is limited by the cross-sectional study design and lack of accounting for urine dilution. All key confounders were considered in the study design or analysis, but there is potential for the presence of arsenic to bias toward the null.

Xiang *et al.* (2011)

Study Details:

- ***Study design*:** Cross-sectional
- ***Population*:** Children aged 8–13 years (same study population as Xiang *et al.* 2003a)
- ***Study area:*** Wamiao and Xinhuai villages located in Sihong County, Jiangsu Providence, China
- ***Sample size:*** 512 school children
- ***Data relevant to the review:*** Mean IQ scores and odds ratio for having an IQ < 80 presented by serum fluoride quartiles.
- ***Reported association with fluoride exposure:*** Yes: Significant linear trend across quartiles of serum fluoride and children's IQ score < 80 (adjusted ORs for Q1 and Q2; Q1 and Q3; and Q1 and Q4, respectively: 1; 2.22 [95% CI: 1.42, 3.47]; and 2.48 [95% CI: 1.85, 3.32]); significant effects observed at ≥ 0.05 mg/L serum fluoride.

Risk of Bias:

- **Author contacts:**
  - Authors were not contacted for additional information because it was not necessary.
- ***Population selection:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* The study population is the same as that was used in the Xiang *et al.* (2003a) study, but a few more measurements were available and different analyses were conducted. The comparison population is considered the same as previously based on

the study populations being recruited from similar populations, using similar methods, during the same time frame. Demographic characteristics were not provided.

- *Basis for rating:* Probably low risk of bias based on indirect evidence that the exposure groups were similar and were recruited using the same methods within the same time frame, with direct evidence that there was no difference in participation/response rates.

- ***Confounding:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* As was noted in the 2003 publication, information was collected on personal characteristics, medical history, education levels in the children and parents, family SES, and lifestyle. In the logistic regression model, age and gender were adjusted in the analysis. In the previous report, no significant associations were observed between groups for family income and parents' education. Urinary iodine and blood lead levels were also stated to be measured and were noted not to be significantly different between the groups. Although the iodine levels were reported in the previous publication, the lead levels were not reported nor were the methods. Lead information is reported in a letter to the editor (Xiang *et al.* 2003b) and was not significantly different between the areas. Although arsenic was not addressed specifically in this publication, Xiang *et al.* (2013) measured both fluoride and arsenic in the Wamiao and Xinhuai areas. Xinhuai (the low fluoride area) had significantly higher arsenic levels compared to Wamiao (the endemic fluorosis area). This is likely to bias toward the null; however, the study observed a significantly lower IQ score in the endemic fluorosis area and with increasing serum fluoride.
  - *Potentially important study-specific confounders:* Arsenic often occurs in the drinking water along with fluoride in some Chinese populations; however, based on information provided in Xiang *et al.* (2013), arsenic concentrations were higher in the low fluoride area compared to the high fluoride area. Because there were significant effects on IQ observed in the high fluoride areas, the impact of co-exposure to arsenic is less of a concern. The presence of arsenic in the control village may cause an underestimation of the effect of fluoride, and despite this potential impact, there was still a significant association between fluoride exposure and IQ.
    - *Direction/magnitude of effect***:** Presence of arsenic in this study population would potentially bias toward the null.
  - *Basis for rating:* Probably low of risk bias because there is indirect evidence that the key confounders are taken into account, methods used for collecting the information were valid and reliable, and co-exposures to arsenic and lead and iodine deficiency are not attributing to the effects observed in this area. The potential bias toward the null combined with the reporting of an effect increases confidence that there is an effect.
- ***Attrition:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Data are reported for all 512 children noted to be included in the study.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that there was no attrition.
- ***Exposure:***
  - *Rating:* Probably low risk of bias (+)

- *Summary:* Fluoride levels were measured in serum with a fluoride ion-selective electrode. A fasting venous blood sample was used. No details are provided on validation (including correlation with drinking water levels) or QA. Children who did not reside in their village for at least 2 years were excluded. Results were provided in quartiles, but they combined the lower two quartiles. After combining the two lower quartiles into one, the exposure levels ranged from <0.05 mg/L (Q1 + Q2) to >0.08 mg/L (Q4).
  - *Direction/magnitude of effect***:** Serum fluoride may not be the best estimate for exposure. There is potential for exposure misclassification because only current levels were assessed. Migration of subjects in or out of the area was not assessed, but the study authors noted that, if the children had been absent from the village for 2 or more years, they were excluded. Misclassification would likely be non-differential, which could bias results in either direction.
- *Basis for rating:* Probably low risk of bias based on indirect evidence that exposure was consistently assessed using well-established methods that directly measured exposure.

- ***Outcome:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* IQ was assessed as part of the 2003 evaluation. IQ was measured with the Combined Raven's Test for Rural China which is appropriate for this population (++ for methods). Although this study does not provide details, the original study article from 2003 provides specific details. The study authors indicate in the 2003 publication that the tests were conducted in a double-blind manner and these are the same results and population (++ for methods). Overall rating=++
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that the outcome was blindly assessed using instruments that were valid and reliable in the study population.
- ***Selective Reporting:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* All outcomes outlined in the abstract, introduction, and methods are reported in sufficient detail.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that all measured outcomes were reported.
- ***Other potential threats:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:*
    - *Statistical analyses:* Statistical analyses conducted were appropriate for the study. Chi square tests were used to compare categorical variables, and multiple logistic regression was used to evaluate the association between serum fluoride levels and risk of low IQ. A potential concern raised by the NASEM (2020) peer review was the lack of accounting for relationships in exposure between persons from the same village. Although only two villages were included, in the analyses which consisted of village-level comparisons it is likely that the standard error of the difference in mean IQ between villages will be biased. This is less of a concern for the mean IQ comparisons across quartiles of serum fluoride levels, and for the logistic regression analyses of risk of low IQ and

individual-level serum fluoride levels. Without controlling for village effects and given the large differences in fluoride concentrations and IQ between villages, the apparent dose-response relationship could be due to a village effect in addition to a fluoride effect. However, the dose-response relationship is still present within the "exposed" village, diminishing the concern for a village-only effect and likely minimizing the impact on the effect estimates.

        - *Other potential concerns:* None identified.
    - *Basis for rating:* Probably low risk if bias based on indirect evidence that the statistical analyses were appropriate and there were no other potential threats to risk of bias identified.
- ***Basis for classification as low risk-of-bias study overall:*** Definitely or probably low risk-of-bias ratings in confounding, exposure, and outcome. Study strengths include individual exposure measurements with blinding at outcome assessment but is limited by the cross-sectional study design and use of serum concentrations. All key confounders were considered in the study design or analysis, but there is potential for the presence of arsenic to bias toward the null.

Yu *et al.* (2018)

Study Details:

- ***Study design*:** Cross-sectional
- ***Population*:** Children aged 7–13 years
- ***Study area:*** Tianjin City, China
- ***Sample size:*** 2,886 school children
- ***Data relevant to the review:*** IQ for normal (≤ 1 mg/L) versus high (> 1 mg/L) water fluoride; betas for IQ score by water and urine fluoride groupings; ORs by IQ category using water and urine fluoride levels.
- ***Reported association with fluoride exposure:*** Yes: Significant difference in mean IQ scores in high water fluoride areas (>1.0 mg/L; 106.4 ± 12.3 IQ) compared to the normal water fluoride areas (≤1.0 mg/L; 107.4 ± 13.0) water fluoride areas. Distribution of IQ scores was also significantly different (p = 0.003). Every 0.5-mg/L increase in water fluoride (between 3.40 and 3.90 mg/L) was associated with a 4.29 lower IQ score (95% CI: −8.09, −0.48).

Risk of Bias:

- **Author contacts:**
    - Authors were contacted in September 2018 to obtain additional information for the risk-of-bias evaluation.
- ***Population selection:***
    - *Rating:* Definitely low risk of bias (++)
    - *Summary:* School children (2,886), aged 7–13 years, were recruited from the rural areas of Tianjin City, China. After exclusion, 1,636 children were assigned to the "normal-fluoride" exposure group and 1,250 were assigned to the "high-fluoride" exposure group based on a cut-off water fluoride level of 1.0 mg/L. A multi-stage random sampling technique, stratified by area, was performed to select representative samples among local children who were permanent residents since birth. Detailed characteristics of the study population are provided. Exclusion criteria included: 1) children who had

congenital or acquired diseases affecting intelligence, 2) children with a history of cerebral trauma and neurological disorders, 3) children with a positive screening test history (like hepatitis B virus infection, Treponema palladium infection and Down's syndrome), and 4) children with adverse exposures (smoking and drinking) during maternal pregnancy. A table of characteristics was provided by fluoride level with differences adjusted in the analysis.

- *Basis for rating:* Definitely low risk of bias based on direct evidence that the exposed groups were recruited using similar methods during the same time frame and that any differences between the exposed groups were considered in the statistical analyses.

- ***Confounding:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Demographic data were collected by trained investigators during a face-to-face interview with the recruited children and their parents. Questionnaires were not stated to be validated. The developmental status of the children was further assessed by calculation of BMI, and all measurements were conducted by nurses based on recommended standard methods. Variables that presented differential distribution between the normal-fluoride and high-fluoride exposure groups were adjusted in the linear regression analysis of IQ data and included age, sex, paternal and maternal education levels, and low birth weight. Children exposed to smoking in utero were excluded from the study. Sensitivity analyses were conducted by modifying covariates adjusted in multivariable models among demographics (age and sex); development (BMI); socioeconomics (maternal education, paternal education, and household income); history of maternal disease during pregnancy (gestational diabetes, malnutrition, and anemia); and delivery conditions (hypoxia, dystocia, premature birth, post-term birth, and low birth weight). None of the study sites selected were in areas endemic for iodine deficiency disorders nor were other potential neurotoxins like lead, arsenic, and mercury present. Variables such as parental BMI and behavioral and mental health disorders were not addressed.
  - *Potentially important study-specific confounders:* All key confounders were considered in this study.
    - *Direction/magnitude of effect***:** Not applicable.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that methods of obtaining the information were valid and reliable and direct evidence that all key confounders and co-exposures were addressed.
- ***Attrition:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* There were 1,636 children assigned to the "normal-fluoride" exposure group based on water fluoride, and 1,250 children were assigned to the "high-fluoride" exposure group. Exclusion from the original group of 2,886 children was adequately described. A total of 2,380 children provided urine samples. There is no indication that the data presented excludes any additional children or urine samples, but results do not indicate a sample size for all results.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that exclusion of subjects from analyses was adequately addressed, and reasons were documented when subjects were removed from the study or excluded from analyses.

- ***Exposure:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* According to the annual surveillance data from the CDC, the drinking water sources and water fluoride concentrations in each village had remained at stable levels over the past decade. During the investigation, water samples were collected randomly from the public water supplies in each village. Spot (early-morning) urine samples from every child and water samples from each village were collected in pre-cleaned, labeled polythene tubes and transported to the lab within 24 hours while frozen. Samples were stored at −80°C until analysis. Concentrations of fluoride ions (mg/L) were analyzed using the national standardized ion-selective electrode method in China; the detection limit was 0.01 mg/L. Samples were diluted with an equal volume of total ionic strength adjusted buffer (TISAB) of pH 5–5.5 for optimal analysis. Double-distilled deionized water was used throughout the experiment. There is no reporting of any QC methods.
    - *Direction/magnitude of effect***:** Spot urine samples may lead to non-differential exposure misclassification. The large population size likely dilutes any potential effects of occasional misclassification. Because the drinking water sources of fluoride had been noted to be stable for the past decade and the children were 13 years or younger, there would only be exposure misclassification if there was a lot of migration between areas.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that exposure was consistently assessed using well-established methods that directly measured exposure.
- ***Outcome:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* IQ scores were measured using the second edition of Combined Raven's Test-The Rural in China (CRT-RC2) for children aged 7–13 years (++ for methods). The test was completed by each participant within 40 minutes according to the instruction manual. For each test, 40 children were randomly allocated to one classroom to take the test independently under the supervision of four trained professionals. There is no mention of whether the evaluators were blinded to the fluoride group of each child (normal vs. high fluoride) or whether there were steps taken to ensure consistency in scoring across the evaluators. It is also not clear if the 40 children randomly assigned to the classroom were specific to the village or if a local center was used. Correspondence with the study authors indicated that the four professionals worked together throughout the examination without knowledge of the child's fluoride exposure (++ for blinding).
  - *Basis for rating:* Definitely low risk of bias based on the direct evidence that the outcome was blindly assessed using instruments that were valid and reliable.
- ***Selective Reporting:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* All outcomes outlined in the abstract, introduction, and methods are reported in sufficient detail.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that all measured outcomes were reported.
- ***Other potential threats:***
  - *Rating:* Probably low risk of bias (+)

- *Summary:*
  - *Statistical analyses:* Statistical analyses used were appropriate for the study. Univariate and multivariable piecewise linear regression models were used to estimate the associations between water fluoride or urinary fluoride levels and IQ scores. Multiple logistic regression analysis was used to evaluate the association between water or urinary fluoride levels and IQ degree using the normal intelligence group as the control. Sensitivity analyses were conducted. There is no evidence that residual diagnostics were used to examine model assumptions or that the complex sampling design (stratified multistage random sampling) was accounted for in the analysis using sampling weights and adjustment for clustering. The impact of these factors on the effect estimates is expected to be minimal given the use of individual-level data and adjustment for and numerous potential confounders.
  - *Other potential concerns:* None identified.
- *Basis for rating:* Probably low risk if bias based on indirect evidence that the statistical analyses were appropriate and there were no other potential threats to risk of bias identified.

- ***Basis for classification as low risk-of-bias study overall:*** Definitely or probably low risk-of-bias ratings in confounding, exposure, and outcome. Study strengths include individual exposure measurements with blinding at outcome assessment but is limited by the cross-sectional study design and lack of accounting for urine dilution. All key confounders including potential co-exposures were considered in the study design or analysis.

Zhang *et al.* (2015b)

Study Details:

- ***Study design*:** Cross-sectional
- ***Population*:** Children aged 10–12 years
- ***Study area:*** Tianjin City, China
- ***Sample size:*** 180 children
- ***Data relevant to the review:*** IQ by control and high fluoride groups; IQ correlations with water, serum, or urinary fluoride levels; betas for IQ with urinary fluoride levels (by genotypes)
- ***Reported association with fluoride exposure:*** Yes: S Significant correlation between IQ score and children's serum fluoride (r = –0.47) and urinary fluoride (r = –0.45); significant difference in mean IQ score for high-fluoride area (defined as >1 mg/L in drinking water; 102.33 ± 13.46) compared with control area (<1 mg/L; 109.42 ± 13.30).

Risk of Bias:

- **Author contacts:**
  - Authors were not contacted for additional information because it was not necessary.
- ***Population selection:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary*: Subjects were similar and recruited during the same time frame using the same methods. Authors recruited schoolchildren from a high fluoride area (1.40 mg/L) and a control area (0.63 mg/L) in Tianjin City, China. In accordance with the principles of

matching social and natural factors such as educational standard, economic situation, geological environments as much as possible, two areas with different fluoride concentrations in the groundwater were selected by a stratified cluster random sampling of this region. A total of 180 5th grade children aged 10 to 12 years from two primary schools located 18 km apart in the Jinnan District were recruited—Gegu Second Primary School (from an endemic fluorosis area) and Shuanggang Experimental Primary School (from a non-endemic fluorosis area). The areas are not affected by other drinking water contaminants, such as arsenic or iodine. All subjects were unrelated ethnic Han Chinese and residents in Tianjin with similar physical and mental health status. The authors excluded subjects with known neurological conditions including pervasive developmental disorders and epilepsy. Descriptive statistics of the study population are presented by exposure group in Table 1 of the study. A number of potential differences are taken into account in the statistical analyses.

- *Basis for rating*: Definitely low risk of bias based on direct evidence that the exposure groups were similar and recruited using similar methods during the same time frame.

- **Confounding:**
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Covariates included in the statistical models were child's age, child's gender, educational levels of parents, drinking water fluoride (mg/L), and levels of thyroid hormones (T3, T4, and TSH). Authors report that the study areas are not affected by other contaminants such as arsenic or iodine and residents were of similar physical and mental health status. Other important confounders (maternal demographics, smoking, reproductive health) were not considered. Covariate data were obtained from a study questionnaire.
  - *Potentially important study-specific confounders:* All key confounders were considered in this study.
    - *Direction/magnitude of effect*: Not applicable.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the methods used to collect the information were valid and reliable and direct evidence that key confounders including potential co-exposures were addressed.
- ***Attrition:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Results are complete for the 180 children selected for the study.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that there was no attrition.
- ***Exposure:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Drinking water samples (10 mL) were collected from the tube wells of each child's household. Three fasting venous blood samples were also collected. Urine samples were collected in the early morning before breakfast. Fluoride contents in drinking water (W-F), serum (S-F), and urine (U-F) were measured using an ion analyzer EA940 with a fluoride ion-selective electrode (Shanghai constant magnetic electronic technology Co, Ltd, China) according to the China standard GB 7484-87. All reference solutions for the fluoride determinations were double-deionized water. Parallel samples were set for determination and averages were taken. The quantitation limits of this

method for W-F, S-F, and U-F were 0.2, 0.012, and 0.5 mg/L, respectively. Recovery rates for this method were in the range of 94.3%–106.4%. The intra- and inter-assay coefficients of variation for fluoride were 2.7% and 6.7%, respectively. Dilution of the urinary fluoride was not addressed.
        - *Direction/magnitude of effect*: Not applicable.
    - *Basis for rating:* Definitely low risk of bias based on direct evidence that the exposure was consistently assessed using well-established methods that directly measured exposure.
- ***Outcome:***
    - *Rating:* Definitely low risk of bias (++)
    - *Summary:* A Combined Raven's Test for Rural China (CRT-RC) was taken to evaluate the IQ of each child (++ for methods). The study report stated that all tests were administered at school by a trained examiner who was masked to participants' drinking water fluoride levels (++ for blinding). Overall rating for methods and blinding=++.
    - *Basis for rating:* Definitely low risk of bias based on direct evidence that the outcome was blindly assessed using instruments that were valid and reliable in the study population.
- ***Selective Reporting:***
    - *Rating:* Definitely low risk of bias (++)
    - *Summary:* All results outlined in the abstract, introduction, and methods sections were reported in sufficient detail.
    - *Basis for rating:* Definitely low risk of bias based on direct evidence that all measured outcomes were reported.
- ***Other potential threats:***
    - *Rating:* Probably low risk of bias (+)
    - *Summary:*
        - *Statistical analyses:* Associations between serum and urinary fluoride levels and IQ score were estimated using general linear models and multivariate linear regression by COMT polymorphism. Normality (Kolmogorov-Smirnov test) was evaluated for all continuous variables. There is no evidence that residual diagnostics were used to examine model assumptions or that the complex sampling design (stratified multistage random sampling) was accounted for in the analysis using sampling weights and adjustment for clustering. The impact of these factors on the regression effect estimates is expected to be minimal given the use of individual-level data and adjustment for numerous potential confounders.
        - *Other potential concerns:* None identified.
    - *Basis for rating:* Probably low risk if bias based on direct evidence that the statistical analyses were appropriate and there were no other potential threats to risk of bias identified.
- ***Basis for classification as low risk-of-bias study overall:*** Definitely or probably low risk-of-bias ratings in confounding, exposure, and outcome. Study strengths include individual exposure measurements, outcomes blindly assessed, and assessment of potential key confounders including potential co-exposures.

Other Neurodevelopmental Studies

Barberio *et al.* (2017b)

Study Details:

- ***Study design*:** Cross-sectional
- ***Population*:** Canadian Health Measures Survey (cycles 2 and 3) participants (children aged 3−12 years)
- ***Study area:*** general population of Canada
- ***Sample size:*** 2,221 children (1,120 from Cycle 2, 1,101 from Cycle 3)
- ***Data relevant to the review:*** Associations between learning disability or ADHD (Cycle 2 only) assessed by parent or child self-report and urinary fluoride.
- ***Reported association with fluoride exposure:*** Yes: Significant increase in adjusted OR for learning disability with unadjusted urinary fluoride (1.02; 95% CI: 1.00, 1.03) when Cycle 2 and 3 were combined. No significant associations with creatinine-adjusted or specific gravity-adjusted urinary fluoride. No significant association between urinary fluoride and ADHD.

Risk of Bias:

- **Author contacts:**
  - Authors were not contacted for additional information because it was not necessary.
- ***Population selection:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* The comparison groups were selected from Cycles 2 and 3 of the Canadian Health Measures Survey. This is a nationally representative sample of residents living in 10 provinces, with clear exclusion criteria provided. Exclusion only represented about 4% of the target population (all Canadian residents 3−79 years old living in 10 provinces). A table of characteristics of the study population is provided.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that the subjects were recruited from the same population using the same methods during the same time frame and exposure groups were similar.
- ***Confounding:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* The study adjusted for sex, age (3–12 years old), household education, and household income adequacy. Variables to discern fluoride source, including drinking water and dental products, were also considered. Cycle 2 data also included adjustments for: 1) children for whom tap water (vs. bottled or other) was the primary source of drinking water at home or away from home and 2) children who had lived in his or her current home for 3 or more years. Confounders such as parental behavioral and mental health disorders, smoking, and nutrition were not discussed. The study used data from the Canadian Health Measures Survey which consists of a nationally representative sample of Canadians. Most Canadians (~89%) receive water from municipal water supplies, which monitor for levels of lead and arsenic. Therefore, co-exposure to lead and arsenic are less likely an issue in this population and the lack of information is not considered to appreciably bias the results.
  - *Potentially important study-specific confounders:* All key confounders were considered in this study.

        - *Direction/magnitude of effect*: Not applicable.
    - *Basis for rating:* Probably low risk of bias based on direct evidence that key confounders were addressed and indirect evidence that the methods used to collect the information were valid and reliable and that co-exposures were not an issue.
- ***Attrition:***
    - *Rating:* Probably low risk of bias (+)
    - *Summary:* Covariate data were missing for less than 5% of all analyses, apart from household income; household income was reported for only 71–77% of participants and was imputed for the remainder.
    - *Basis for rating:* Probably low risk of bias based on indirect evidence that exclusion of subjects from analyses was adequately addressed, and reasons were documented when subjects were removed from the study or excluded from analyses.
- ***Exposure:***
    - *Rating:* Probably low risk of bias (+)
    - *Summary:* Estimates of urinary fluoride (µmol/L) from spot urine were available for a subsample of respondents. Analysis was performed under standardized operating procedures at the Human Toxicology Laboratory of the Institut National de Santé Publique du Québec (accredited under ISO 17025). Fluoride content of urine samples was analyzed using an Orion pH meter with a fluoride ion-selective electrode with limits of detection of 20 µg/L (Cycle 2) and 10 µg/L (Cycle 3). Urinary dilution was addressed by using creatinine-adjusted levels as well as specific gravity-adjusted levels. In Cycle 3 only, estimates of the fluoride concentration of tap water samples collected from randomly selected households were available. The subsample of households selected for tap water sample collection corresponded to the person-level urine fluoride subsample. Analysis of the fluoride concentration of tap water was performed using a basic anion exchange chromatography procedure, with a limit of detection of 0.006 mg/L. QC methods were not addressed.
        - *Direction/magnitude of effect*: There is not any specific direction or magnitude of bias expected. Urinary fluoride levels are reflective of a recent exposure. Having a single concurrent measurement may not be reflective of the exposure associated with the outcome, but if subjects lived in the same area throughout life the exposure may be an adequate representation. Although there is possible exposure misclassification it would be non-differential.
    - *Basis for rating:* Probably low risk of bias based on indirect evidence that exposure was consistently assessed using well-established methods that directly measured exposure.
- ***Outcome:***
    - *Rating:* Probably high risk of bias (-)
    - *Summary:* The primary outcome variable, diagnosis of a learning disability by a health professional, was based on a single item from a household survey asked to all respondents: "Do you have a learning disability?". Answer options were: "yes", "no", "don't know", or the participant refused to answer. For Cycle 2, those who indicated having a learning disability were also asked what kind, with the answer options of: "ADD", "ADHD", "dyslexia", or "other". This question was omitted in Cycle 3 and the reason for omission is not described. Parents or guardians answered all questions for children aged 3–11 years, while children 12 years and older answered questions

themselves. The self-reporting of a learning disability did not appear to have been confirmed by medical records or a health professional. (- for methods based on self-report of diagnosis by a health care professional also in Cycle 3 no specific disabilities were described). Blinding was not a concern as spot urine samples were sent to a separate lab and self-reports would not have knowledge of their urine or tap water exposure level (+ for blinding). Overall rating = -.

- *Basis for rating:* Probably high risk of bias based on indirect evidence that the outcome was measured using an insensitive method in the study population.

- ***Selective Reporting:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* All outcomes outlined in the abstract, introduction, and methods sections were reported in sufficient detail.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that all measured outcomes were reported.
- ***Other potential threats:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:*
    - *Statistical analyses:* Logistic regression analyses, adjusted and unadjusted for covariates, examined the associations between fluoride exposure and diagnosis of learning disability. Analyses were performed for Cycle 2 only (urinary fluoride and type of learning disability diagnosis), Cycle 3 only (urinary fluoride, water fluoride, and learning disability diagnosis), and Cycles 2 and 3 combined. Analyses used survey weights and bootstrapped weights to ensure proper computation of variance estimates. Results are reported as unadjusted and adjusted ORs with 95% CIs.
    - *Other potential concerns:* None identified.
  - *Basis for rating:* Definitely low risk if bias based on direct evidence that the statistical analyses were appropriate and there were no other potential threats to risk of bias identified.
- ***Basis for classification as low risk-of-bias study overall:*** Probably low risk-of-bias ratings in confounding and exposure. Study strengths include individual exposure measurements and the addressing of potential key confounders but was limited by the cross-sectional study design and insensitive outcome measures.

Bashash *et al.* (2017)

Study Details:

- ***Study design*:** Prospective cohort
- ***Population*:** Early Life Exposures in Mexico to Environmental Toxicants (ELEMENT) participants (pregnant mothers and their children aged 4 or 6–12 years).
- ***Study area:*** Mexico City, Mexico
- ***Sample size:*** 299 mother–child pairs, of whom 287 had data for the general cognitive index (GCI).
- ***Data relevant to the review:*** Adjusted and unadjusted associations between GCI and maternal or child's urinary fluoride concentrations.

- ***Reported association with fluoride exposure:*** Yes: Significant association between maternal urinary fluoride and GCI score (adjusted β = −3.15; 95% CI: −5.42, −0.87). No significant associations with children's urinary fluoride.

Risk of Bias:

- **Author contacts:**
  - Authors were not contacted for additional information because it was not necessary.
- ***Population selection:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Study participants were selected from two different cohorts from three hospitals in Mexico City that serve low-to-moderate income populations. One cohort was from an observational study of prenatal lead exposure and neurodevelopment outcomes and the other was from a randomized trial of the effect of calcium on maternal blood lead levels. The authors state that participants had no history of psychiatric disorders, high-risk pregnancies, gestational diabetes, illegal drug use, or continuous prescription drugs, but they do not include any information on smoking habits. Study populations appear to be similar, but there may be some differences because subjects were selected from two different cohorts that were recruited from slightly different time periods.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the exposure groups were similar despite the subjects coming from different original study populations where different methods were used for recruitment.
- ***Confounding:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Data were collected via questionnaire on maternal age, education, marital status at first prenatal visit, birth order, birth weight, gestational age at delivery, maternal smoking, maternal IQ, and HOME scores. All models were adjusted for gestational age at birth, child's sex, birth weight, birth order, child's age at testing, maternal marital status, smoking history, age at delivery, maternal IQ, education, and cohort, with additional testing for children's urinary fluoride, mercury, lead, and calcium. Sensitivity analyses additionally adjusted for HOME score. Confounders not considered included BMI, iodine deficiency, arsenic, and maternal mental health and nutrition. Arsenic is assumed not to be a potential co-exposure in this population as the study authors did not discuss it as an issue but did discuss other co-exposures. Arsenic is included in the water quality control program in Mexico City and is not considered a concern in this population.
  - *Potentially important study-specific confounders:* All key confounders were addressed.
    - *Direction/magnitude of effect***:** Not applicable.
  - *Basis for rating:* Probably low risk of bias based on direct evidence that key confounders including other potential co-exposures were addressed and indirect evidence that the methods used to collect the information were valid and reliable and that arsenic is not likely to be an issue in this study population.
- ***Attrition:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Although there was a large amount of attrition, the study authors clearly describe all reasons for attrition and also provide characteristics to compare those

participants included to those excluded. There were some slight differences between those included and those excluded, but there is nothing to indicate that the attrition would potentially bias the results.
    - *Basis for rating:* Probably low risk of bias based on indirect evidence that exclusion of subjects from analyses was adequately addressed, and reasons were documented when subjects were removed from the study or excluded from analyses.
- ***Exposure:***
    - *Rating:* Definitely low risk of bias (++)
    - *Summary:* Urinary fluoride concentrations were determined in spot urine samples (2nd morning void) collected from mothers (during at least one trimester) and children ages 6–12 years. Fluoride content was measured using ion-selective electrode-based assays. QC methods were described including between laboratory correlations. All samples were measured in duplicate. Extreme outliers were excluded. Urinary dilution was addressed by using creatinine-adjusted levels.
        - *Direction/magnitude of effect***:** Not applicable.
    - *Basis for rating:* Definitely low risk of bias based on direct evidence that exposure was consistently assessed using well-established methods that directly measured exposure.
- ***Outcome:***
    - *Rating:* Definitely low risk of bias (++)
    - *Summary:* Outcome was assessed using the McCarthy Scales of Children's Abilities (MSCA) in 4-year-old children (translated into Spanish) and the Wechsler Abbreviated Scale of Intelligence (WASI) in 6–12-year-olds. The WASI is a well-established test and the validity of both tests is well documented by the authors. Inter-examiner reliability was evaluated and reported with a correlation of 0.99 (++ for methods). The study report stated that psychologists were blind to the children's fluoride exposure (++ for blinding). Overall rating for methods and blinding = ++.
    - *Basis for rating:* Definitely low risk of bias based on direct evidence that the outcome was blindly assessed using instruments that were valid and reliable in the study population.
- ***Selective Reporting:***
    - *Rating:* Definitely low risk of bias (++)
    - *Summary:* All outcomes outlined in the abstract, introduction, and methods are reported in sufficient detail.
    - *Basis for rating:* Definitely low risk of bias based on direct evidence that all measured outcomes were reported.
- ***Other potential threats:***
    - *Rating:* Definitely low risk of bias (++)
    - *Summary:*
        - *Statistical analyses:* Statistical analyses used were appropriate for the study. Statistical tests of bivariate associations [using Chi-square tests for categorical variables and analysis of variance (ANOVA)] were used to compare the means of the outcomes or exposure within groups based on the distribution of each covariate. Generalized additive models (GAMs) were used to estimate the adjusted association between fluoride exposure and measures of children's intelligence. Residual diagnostics were used to examine model assumptions and

identify any potentially influential observations. Results are reported as adjusted effects and 95% CIs. In sensitivity analyses, regression models accounted for clustering at the cohort level by using cohort as a fixed effect in the models. Although using cohort as a random effect would be more appropriate, using individual-level exposure data and accounting for numerous potential confounders in the models likely captured the cohort effect. Additional models with cohort as a random effect were also subsequently made available via personal communication with the study authors and showed similar results to the main model.

        - *Other potential concerns:* None identified.
    - *Basis for rating:* Definitely low risk if bias based on direct evidence that the statistical analyses were appropriate and there were no other potential threats to risk of bias identified.
- ***Basis for classification as low risk-of-bias study overall:*** Definitely or probably low risk-of-bias ratings in confounding, exposure, and outcome. Study strengths include individual exposure measurements, outcome blindly assessed, and the prospective cohort study design.

Bashash *et al.* (2018)

Study Details:

- ***Study design*:** Prospective cohort
- ***Population*:** ELEMENT participants (pregnant mothers and their children aged 6–12 years)
- ***Study area:*** Mexico City, Mexico
- ***Sample size:*** 210 mother–child pairs
- ***Data relevant to the review:*** Associations between ADHD and other attention/impulsivity scores and maternal urinary fluoride concentrations.
- ***Reported association with fluoride exposure:*** Yes: Significant associations between maternal urinary fluoride and Conners' Rating Scales-Revised (CRS-R) scores, including Cognitive Problems and Inattention Index (adjusted β = 2.54; 95% CI: 0.44, 4.63), DSM-IV Inattention Index (adjusted β = 2.84; 95% CI: 0.84, 4.84), DSM-IV ADHD Total Index (adjusted β = 2.38; 95% CI: 0.42, 4.34), and ADHD Index (adjusted β = 2.47; 95% CI: 0.43, 4.50).

Risk of Bias:

- **Author contacts:**
    - Authors were not contacted for additional information because it was not necessary.
- ***Population selection:***
    - *Rating:* Probably low risk of bias (+)
    - *Summary:* Participants were a subset of mother-child dyads enrolled in various longitudinal birth cohort studies of the Early Life Exposure in Mexico to Environmental Toxicants (ELEMENT) project. Subjects were included from two of the four cohorts for which maternal urinary samples were available. Participants in cohort 2A were recruited between 1997 and 1999, and participants in cohort 3 were recruited from 2001 to 2003. Inclusion and exclusion criteria were applied consistently across the two cohorts. A table of subject characteristics was provided in the study and any differences were considered in the analysis. Study populations appear to be similar, but there may be some

differences because subjects were selected from two different cohorts: one from an observational study on prenatal lead exposure and the other from a randomized trial on the effects of calcium on blood lead levels. In addition, they were recruited from slightly different time periods.

- *Basis for rating:* Probably low risk of bias based on indirect evidence that the exposed groups were similar, and any differences were taken into account in the analysis.

- ***Confounding:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Questionnaires were used to collect information on maternal age, maternal education, history of smoking, and marital status during the first pregnancy visit. Child information at birth included birth weight, sex, birth order, and gestational age as calculated by the nurse. Mothers also responded to an SES questionnaire during the visit when the psychometric tests were administered. The Home Observation for Measurement of the Environment (HOME) score was evaluated in a subset of participants. Covariates were selected a priori. Models adjusted for maternal age at delivery, years of education, marital status, smoking history, gestational age at birth, age at outcome assessment, child's sex, birth order, SES, cohort, and calcium intervention. Arsenic is included in the water quality control program in Mexico City and is not considered a concern in this population.
  - *Potentially important study-specific confounders:* None identified, although this study did not specifically address arsenic or other co-exposures. Bashash *et al.* (2017) addressed potential co-exposure to lead and mercury but did not address arsenic. Arsenic was potentially addressed as part of the water quality program in Mexico City.
    - *Direction/magnitude of effect***:** Not applicable.
  - *Basis for rating:* Probably low risk of bias based on direct evidence that key confounders were addressed and indirect evidence that the methods used to collect the information were valid and reliable and that arsenic and other potential co-exposures are not likely to be an issue in this study population.
- ***Attrition:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Although there was a large amount of attrition from the original cohorts, it was unlikely related to outcome or exposure and there were very little missing data from those included in the study. Of the 231 mothers with a minimum of one maternal urine fluoride measurement and matching outcome identified for the project, only 17 were excluded based on incomplete demographic and outcome information.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that exclusion of subjects from analyses was adequately addressed, and reasons were documented when subjects were removed from the study or excluded from analyses.
- ***Exposure:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Mothers provided at least one spot urine sample during pregnancy. As described in Bashash *et al.* (2017), urinary concentrations were determined on second morning void. Fluoride content was measured using ion-selective electrode-based assay. Bashash *et al.* (2017) describes QC methods. All samples were measured in duplicate

and extreme outliers were excluded. Urinary dilution was addressed by using creatinine-adjusted levels.
        - *Direction/magnitude of effect*: N/A
    - *Basis for rating:* Definitely low risk of bias based on direct evidence that exposure was consistently assessed using well-established methods that directly measured exposure.
- ***Outcome:***
    - *Rating:* Definitely low risk of bias (++)
    - *Summary:* Behaviors associated with ADHD were assessed using the Spanish version of the Conners' Rating Scales-Revised, which has been validated for the evaluation of ADHD. Mothers completed the CRS-R at the same follow-up visit that the child completed the CPT-II tests. All tests were applied under the supervision of an experienced psychologist (++ for methods); however, a limitation of the study noted by the authors was only using parent reports and not teacher reports as they can vary from one another. Blinding was not reported, but it is unlikely that the mothers were aware of their urinary fluoride levels. Although mothers may have had knowledge that they were receiving fluoride through fluoridated salt or naturally occurring fluoride in their water, they would not have knowledge that this was relevant to the study purpose as the ADHD tests were conducted for the original cohort (as was acknowledged by the study authors in the discussion). (++ for blinding). Overall rating = ++.
    - *Basis for rating:* Definitely low risk of bias based on direct evidence that the outcome was blindly assessed using instruments that were valid and reliable in the study population.
- ***Selective Reporting:***
    - *Rating:* Definitely low risk of bias (++)
    - *Summary:* All outcomes outlined in the abstract, introduction, and methods were reported in sufficient detail.
    - *Basis for rating:* Definitely low risk of bias based on direct evidence that all measured outcomes were reported.
- ***Other potential threats:***
    - *Rating:* Definitely low risk of bias (++)
    - *Summary:*
        - *Statistical analyses:* Bivariate analyses included Chi-square tests for categorical variables and ANOVA for continuous outcomes. Appropriate univariate statistics and transformations were performed before bivariate analyses. Residuals from fully adjusted linear regressions were checked and suggested skewness. Gamma regression with an identity link was used to examine the adjusted association between prenatal fluoride and each neurobehavioral outcome (instead of using log transformation). Generalized additive models were used to visually examine potential non-linearity. Sensitivity analyses examined impact of other potential confounders. Diagnostics were used to assess violations of the model assumptions and to identify remaining influential observations. The Benjamini–Hochberg false discovery rate (FDR) procedure was used to correct for multiple testing.
        - *Other potential concerns:* None identified.

  - *Basis for rating:* Definitely low risk if bias based on direct evidence that the statistical analyses were appropriate and there were no other potential threats to risk of bias identified.
- ***Basis for classification as low risk-of-bias study overall:*** Definitely or probably low risk-of-bias ratings in confounding, exposure, and outcome. Study strengths include individual exposure measurements, outcome blindly assessed, and the prospective cohort study design.

Choi *et al.* (2015)

Study Details:

- ***Study design*:** Cross-sectional
- ***Population*:** First grade children (ages 6–8 years)
- ***Study area:*** Mianning County in southern Sichuan, China
- ***Sample size:*** 51 first grade children
- ***Data relevant to the review:*** Associations between learning, memory, visual motor ability, motor ability, and manual dexterity with continuous urine or drinking water fluoride levels. Study also had information based on dental fluorosis score.
- ***Reported association with fluoride exposure:*** No: None of the outcomes were significantly associated with fluoride exposure.

Risk of Bias:

- **Author contacts:**
  - Authors were not contacted for additional information because it was not necessary.
- ***Population selection:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Subjects were selected during the same time frame using the same methods. Fifty-one first-grade children residing in Mianning County in southern Sichuan, China were included in this pilot study. It is not specified if the 51 children represented all the first-grade children from this area or if some refused to participate. Children who did not speak Chinese, were not students at the Primary School of Sunshui Village in Mianning County, or those with chronic or acute disease that might affect neurobehavioral function tests were excluded. Demographic characteristics are presented in Table 1 of the study, which indicates that subjects were similar. Potential confounders are adjusted for in the statistical analyses.
  - *Basis for Rating:* Definitely low risk of bias based on direct evidence that the exposure groups were similar and were recruited within the same time frame using the same methods with no evidence of differences in participation/response rates.
- ***Confounding:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* The parents or guardians completed a questionnaire on demographic and personal characteristics of the children (sex, age at testing, parity, illnesses before age 3, and past medical history) and caretakers (age, parity, education and occupational histories, residential history, and household income). A 20-µL capillary blood sample was collected at the school by a Mianning County Center for Disease Control (CDC) health practitioner and tested for possible iron deficiency which could be used as a

covariate of neurodevelopmental performance. Confounders that were not assessed include: maternal BMI, parental mental health, maternal smoking status, maternal reproductive factors, parental IQ, and HOME score. However, the study authors noted that confounding bias appeared to be limited due to the minimal diversity in the social characteristics of the subjects. The study authors indicated that CDC records documented that levels of other contaminants including arsenic and lead were very low in the area. Iodine differences were not specifically addressed, but there is no indication from the information provided that this might be a concern.

- *Potentially important study-specific confounders:* All key confounders were considered in this study.
  - *Direction/magnitude of effect*: Not applicable.
- *Basis for rating:* Probably low risk of bias because there is direct evidence that the key confounders are taken into account and indirect evidence that co-exposure to arsenic is likely not an issue in this area and that methods used for collecting the information were valid and reliable.

- ***Attrition:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* The majority of results were reported for the 51 children stated to be included in the pilot study. In Table 5 of the study, the N for each dental fluorosis category only totals 43, but the text indicates 8 children did not have a Dean Index because permanent teeth had not erupted.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that exclusion of subjects from analyses was adequately addressed, and reasons were documented when subjects were removed from the study or excluded from analyses.
- ***Exposure:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* The study used three different measurements of fluoride exposure: well water fluoride concentrations from the residence during pregnancy and onwards, fluoride concentrations from children's first morning urine samples, and degree of children's dental fluorosis. Fluoride concentrations in community well water were measured and recorded by Mianning County CDC; specific methods were not reported, but they likely used standard methods as they were conducted by the CDC and were likely the same as those used to measure the fluoride in urine. Migration of subjects was noted to be limited. Well water fluoride concentrations of the mother's residence during pregnancy and onward were used to characterize a child's lifetime exposure. To provide a measure of the accumulated body burden, each child was given a 330-mL (11.2-oz) bottle of Robust© distilled water (free from fluoride and other contaminants) to drink the night before the clinical examinations, after emptying the bladder and before bedtime. The first urine sample the following morning was collected at home, and the fluoride concentration was determined on a 5-mL sample using an ion-specific electrode at the Mianning CDC. There is no indication that urinary fluoride levels accounted for dilution nor was it clear that the method of administering water to the children and collection methods sufficiently controlled for differences in dilution. One of the investigators, a dentist, performed a blinded dental examination on each child's permanent teeth to rate the degree of dental fluorosis using the Dean Index. The Dean

Index is a commonly used index in epidemiological studies and remains the gold standard in the dentistry armamentarium. The Index has the following classifications: normal, questionable, very mild, mild, moderate, and severe. Quality control (QC) procedures are not reported but were likely appropriate.

- *Direction/magnitude of effect*: Current levels were used to assess lifetime exposure. This is likely to be a non-differential exposure misclassification and direction of bias is unknown. Because subject migration appears to be limited, it is likely that the current fluoride levels are adequate reflections of past exposure. Dental fluorosis would be an indicator that exposure occurred in the past and there was a fair correlation between degree of dental fluorosis and current urine and water fluoride levels, with both increasing with increasing levels of dental fluorosis.

- *Basis for rating:* Probably low risk of bias based on indirect evidence that exposure was consistently assessed using well-established methods that directly measure exposure.

- ***Outcome:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* The study authors adopted culture-independent tests considered feasible for children aged 6 to 8 years. The Wide Range Assessment of Memory and Learning (WRAML) was used for the assessment of memory and learning. Three subtests were also used. The Finger Windows subtest assesses sequential visual memory. The Design Memory subtest assesses the ability to reproduce designs from memory following a brief exposure. The Visual Learning subtest assesses the ability to learn the locations of pictured objects over repeated exposures. The Wechsler Intelligence Scale for Children-Revised (WISC-IV) included digit span for auditory span and working memory and block design for visual organization and reasoning. The grooved pegboard test assesses manual dexterity. The tests used have been validated on a western population. Although there is no information provided to indicate that they were validated on the study population, the study authors indicated that the tests were culture-independent (+ for methods). Blinding of the outcome assessors or steps to minimize potential bias was not reported. However, it is unlikely that the assessors had knowledge of the individual exposure as children all came from the same area, and water and urine levels were tested at the CDC. (+ for blinding). Overall = +.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that all outcomes were assessed blindly using instruments that were valid and reliable in the study population.
- ***Selective Reporting:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* All outcomes outlined in the abstract, introduction, and methods are reported in sufficient details.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that all measured outcomes were reported.
- ***Other potential threats:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:*

        - *Statistical analyses:* Statistical analyses were appropriate. Multiple regression models evaluate the associations between exposure indicators and test scores after adjusting for potential confounders. Specific regression models are not described or refenced, just stated to be "standard regression analysis with confounder adjustment." The distributions of fluoride concentrations in urine and water were skewed and were log10-transformed to approximate a Gaussian distribution (test not specified). Results are reported as adjusted effects and 95% CIs. There is no evidence that residual diagnostics were used to examine model assumptions; however, the impact on the effect estimates is expected to be minimal.
        - *Other potential concerns:* It should be noted that this study was a pilot study and, therefore, had a relatively small sample size (i.e., 51 children).
    - *Basis for rating:* Probably low risk if bias based on indirect evidence that the statistical analyses were appropriate and there were no other potential threats to risk of bias identified.
- ***Basis for classification as low risk-of-bias study overall:*** Probably low risk-of-bias ratings in the confounding, exposure, and outcome risk-of-bias domains. Study strengths include individual fluoride measurements with blinding at outcome assessment likely. All key confounders and many other confounders were taken into account in the study design or analysis.

Li *et al.* (2004) [translated in Li *et al.* 2008a]

Study Details:

- ***Study design*:** Cross-sectional
- ***Population*:** Full term, normal neonates 24−72 hours old from healthy mothers
- ***Study area:*** Zhaozhou County, Heilongiang Province, China
- ***Sample size:*** 91 neonates (46 males and 45 females)
- ***Data relevant to the review:*** Comparison of neurobehavioral capacity between children in the high-fluoride area compared to the control area.
- ***Reported association with fluoride exposure:*** Yes: Significant differences in neurobehavioral assessment total scores between high-fluoride (36.48 ± 1.09) and control (38.28 ± 1.10) groups; significant differences in total neurobehavioral capacity scores as measured by non-biological visual orientation reaction and biological visual and auditory orientation reaction between the two groups (11.34 ± 0.56 in controls compared to 10.05 ± 0.94 in high-fluoride group).

Risk of Bias:

- **Author contacts:**
    - Authors were not contacted for additional information because it was not necessary.
- ***Population selection:***
    - *Rating:* Probably low risk of bias (+)
    - *Summary:* There is indirect evidence that the exposure groups were similar. They were recruited during the same time frame using the same methods. From 2002 to 2003, 273 neonates were born in a hospital in Zhaozhou County, China. Ninety-one of 273 full-term neonates (46 males, 45 females) were randomly selected. Mothers ranged in age

from 20 to 31 years, met multiple health criteria, and had not changed residence during pregnancy. Authors report that the two study groups are located in the same area with similar climate, living habits, economic and nutritional conditions, and cultural backgrounds, but do not provide these data in the manuscript. There is no statistically significant difference in the mode of delivery, birth weight, infant length, or sex. Subjects were separated into exposure groups after random selection.

- *Basis for Rating:* Probably low risk of bias based on indirect evidence that the exposure groups were similar and were recruited within the same time frame using the same methods with no evidence of differences in participation/response rates.

- ***Confounding:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* No confounders were specifically controlled in the analysis. The study authors note similarities in characteristics in the two populations (i.e., living habits, economic and nutritional conditions, and cultural backgrounds), but do not provide these data nor do they indicate what specific characteristics were considered. There were no significant differences in infant gender, birth method, gestational age, or infant weight and length. All tests were conducted when children were 1–3 days old. No potential co-exposures were discussed. Although arsenic is considered a potential issue in China, water quality maps indicate that there is a 25–50% probability that the drinking water in that area exceeds the WHO guideline for arsenic of 10 µg/L.
  - *Potentially important study-specific confounders:* Key confounders, including child's age, child's gender, and measures of socioeconomic status (SES), were similar between exposure groups; however, arsenic was not taken into account. Arsenic often occurs in the drinking water along with fluoride in some Chinese populations; however, based on water quality maps, arsenic does not appear to be an issue in Zhaozhou County of the Heilongjiang Province. Iodine deficiencies are not mentioned.
    - *Direction/magnitude of effect***:** Conceptually, the presence of arsenic would potentially bias away from the null if it were present with fluoride. Deficiencies in iodine would potentially bias away from the null if it were present in areas of higher fluoride, but toward the null if it were present in areas of lower fluoride. Neither of these are considered a concern in this study for reasons detailed above.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the key confounders are taken into account, co-exposure to arsenic is likely not an issue in this area, and methods used for collecting the information are valid and reliable.
- ***Attrition:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Although authors did not discuss why they only randomly selected 91 of the 273 neonates available, results were available for all 91 subjects.
  - *Basis for rating:* Definitely low risk of bias based on results being available for all subjects.
- ***Exposure:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Subjects were split into control and high-fluoride groups based on fluoride levels in their places of residence. Although the levels were provided (1.7–6.0 mg/L for

the high-fluoride group compared to 0.5–1.0 mg/L for the control group), it was not reported how or when these levels were measured. Urine was collected when women were hospitalized, but before labor began. Urine samples were sent to a specific lab for measurement using fluoride ion-selective electrode. It was noted that this procedure strictly followed the internal controls of the laboratory indicating quality control. Level of detection (LOD) was not provided. Urinary fluoride levels were significantly higher in the high-fluoride mothers (3.58 ±1.47 mg/L) compared to the control-group mothers (1.74±0.96 mg/L). There was indirect evidence that exposure was consistently assessed using well-established methods that directly measure exposure. Although results were mainly based on exposure area, they were supported by urine data making exposure misclassification less of a concern.

        - *Direction/magnitude of effect*: There is high variability in both water fluoride and urine fluoride in the subjects from the high-exposure area. Although there is no overlap in the water fluoride levels in the exposure areas, there is some overlap in the urine concentrations in the mothers from the two areas. This may reflect the single measurement and pose no specific bias, or it could indicate that some mothers in the high-fluoride area have lower fluoride exposure, which could bias the results toward the null.
    - *Basis for rating:* Probably low risk of bias based on indirect evidence that exposure was consistently assessed using well-established methods that directly measure exposure.
- ***Outcome:***
    - *Rating:* Probably low risk of bias (+)
    - *Summary:* A standard neonatal behavioral neurological assessment method was carried out by professionals in the pediatric department working in neonatal section trained specifically for these programs and passing the training exams. (+ for methods). The examinations were carried out 1 to 3 days after delivery. Because urine samples were collected on the day of delivery and sent to a separate laboratory, it is likely that the outcome assessors were blind. Although the subjects were separated by fluoride exposure area, it is not likely that the professionals were aware of the exposure as the tests were conducted in the hospital (+ for blinding).
    - *Basis for rating:* Probably low risk of bias based on indirect evidence that the outcome was assessed blindly using instruments that were valid and reliable in the study population.
- ***Selective Reporting:***
    - *Rating:* Probably low risk of bias (+)
    - *Summary:* The study authors reported numerous endpoints in sufficient detail; however, because they did not provide a list of endpoints tested there is no direct evidence that all were reported.
    - *Basis for rating:* Probably low risk of bias based on indirect evidence that all the study's measured outcomes were reported.
- ***Other potential threats:***
    - *Rating:* Probably low risk of bias (+)
    - *Summary:*
        - *Statistical analyses:* Statistical analyses are described only as a t-test. Consideration of heterogeneity of variance was not reported. Results are

reported as mean and standard deviations of neurological scores. Maternal urinary fluoride levels were only used to compare exposures between exposed and control groups. Infants in the control group were from four villages, and those in the exposed group were from five villages within the same district. Infants were randomly selected before they were assigned to exposed or control groups. In the comparisons, there was no accounting for clustering at the village level. It is likely that the standard error of the difference in mean neurobehavioral assessment scores between the high fluoride group and control group will be biased, making differences appear stronger than they actually are. However, the use of multiple villages per exposure group is likely to mitigate some of the impact of this lack of accounting for clustering, and the overall impact on effect estimates is expected to be minimal.

        - *Other potential concerns:* It should be noted that, although the study states that subjects were randomly selected, it is unclear why only 91 subjects were included and if they were randomly selected to obtain equal groups in the high-fluoride and control groups.
    - *Basis for rating:* Probably low risk of bias based on indirect evidence that statistical analyses were appropriate and that there were no other potential threats to risk of bias.
- ***Basis for classification as low risk-of-bias study overall:*** Probably low risk-of-bias ratings in the confounding, exposure, and outcome risk-of-bias domains. Study strengths include individual fluoride measurements to support the differences in the two areas. Tests were noted to be conducted at the hospital providing indirect evidence that blinding was not a concern during the outcome evaluation. Although there was some potential for bias due to the lack of accounting for arsenic or iodine deficiencies, co-exposure to arsenic is likely not a major concern according to groundwater quality maps.

Riddell *et al.* (2019)

Study Details:

- ***Study design*:** Cross-sectional
- ***Population*:** Canadian Health Measures Survey (cycles 2 and 3) participants (children aged 6−17 years)
- ***Study area:*** general population, Canada
- ***Sample size:*** 3,745 children
- ***Data relevant to the review:*** Adjusted odds ratios for ADHD and attention symptoms per 1 unit increase in urinary fluoride, by water fluoride in the tap water, or community fluoridation status.
- ***Reported association with fluoride exposure:*** Yes: Significantly increased odds of ADHD diagnosis (adjusted OR = 6.10; 95% CI: 1.60, 22.8) or hyperactivity/inattentive symptoms (adjusted β = 0.31; 95% CI: 0.04, 0.58) per 1-mg/L increase in tap water fluoride. Also, a significant association between ADHD diagnosis (adjusted OR = 1.21; 95% CI: 1.03, 1.42) or hyperactivity/inattentive symptoms (adjusted β = 0.11; 95% CI: 0.02, 0.58) and community water fluoridation status. No significant associations with urinary fluoride levels.

Risk of Bias:

- **Author contacts:**
  - Authors were not contacted for additional information because it was not necessary.
- ***Population selection:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Subjects were part of Cycles 2 and 3 of the Canadian Health Measures Survey. This is a nationally representative sample of residents living in 10 provinces. Specific inclusion criteria were provided. This study was restricted to children 6–17 years of age with different fluoride measurements that consisted of three participant samples. One of the samples was only available in Cycle 3.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that the exposed groups were similar and were recruited with the same methods during the same time frame.
- ***Confounding:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Covariates included in all models included child's age at test, child's sex, ethnicity, BMI, parents' education, total household income, exposure to cigarette smoke inside the home, and log-transformed concurrent blood lead levels. Confounders such as parental behavioral and mental health disorders, quantity and quality of caregiving environment, and co-exposure to arsenic were not discussed. The study used data from the Canadian Health Measures Survey which consists of a nationally representative sample of Canadians. Most Canadians (~89%) receive water from municipal water supplies, which monitor for levels of arsenic. Therefore, co-exposure to arsenic is not likely an issue in this population. Rationale for selection of covariates was based on relationship to ADHD diagnosis and to fluoride metabolism based on literature review and consultation with an ADHD expert. There is no information of the source if data for covariates, but this is likely the questionnaires from the Canadian Health Measures Survey, which are considered standardized and validated.
  - *Potentially important study-specific confounders:* All key confounders were considered in this study.
    - *Direction/magnitude of effect***:** Not applicable.
  - *Basis for rating:* Probably low risk of bias because there is indirect evidence that the key confounders are taken into account, co-exposure to arsenic is likely not an issue in this area, and methods used for collecting the information were valid and reliable.
- ***Attrition:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* There is no information indicating that there were any data excluded due to missing covariates. All exclusions of children were described and reasonable (i.e., drinking bottled water when considered city fluoridation as a measure of fluoride exposure). Outliers were stated to be excluded, but methods for determining this were provided and it was noted that the outliers were 0.27% of the values.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that exclusion of subjects from analyses was adequately addressed, and reasons were documented when subjects were removed from the study or excluded from analyses.

- ***Exposure:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* **Urinary Fluoride:** Spot urine samples were collected under normal non-fasting conditions and analyzed using an Orion pH meter with a fluoride ion-selective electrode after being diluted with an ionic adjustment buffer. Analysis was performed at the Human Toxicology Laboratory of the Institut National de Sante Publique du Quebec. The precision and accuracy of the fluoride analyses, including quality control and quality assurance, were described by Health Canada (2015). The limits of detection were 20 µg/L for Cycle 2 and 10 µg/L for Cycle 3 with no values below detection. Fluoride levels were adjusted for specific gravity.
    Water Fluoride in Tap water: Tap water was collected at the subjects' homes in Cycle 3 only. Samples were analyzed for fluoride concentrations using anion exchange chromatography procedure with a LOD of 0.006 mg/L. Values below the LOD were imputed with LOD/square root 2. Of the 980 samples, 150 (16%) were below detection.
    Chlorinate Water Fluoride status: This was determined by viewing reports on each city's website or contacting the water treatment plant (provided in supplemental material). Children were excluded if they drank bottled water, had a well, had a home filtration system, lived in the current residence for 2 years or less, or lived in an area with mixed city fluoridation.
    - *Direction/magnitude of effect***:** There is not any specific direction or magnitude of bias expected. Urinary fluoride levels are reflective of a recent exposure, but the study authors adjusted to account for dilution. The possibility of exposure misclassification would be similar in all subjects and would be non-differential. There is less potential for exposure misclassification in regard to tap water or chlorinated water fluoride status as children who drank bottled water were excluded and children who had a home filtration system were excluded from the chlorinated water status.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that exposure was consistently assessed using well-established methods that directly measured exposure.
- ***Outcome:***
  - *Rating:* Probably high risk of bias (-)
  - *Summary:*
    Strengths and Difficulties Questionnaire (SDQ): The questionnaire was administered to youths under 18 years. Children aged 6–11 years had SDQ ratings provided by parents and guardians, but youths aged 12−17 years completed the questionnaire themselves. Tests consist of 25 items with a 3-point scale. Items were divided into five subscales: emotional problems, conduct problems, hyperactivity-inattention, peer problems, and prosocial behavior. The current study only used the hyperactivity-inattention subscale. Validation of this method was not reported (- for methods).
    ADHD: Ninety percent of youths with ADHD are diagnosed after age 6 years. For children aged 6–11 years, ADHD diagnosis was provided by parents, but youths aged 12−17 years completed the questionnaire themselves. Cycle 2 asked "Do you have a learning disability?" and if yes asked to specify the type (4 options available and described). In Cycle 3, parents were asked directly whether they had ADHD, and children 12 years and older were asked if they had a physician diagnosis of ADHD and, if so, what subtype. (- for methods because different methods were used and only the children 12 years and older in cycle 3 were asked specifically about doctor diagnosis). Both were

measured in both cycles. Blinding is not likely an issue as subjects would not have knowledge of the urine or tap water fluoride levels. However, they would likely have knowledge of the city.
    - *Basis for rating:* Probably high risk of bias based on indirect evidence that the outcome was assessed using insensitive methods that varied based subject age.
- ***Selective Reporting:***
    - *Rating:* Definitely low risk of bias (++)
    - *Summary:* All outcomes outlined in the abstract, introduction, and methods sections were reported in sufficient details.
    - *Basis for rating:* Definitely low risk of bias based on direct evidence that all measured outcomes were reported.
- ***Other potential threats:***
    - *Rating:* Probably low risk of bias (+)
    - *Summary:*
        - *Statistical analyses:* Robust logistic regression was used to examine the association between fluoride exposure and ADHD diagnosis, adjusting for covariates. Box-Tidewell tests were used to check the linearity of the relationship with the continuous predictors. Linear regression was used for the SDQ scores using Huber-White standard errors. Multicollinearity was evaluated using variance inflation factor (VIF) statistics. Outliers with high studentized residuals, high leverage, or large Cook's distance values were removed from all analyses with urinary fluoride. All regressions were tested for interactions between age and fluoride, and sex and fluoride. Sensitivity analyses were conducted to test the different survey cycles. There is no mention of adjustment for the complex survey design using survey weights or bootstrapped weights to ensure appropriate calculation of the estimated variances; however, the overall impact on effect estimates is expected to be minimal.
        - *Other potential concerns:* None identified.
    - *Basis for rating:* Probably low risk if bias based on indirect evidence that the statistical analyses were appropriate and there were no other potential threats to risk of bias identified.
- ***Basis for classification as low risk-of-bias study overall:*** Probably low risk-of-bias ratings in confounding and exposure. Study strengths include individual exposure measurements and the addressing of potential key confounders but was limited by the cross-sectional study design and insensitive outcome measures.

Rocha-Amador *et al.* (2009)

Study Details:

- ***Study design*:** Cross-sectional
- ***Population*:** Children aged 6–11 years
- ***Study area:*** Durango, Mexico
- ***Sample size:*** 80 children

- ***Data relevant to the review:*** Associations between visuospatial organization and visual memory (using the Rey-Osterrieth Complex Figure Test, children's version) and urinary fluoride levels in the children.
- ***Reported association with fluoride exposure:*** Yes: Significant correlation between urinary fluoride and visuospatial organization (r = −0.29) and visual memory (r = −0.27) scores. No significant correlations with arsenic.

Risk of Bias:

- **Author contacts:**
  - Authors were not contacted for additional information because it was not necessary.
- ***Population selection:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Subjects were from the same population and were recruited during the same time frame using the same methods. Although this study compared three sites with antecedents of environmental pollution to mixtures of either F–As, Pb–As, or DDT–PCBs, authors evaluated each contaminant separately. The only area of interest is the area with F and As contamination. The area in Durango state (5 de Febrero) where drinking water is polluted naturally with F and As at levels exceeding 6 and 19 times, respectively, the World Health Organization (WHO) limits (WHO 2008). Children attending public schools were screened through personal interviews for study eligibility. Inclusion criteria were children between 6 and 11 years old, living in the study area since birth, and whose parents signed the agreement to participate. Children with a neurological disease diagnosed by a physician and reported by the mother were excluded from the study. The final sample for the F–As was 80. Participation rates were not reported. Selected demographic characteristics are presented in Table 1 of the study.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the populations were similar and recruited during the same time frame using the same methods.
- ***Confounding:***
  - *Rating:* Probably high risk of bias (-)
  - *Summary:* Confounding factors in children tested in the analysis included blood lead (PbB), age, gender, and height-for-age z-scores; only age had significant associations and was included in the final analysis. Arsenic was also assessed and analyzed separately from fluoride. Arsenic in urine was analyzed by atomic absorption spectrophotometer coupled to a hydride system (Perkin-Elmer model AAnalyst 100). Although the model did not adjust for arsenic, arsenic in the F–As group was not associated with either endpoint; therefore, arsenic as a co-exposure is not considered a major concern in this study. PbB was analyzed with a Perkin-Elmer 3110 atomic absorption spectrophotometer using a graphite furnace. Authors note that the mean blood lead level in the F–As study area was 5.2 µg/dL and 8% of the children had values above the reference value of 10 µg/dL. PbB was stated not to affect results and was not included in the final analysis. Other confounding data were obtained during the study interview. Father's education was provided and, in the F–As group, was stated to range from 0–16 years, but this was not considered. Maternal education, smoking, and SES were also not

considered. The authors provide an SES score of 5.9 ± 1.4 for the 5 de Febrero region (the fluoride region). It is not clear if this would vary by fluoride or arsenic levels.

- *Potentially important study-specific confounders:* SES.
  - *Direction/magnitude of effect*: There are insufficient data to determine the magnitude or direction of effect. If there is an association between fluoride exposure and SES, the direction of effect would depend on the association.
- *Basis for rating:* Probably high risk of bias based on indirect evidence that the SES was not accounted for in the study design or analysis and may have varied by fluoride levels.

- ***Attrition:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Data are complete. All 80 participants stated to be the final sample for the site of interest (F–As) were included in all analyses.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that there was no attrition.
- ***Exposure:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Fluoride in urine (FU) was analyzed according to method 8308 (''fluoride in urine'') from the National Institute of Occupational Safety and Health (NIOSH 1984) with a sensitive specific ion electrode. As a quality control check, reference standard ''fluoride in freeze dried urine'' (NIST SRM 2671a) was analyzed. The accuracy was 97.0 +/- 6.0%. Levels of FU and AsU were adjusted for urinary creatinine, which was analyzed by a colorimetric method (Bayer Diagnostic Kit, Sera-Pak1 Plus). However, details on the collection methods were not reported.
    - *Direction/magnitude of effect*: Spot urine samples in a small sample size (i.e., 80 children) may have some exposure misclassification. Adjusting for dilution reduces the potential for misclassification based on differences in dilution. Exposure misclassification would be non-differential.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that exposure was consistently assessed using well-established methods that directly measured exposure.
- ***Outcome:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* IQ is assessed through the Rey-Osterrieth Complex Figure Test (ROCF). This is a less well-established method, although the authors provide citations suggesting it has been validated and standardized for the Mexican population (+ for methods). According to the study report, the neuropsychologist who administered the test was blinded to all exposure types and levels. (++ for blinding). Overall rating for methods and blinding = +.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the outcome was blindly assessed using instruments that were valid and reliable in the study population.
- ***Selective Reporting:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* All outcomes outlined in the abstract, introduction, and methods were reported in sufficient details.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that all measured outcomes were reported.

- ***Other potential threats:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:*
    - *Statistical analyses:* Statistical analyses used log-transformed exposure variables (although rationale was not provided). Crude and partial correlations were calculated to evaluate associations between serum fluoride levels and TOCF scores. There is no other description of the regression model, and regression diagnostics to evaluate model assumptions are not presented; however, the overall impact on effect estimates is expected to be minimal.
    - *Other potential concerns:* None identified.
  - *Basis for rating:* Probably low risk if bias based on indirect evidence that the statistical analyses were appropriate and there were no other potential threats to risk of bias identified.
- ***Basis for classification as low risk-of-bias study overall:*** Probably low risk-of-bias ratings in exposure and outcome. Study strengths include individual exposure measurements and outcomes blindly assessed, but it is limited by the cross-sectional study design, lack of addressing SES in the study population, co-exposure with arsenic, and use of spot samples in a small population.

Valdez Jimenez *et al.* (2017)

Study Details:

- ***Study design*:** Prospective cohort
- ***Population*:** Infants aged 3–15 months
- ***Study area:*** Durango City and Lagos de Moreno, Jalisco, Mexico
- ***Sample size:*** 65 infants
- ***Data relevant to the review:*** The Bayley Scales of Infant Development II was used to assess Mental Development Index Scale and the Psychomotor Development Index scale in children 3 to 15 month and evaluated for associations with first and second trimester maternal urine fluoride.
- ***Reported association with fluoride exposure:*** Yes: Significant association between maternal urinary fluoride and MDI score during first trimester (adjusted β = −19.05; SE = 8.9) and second trimester (adjusted β = −19.34; SE = 7.46). No association between maternal fluoride during any trimester and Psychomotor Developmental Index (PDI).

Risk of Bias:

- **Author contacts:**
  - Authors were not contacted for additional information because it was not necessary.
- ***Population selection:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Subjects were recruited from two endemic areas in Mexico. The study authors do not provide information on the similarities or differences between the two areas nor do they indicate if there were different participation rates. However, recruitment methods were the same. Women receiving prenatal care in health centers located in Durango City and Lagos de Moreno, Jalisco, Mexico were recruited in 2013–2014. Participation rates are not likely to be an issue as characteristics were similar

between those who participated and those who did not. Although they did not provide characteristics by area, the characteristics provided do not indicate any differences that may be biased by the selection. Considering the age range for the non-participants, the mean age for non-participants appears to be incorrect (or the age range is incorrect); however, there does not appear to be a difference that would potentially indicate selection bias.

- *Basis for rating:* Probably low risk of bias based on indirect evidence that the exposure groups were similar and were recruited with the same methods in the same time frame, with no evidence of differences or issues with participation/response rates.

- ***Confounding:***
  - *Rating:* Probably high risk of bias (-)
  - *Summary:* Questionnaires were used to obtain information about sociodemographic factors, prenatal history, mother's health status before pregnancy (e.g., use of drugs, vaccines, diseases) and the type of water for drinking and cooking. The marginalization index (MI) was obtained from the National Population Council (CONAPO). Two additional surveys were conducted during the 2nd and 3rd trimester of pregnancy to get information about the mother's health, pregnancy evolution, and sources of water consumption. A survey was also conducted to get information about childbirth (type of birth, week of birth, weight and length of the baby at birth, Apgar and health conditions of the baby during the first month of life). This information was corroborated with the birth certificate. Linear regression models included gestational age, children's age, marginality index, and type of drinking water. Bivariate analysis was conducted on the other factors including child's gender prior to conducting multivariable regression models. Some important confounders were not considered, including parental mental health, IQ, smoking, and potential co-exposures. Water quality maps indicate a potential for arsenic to be present in the study area.
  - *Potentially important study-specific confounders:* Arsenic is a potential co-exposure in this area of Mexico.
    - *Direction/magnitude of effect***:** If arsenic were present as a co-exposure it would bias the results away from the null.
  - *Basis for rating:* Probably high risk of bias based on indirect evidence that there is a potential for co-exposure with arsenic that was not addressed.
- ***Attrition:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Out of the 90 women selected for inclusion in the study, 65 approved the participation of their infants. The authors provide a table of characteristics between women who consented to their children's cognitive evaluation and those that only participated in biological monitoring. There were no significant differences between the groups. There were fewer women who provided urine during the second and third trimesters. All specified children are included in the relevant analyses.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that exclusion of subjects from analyses was adequately addressed, and reasons were documented when subjects were removed from the study or excluded from analyses.
- ***Exposure:***
  - *Rating:* Definitely low risk of bias (++)

- *Summary:* Fluoride exposure is assessed through morning urine samples and water fluoride levels collected from the children's homes. Sampling methodology is appropriately documented, and water levels were quantified through specific ion-sensitive electrode assays. QC was described and accuracy was >90%. Urinary fluoride was corrected by specific gravity.
  - *Direction/magnitude of effect***:** Not applicable.
- *Basis for rating:* Definitely low risk of bias based on direct evidence that exposure was consistently assessed using well-established methods that directly measured exposure.

- ***Outcome:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Neurodevelopment was assessed with the Bayley Scales of Infant Development II (BSDI-II) that was noted to be reliable and valid for evaluating children from 3 months to 5 years of age. The average age of children assessed was 8 months, with a range of 3–15 months) (++ for methods). The study report stated that a trained psychologist who was blinded about the mother's fluoride exposure evaluated the infants at home (++ for blinding). Overall rating for methods and blinding = ++.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that the outcome was blindly assessed using instruments that were valid and reliable in the study population.
- ***Selective Reporting:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* All outcomes outlined in the abstract, introduction, and methods were reported. Table 4 of the study only displays data for trimesters 1 and 2. Although 3rd trimester data were collected, they were not reported, likely because data were only available for 29 subjects. No discussion of this was provided.
  - *Basis for rating:* Probably low risk of bias because, although it appears some data were not reported, it is likely because there were insufficient data and not because the authors were selectively reporting the results.
- ***Other potential threats:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:*
    - *Statistical analyses:* Statistical analyses used log10-transformed exposure variables. Normality, homoscedasticity, and linearity assumptions were tested and satisfied for MDI and PDI scores. Bivariate analyses included correlations, t-tests, and ANOVA. Multiple linear regression models by the 1st and 2nd trimester of pregnancy were used to evaluate the association between maternal fluoride exposure and MDI and PDI scores. The best-fit model was selected using a "stepwise method" and the best-fit line was evaluated using "the curve fitting method." It is not further specified or cited what these methods entailed. Best-fit or goodness-of-fit statistics are not reported. It is unclear how a best-fit model could be selected when the authors state that all models adjusted for the same set of covariates regardless of significance, and these covariates also appear in the final model—presumably the best-fit model. It is unlikely that a stepwise method would retain all those covariates unless they were forced in the model. Residual analysis was conducted to assess model validity; however,

there is no description of the results of the residual analysis. Nonetheless, the impact on effect estimates is expected to be minimal.

- *Other potential concerns:* No other potential concerns were identified. In the peer-review report, NASEM (2020) cited the following as potential concerns: "the large difference in numbers of males and females in the offspring (20 males, 45 females), and apparently incorrect probabilities were reported for age differences between participants and nonparticipants, high rates of cesarean deliveries and premature births among participants (degree of overlap not reported), and incorrect comparisons of observed prematurity rates with national expected rates." However, these concerns were taken in consideration in other domains (***Selection, Confounding)***.

Basis for rating: Probably low risk if bias based on indirect evidence that the statistical analyses were appropriate and there were no other potential threats to risk of bias identified.

- ***Basis for classification as low risk-of-bias study overall:*** Definitely low risk-of-bias ratings in exposure and outcome. Study strengths include individual exposure measurements and outcome blindly assessed, but it is limited by the cross-sectional study design and lack of accounting for potential co-exposures to arsenic.

Wang *et al.* (2020a)

Study Details:

- ***Study design*:** Cross-sectional
- ***Population*:** School children aged 7–13 years
- ***Study area:*** Tongxu County, China
- ***Sample size:*** 325 school children
- ***Data relevant to the review:*** Associations between ADHD and other measures of learning disability with urine fluoride concentrations.
- ***Reported association with fluoride exposure:*** Yes: Significant association between psychosomatic problems and urinary fluoride (per 1-mg/L increase; adjusted β = 4.01 [95% CI: 2.74, 5.28]) and increased risk of a T-score > 70 with urinary fluoride (per 1-mg/L increase; adjusted OR = 1.97 [95% CI: 1.19, 3.27]). No significant associations with ADHD or other measures of learning disability.

Risk of Bias:

- **Author contacts:**
  - Authors were contacted in July of 2020 to obtain additional information for risk-of-bias evaluation. No response was received.
- ***Population selection:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Subjects were recruited in 2017 from Tongxu County, China. Children were selected from four randomly selected primary schools in the area. Selection was based on specified inclusion rules. It was noted that the living habits and diets of the participants from the four schools were well matched, but details were not provided. The area did not have industrial pollution within 1 km of the living environment of the children, and it was noted that the children were not exposed to other

neurodevelopmental toxicants (lead, cadmium, arsenic, or mercury). A table of subject characteristics was provided in the study, but not by school or exposure. This is a pilot study, and it is not explicitly stated if all eligible subjects participated in the study. There is no information on participation rates or if they varied by school.

- *Basis for rating:* Probably low risk of bias based on indirect evidence that the exposed groups were recruited using similar methods during the same time frame and that any differences between the exposed groups were considered in the statistical analyses.

- ***Confounding:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* It was noted that subjects were well matched in terms of living habits and diets, but there were no specifics provided. It was noted that there was no industrial exposure or exposure to other neurotoxins such as lead, cadmium, arsenic, or mercury. Covariates were collected using a standardized and structured questionnaire completed by the children and their guardians under the direction of investigators, but reliability or validity of the questionnaire was not reported. Information collected included age, gender, weight, height, parental education level, and parental migration (or work as migrant workers). IQ scores evaluated by the Combined Raven's Test-the Rural in China were used to represent basic cognitive function. Models were adjusted for age, BMI, gender, mother and father migration, and urinary creatinine. Adjustments were not made for parental education, race/ethnicity, maternal demographics (e.g., maternal age, BMI), parental behavioral and mental health disorders (e.g., ADHD, depression), smoking (e.g., maternal smoking status, secondhand tobacco smoke exposure), reproductive factors (e.g., parity), iodine deficiency/excess, maternal (and paternal) IQ, quantity and quality of caregiving environment (e.g., HOME score), or SES other than parental migration. There is no evidence to suggest that SES would differ substantially among the four rural schools in the same area of China that were randomly selected.
  - *Potentially important study-specific confounders:* SES.
    - *Direction/magnitude of effect***:** Direction and magnitude is unknown. It was noted that the subjects were matched in terms of living habits and diet and this could be an indication that SES was not different among the groups, but details were not provided.
  - *Basis for rating:* Probably low risk of bias because there is indirect evidence that the key confounders are considered, that the methods for collecting the information were valid and reliable, and that co-exposure to arsenic is not an issue in this area.
- ***Attrition:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Data are complete. It was noted that there were 325 subjects included and results were available on all subjects.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that there was no attrition.
- ***Exposure:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Spot urine samples were collected from each child in the early morning into cleaned polyethylene tubes. Fluoride concentrations were measured using fluoride ion-selective electrode (with reference to Ma *et al.* (2017); however, that reference cites

Zhou *et al.* (2012)). Therefore, no QC methods or LODs were available. Fluoride concentrations were creatinine-adjusted.

- *Direction/magnitude of effect*: Spot urine samples only account for recent exposure. Although this could cause there to be some exposure misclassification, the number of subjects should help dilute any issues with the non-differential misclassification.

- *Basis for rating:* Probably low risk of bias based on indirect evidence that exposure was consistently assessed using acceptable methods that provide individual levels of exposure.

- ***Outcome:***
  - *Rating:* Probably high risk of bias (NR)
  - *Summary:* Children's behavior was assessed by the Chinese version of the Conners' Parent Rating Scale-Revised (CPRS-48). The homogeneity reliability of Cronbach α in the Chinese version of CPRS-48 was 0.932; the correlation of Spearman-brown split-half was 0.900; and the retest reliability of total score was 0.594. Raw scores for each subscale are converted into sex- and age-adjusted T-scores within a mean ± standard deviation (SD) of 50 ± 10. The guardians independently completed the CPRS-48 according to the instruction manual under the direction of trained investigators (++ for methods). Blinding is not reported. Although it is unlikely that the outcome assessors were aware of the fluoride levels in the urine, it is unclear if subjects were selected based on areas with endemic fluoride or if parents were aware of fluoride concentrations in the areas. (NR for blinding). Overall rating for methods and blinding = NR.
  - *Basis for rating:* Probably high risk of bias based on no information provided to indicate that the outcome was blindly assessed.
- ***Selective Reporting:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* All outcomes in the abstract, introduction, and methods are reported in sufficient details.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that all measured outcomes were reported.
- ***Other potential threats:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:*
    - *Statistical analyses:* Multiple linear regression models were used to assess the association between urinary fluoride exposure and each behavioral outcome. Logistic regression was used to assess the risk of behavioral problems (T-scores > 70) due to fluoride exposure. Sensitivity analyses were performed, with models adjusting for combinations of age, BMI, gender, mother migrated, father migrated, and urinary creatinine levels. Regression diagnostics to evaluate model assumptions are not described; however, the overall impact on effect estimates is expected to be minimal.
    - *Other potential concerns:* None identified.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the statistical analyses were appropriate and no other potential threats to risk of bias were identified.

- ***Basis for classification as low risk-of-bias study overall:*** Probably low risk-of-bias ratings in confounding and exposure. Study strengths include individual exposure measurements, but it is limited by the cross-sectional study design and lack of details on blinding of the outcome assessment. All key confounders were considered in the study design or analysis.

Appendix 5. Mechanistic Data from Animal Studies

A number of animal studies were available that presented mechanistic data in several effect categories (see **Figure A5-1**). Limiting the data to studies with at least one exposure at or below 20 ppm fluoride drinking water equivalents (gavage and dietary exposures were back-calculated into equivalent drinking water concentrations for comparison) still provided a sufficient number of studies for evaluation of several mechanistic endpoints while allowing for a more focused look at exposure levels most relevant to human exposures. The following sections summarize the mechanistic data by the effect category. Although there is some evidence of consistency in mechanistic effects, overall, these data are insufficient to increase confidence in the assessment of findings from human epidemiology studies.

Figure A5-1. Number of Animal Mechanistic Studies for Fluoride by Mechanistic Category and Exposure Level*

	Dose Level	
Mechanism	**All**	**≤20 ppm**
Biochemical (brain/neurons)	66	25
Neurotransmitters	53	23
Oxidative stress	78	25
Histopathology	67	30
Apoptosis/cell death	19	7
Inflammation	7	5
Thyroid	50	17
Other	3	2

*Interactive figure and additional study details in Tableau® (https://public.tableau.com/app/profile/ntp.visuals/viz/Animal_Mechanisms_2021/FigureA5-1). The number of studies that evaluated mechanistic effects associated with at least one exposure at or below 20 ppm fluoride is tabulated in the "≤20 ppm" column. The total number of studies per mechanistic category are summarized in the "All" column.

Neurotransmitters

Neurotransmitter and biochemical changes in the brain and neurons were considered to be the mechanistic areas with the greatest potential to demonstrate effects of fluoride on the brain of animals in the lower dose range and provide evidence of changes in the brain that may relate to lower IQ in children (see **Figure A5-2**). Twenty of 23 neurotransmitter studies assessed changes in brain cholinesterase activity associated with fluoride exposure at or below 20 ppm fluoride. Acetylcholine is a major neurotransmitter involved in learning, memory, and intelligence (Chen 2012, Gais and Schonauer 2017). AChE is responsible for the breakdown of acetylcholine in the synapses of nerve cells. Changes in cholinesterase, acetylcholine, or AChE could be related to effects on memory. Evidence of an effect varied among the low risk-of-bias studies that assessed changes in cholinesterase or acetylcholine (n = 11 drinking water studies) (Gao *et al.* 2009, Baba *et al.* 2014, Adedara *et al.* 2017a, Khan *et al.* 2017, Gao *et al.* 2008a, Akinrinade *et al.* 2015a, Sun *et al.* 2000 [translated in Sun *et al.* 2008], Chouhan *et al.* 2010, Mesram *et al.* 2016, Liu *et al.* 2010, Nkpaa and Onyeso 2018), with the majority of studies reporting evidence of an effect that is considered inconsistent with the phenotypic outcome. Decreases in cholinesterase will cause increases in acetylcholine, which can have a positive effect on learning and

memory; however, long-term decreases in cholinesterase can lead to secondary neuronal damage occurring in the cholinergic region of the brain (Chen 2012).

Five of the 11 studies with low risk of bias (Gao *et al.* 2009, Baba *et al.* 2014, Adedara *et al.* 2017a, Khan *et al.* 2017, Nkpaa and Onyeso 2018) found statistically significant decreases in cholinesterase or AChE in brain homogenates (with some brains dissected into specific regions prior to homogenizing) with fluoride concentrations in drinking water at or below 20 ppm, and 4 of the 5 studies found statistically significant decreases in cholinesterase or AChE below 10 ppm. The 5 studies were conducted in rats (Wistar or Sprague-Dawley) with exposure ranging from 28 days to 6 months. An additional 2 out of 11 studies (Gao *et al.* 2008a, Akinrinade *et al.* 2015a) reported decreases in brain homogenate AChE at concentrations at or below 20 ppm fluoride in drinking water, but statistical significance was not reached. These studies were also conducted in rats with exposure for 30 days or 3 months. Gao *et al.* (2008a) reported a dose-dependent decrease in brain homogenate AChE in the low (5 ppm fluoride) and high (50 ppm fluoride) treatment groups compared with the control group, but the decrease was only statistically significant in the high dose group. Similarly, Akinrinade *et al.* (2015a) observed a dose-dependent decrease in percent intensity of AChE immunohistochemistry in the prefrontal cortex associated with 2.1 and 10 ppm sodium fluoride in the drinking water, but neither result was statistically significant. Gao *et al.* (2009) found lower brain homogenate AChE levels in the 5-ppm animals compared with the 50-ppm animals; therefore, the results were not always dose dependent.

Relative to the above-mentioned studies, 2 of the 11 low risk-of-bias studies observed opposite effects on brain cholinesterase levels. Sun *et al.* (2000) [translated in Sun *et al.* 2008] observed a significant increase in brain cholinesterase in Kunming mice associated with fluoride drinking water concentrations from 10 to 100 mg/L, but did not observe a dose response. Chouhan *et al.* (2010) did observe a dose-related increase in AChE levels in brain homogenate of Wistar rats with sodium fluoride concentrations of 1 to 100 ppm for 12 weeks and noted statistically significant results at 1, 50, and 100 ppm but not at 10 ppm.

Mesram *et al.* (2016) did not assess changes in AChE but observed a significant decrease in acetylcholine levels in cerebral cortex homogenate through 30 days of age in rats treated in utero with 20 ppm sodium fluoride, which may suggest an increase in AChE levels. Likewise, Liu *et al.* (2010) did not assess changes in AChE, but measured nicotinic acetylcholine receptors (nAChRs) in brain homogenate of rats following drinking water fluoride exposure, which the authors stated could modulate physiological and pharmacological functions that are involved in learning and memory-related behaviors. Significant decreases in the protein expressions of nAChR subunits at 2.26 ppm fluoride were observed; however, the corresponding receptor subunit mRNAs did not exhibit any changes (Liu *et al.* 2010).

The studies that assessed other neurotransmitters of the brain and neurons were too heterogeneous or limited in number to make any determination on mechanism, even before limiting the review of the data to low risk-of-bias studies. There were only five studies that evaluated dopamine and/or metabolites (Tsunoda *et al.* 2005, Chouhan *et al.* 2010, Reddy *et al.* 2014, Banala *et al.* 2018, Sudhakar and Reddy 2018). Four of the studies observed decreases in dopamine levels in the brain with exposures less than 20 ppm fluoride (Reddy *et al.* 2014, Chouhan *et al.* 2010, Banala *et al.* 2018, Sudhakar and Reddy 2018); however, the fifth study (Tsunoda *et al.* 2005) observed increased dopamine and metabolites at fluoride exposures below 20 ppm (with statistical significance achieved only for the metabolite homovanillic acid in one brain region). No differences from the control group were observed at levels above 20 ppm fluoride. Other neurotransmitters were evaluated at or below 20 ppm fluoride exposure, but generally only in a couple of studies.

Biochemistry (Brain/Neurons)

Similar to above, the endpoints measured in brain biochemistry studies were too heterogeneous or limited in number to make any determination on potential relevance of mechanism, even before limiting the review of the data to low risk-of-bias studies (see **Figure A5-2**). Endpoints related to biochemical changes in the brain or neurons included carbohydrate or lipid changes, RNA or DNA changes, changes in gene expression, or changes in protein expression. For the most part, only a single study was available for any given endpoint. The largest body of evidence on biochemistry was on protein level in various brain regions. Eleven low risk-of-bias studies were identified that evaluated protein levels; however, few studies evaluated the same proteins or areas of the brain. In the few cases where the same protein was evaluated, results were not always consistent. These data are insufficient to increase confidence or support a change to hazard conclusions.

Histopathology

Histological data can be useful in determining whether effects are occurring in the brain at lower fluoride concentrations; however, author descriptions of these effects may be limited thereby making it difficult to directly link histological changes in the brain to learning and memory effects. Histopathology of the brain was evaluated in 31 studies with concentrations at or below 20 ppm fluoride, of which 15 studies were considered low risk-of-bias studies (Adedara *et al.* 2017b, Akinrinade *et al.* 2015a, Bhatnagar *et al.* 2002, Bhatnagar *et al.* 2011, Chouhan *et al.* 2010, Guner *et al.* 2016, Jiang *et al.* 2014, Lou *et al.* 2013, McPherson *et al.* 2018, Mesram *et al.* 2016, Niu *et al.* 2018, Pulungan *et al.* 2016, Nageshwar *et al.* 2018, Zhao *et al.* 2019, Jia *et al.* 2019). In all but one low risk-of-bias study [Pulungan *et al.* (2016); gavage], animals were exposed to fluoride via drinking water. All low risk-of-bias studies were conducted in rodents, and all but three studies were conducted in rats (Wistar [seven studies]; Sprague-Dawley [four studies]; Long-Evans hooded [one study]). Overall, the low risk-of-bias studies that evaluated histopathology in the brain had low potential for bias for key questions regarding randomization and exposure characterization; however, eight studies were rated as probably high risk of bias for the key risk-of-bias question regarding outcome assessment based on lack of reporting of blinding of outcome assessors and/or inadequate description of outcome measures or lesions. Moreover, low image quality in some of the studies hampered the ability to verify the quality of the data. Further technical review of the 15 low risk-of-bias studies was conducted by a board-certified pathologist. Based on confidence in the results for each study, the technical reviewer further categorized the low risk-of-bias studies as studies with higher or low confidence in the outcome assessment, which is reflected in the following summary of the brain histopathology results. Main limitations of the histopathology data identified by the pathologist included lack of information on methods of euthanasia and fixation. Perfusion fixation is generally considered the best practice for lesions of the central nervous system in addition to complete fixation of the brain prior to its removal from the skull (Garman *et al.* 2016). Four of the low risk-of-bias studies reported that they used this method (Bhatnagar *et al.* 2002, Bhatnagar *et al.* 2011, McPherson *et al.* 2018, Pulungan *et al.* 2016). Two of the low risk-of-bias studies handled the brains before fixation was complete, which can produce artifacts that can resemble dead neurons (Zhao *et al.* 2019, Nageshwar *et al.* 2018). Fixation and brain removal details were inadequately described in the remaining low risk-of-bias studies.

Although there was heterogeneity in the endpoints reported (e.g., cell size, shape, and counts; nuclei fragmentation; increased vacuolar spaces) and some variation in the consistency of the evidence based on the area of the brain evaluated, the majority of the low risk-of-bias studies (11 of 14 drinking water studies) found some histological change in the brain of rats or mice treated with fluoride at concentrations at or below 20 ppm, of which 8 studies reported histological changes in the brain at or below 10 ppm. Histological changes in the hippocampus (one of the areas of the brain most evaluated for histological changes) associated with fluoride exposures at or below 20 ppm were reported in three

of four low risk-of-bias studies with higher confidence in the outcome assessment (Bhatnagar *et al.* 2002, Bhatnagar *et al.* 2011, Guner *et al.* 2016) and in three of four low risk-of-bias studies with lower confidence in the outcome assessment (Jiang *et al.* 2014, Niu *et al.* 2018, Nageshwar *et al.* 2018). McPherson *et al.* (2018) was the only drinking water study (with higher confidence in the histopathology outcome assessment) that did not observe any histological changes in hippocampus at 10 or 20 ppm fluoride in male Long-Evans hooded rats exposed in utero through adulthood (>PND80). Although there are too few studies to definitively explain the inconsistency in results, McPherson *et al.* (2018) also did not observe any associations between fluoride exposure and impairments to learning and memory, which is inconsistent with the majority of developmental exposure studies that observed learning and impairments associated with fluoride exposure for other strains of rats. Similarly, histological changes in the cortex were reported in three of the four low risk-of-bias drinking water studies with higher confidence in the outcome assessment (Chouhan *et al.* 2010, Bhatnagar *et al.* 2011, Akinrinade *et al.* 2015a) and in three of four low risk-of-bias studies with lower confidence in the outcome assessment (Lou *et al.* 2013, Mesram *et al.* 2016, Nageshwar *et al.* 2018).

Histological changes were also consistently reported in other areas of the brain in studies with higher confidence in the outcome assessment, including the amygdala, caudate putamen, cerebellum, and hypothalamus, although each of these areas of the brain were only evaluated in one low risk-of-bias study (Bhatnagar *et al.* 2011, Guner *et al.* 2016). Pulungan *et al.* (2016), one of two low risk-of-bias studies with higher confidence in the outcome assessment that did not report histological changes in the brain, observed a decreasing trend in the number of pyramidal cells in the prefrontal cortex with increasing dose, but this was not changed at concentrations below 20 ppm (study administered sodium fluoride via gavage; the 5-mg/kg-day dose was considered to be equivalent to 15.3 ppm fluoride in drinking water) nor were any of the results statistically significant.

Oxidative Stress

Oxidative stress is considered a general mechanistic endpoint that cannot be specifically linked to neurodevelopmental or cognitive effects in humans; however, like histopathology, it may help in identifying changes in the brain occurring at lower concentrations of fluoride. Oxidative stress in the brain was evaluated in 25 studies that examined concentrations at or below 20 ppm fluoride, of which 15 studies had low potential for bias (Adedara *et al.* 2017a, Adedara *et al.* 2017b, Akinrinade *et al.* 2015b, Chouhan *et al.* 2010, Gao *et al.* 2008b, Guner *et al.* 2016, Mesram *et al.* 2016, Nkpaa and Onyeso 2018, Shan *et al.* 2004, Zhang *et al.* 2015a, Chouhan and Flora 2008, Gao *et al.* 2009, Khan *et al.* 2017, Bartos *et al.* 2018, Nageshwar *et al.* 2018). All of the low risk-of-bias studies were conducted in rats (mainly Wistar or Sprague-Dawley) and administered fluoride via drinking water with exposure durations ranging from 28 days to 7 months. Although there was heterogeneity in the endpoints reported (i.e., varying measures of protein oxidation, antioxidant activity, lipid peroxidation, and reactive oxygen species [ROS]) and some variation in the consistency of the evidence based on the endpoint, the majority of the studies (13 of 15 studies) (Adedara *et al.* 2017a, Adedara *et al.* 2017b, Akinrinade *et al.* 2015b, Gao *et al.* 2008b, Gao *et al.* 2009, Guner *et al.* 2016, Mesram *et al.* 2016, Nkpaa and Onyeso 2018, Shan *et al.* 2004, Zhang *et al.* 2015a, Khan *et al.* 2017, Nageshwar *et al.* 2018, Bartos *et al.* 2018) found evidence of oxidative stress in the brains of rats treated with fluoride at concentrations at or below 20 ppm, of which 10 studies reported oxidative stress in the brain below 10 ppm fluoride. The most consistent evidence of oxidative stress in the brain was reported through changes in antioxidant activity. Eleven of the 12 low risk-of-bias studies that evaluated antioxidant activity reported an effect at concentrations at or below 20 ppm (Adedara *et al.* 2017a, Adedara *et al.* 2017b, Akinrinade *et al.* 2015b, Gao *et al.* 2008b, Gao *et al.* 2009, Guner *et al.* 2016, Mesram *et al.* 2016, Nkpaa and Onyeso 2018, Khan *et al.* 2017, Bartos *et al.* 2018, Nageshwar *et al.* 2018). Decreases in antioxidant activity using measures of superoxide dismutase (SOD) activity were reported in seven of

eight low risk-of-bias studies (Adedara *et al.* 2017a, Adedara *et al.* 2017b, Akinrinade *et al.* 2015b, Mesram *et al.* 2016, Nkpaa and Onyeso 2018, Khan *et al.* 2017, Nageshwar *et al.* 2018) and, among these seven studies, all that also measured changes in catalase (CAT) activity (n = 6 studies) also reported decreased activity (Adedara *et al.* 2017a, Adedara *et al.* 2017b, Mesram *et al.* 2016, Nkpaa and Onyeso 2018, Khan *et al.* 2017, Nageshwar *et al.* 2018). A decrease in total antioxidant capacity (T-AOC) as a measure of antioxidant activity was also consistently reported in two low risk-of-bias studies (Gao *et al.* 2008b, Gao *et al.* 2009), and a decrease in glutathione peroxidase (GPx) activity was reported in two of three low risk-of-bias studies (Adedara *et al.* 2017b, Nkpaa and Onyeso 2018).

Relative to the above-mentioned studies, 2 of the 15 low risk-of-bias studies (Chouhan and Flora 2008, Chouhan *et al.* 2010) did not observe statistically significant effects on oxidative stress in the brain with concentrations at or below 20 ppm fluoride; however, the measure of oxidative stress evaluated in Chouhan and Flora (2008) and Chouhan *et al.* (2010) (glutathione [GSH] to oxidized glutathione [GSSG] ratio as an indication of antioxidant activity and ROS levels) were not evaluated in any other low risk-of-bias study. Chouhan and Flora (2008) observed a dose-dependent increase in ROS levels associated with 10, 50, and 100 mg/L sodium fluoride in the drinking water; however, results were not statistically significant at any dose. In Chouhan *et al.* (2010), the levels of ROS were significantly higher at 50 ppm sodium fluoride in drinking water, but statistical significance was not met at doses below 20 ppm fluoride (1 and 10 ppm sodium fluoride) or at 100 ppm sodium fluoride; yet, hydrogen peroxide levels as a measure of ROS were found to be significantly increased at 15 ppm sodium fluoride in drinking water in studies conducted by another group of authors (Adedara *et al.* 2017a, Adedara *et al.* 2017b).

Apoptosis/Cell Death

Seven low risk-of-bias studies were identified that evaluated apoptosis with concentrations at or below 20 ppm fluoride. Results from these studies were inconsistent and were insufficient for evaluating fluoride-induced apoptosis. These data are insufficient to increase confidence or support a change to hazard conclusions.

Inflammation

Five low risk-of-bias studies were identified that evaluated potential effects of fluoride on inflammation with concentrations at or below 20 ppm. The inflammation markers were too heterogeneous or limited in number to make any determination on potential relevance of mechanism, even before limiting the review of the data to low risk-of-bias studies. These data are insufficient to increase confidence or support a change to hazard conclusions.

Thyroid

Seventeen studies were identified that evaluated potential effects of fluoride on the thyroid with concentrations at or below 20 ppm (see **Figure A5-1**). These animal thyroid data are not further described because this endpoint has been directly evaluated in a number of human studies that have failed to identify consistent evidence to suggest that thyroid effects are a requisite mechanism by which fluoride causes neurodevelopmental or cognitive effects in humans.

Figure A5-2. Number of Low Risk-of-bias Animal Studies that Evaluated Biochemical, Neurotransmission, and Oxidative Stress Effects at or Below 20 ppm by Mechanism Subcategory and Direction of Effect*

Mechanism	Mechanism Subcategory	Direction of Effect ↑	↓	NS	Grand Total
Biochemistry (brain/neurons)	Carbohydrate/lipid-related		1	1	2
	Gene expression		1		1
	Protein levels associated with brain function	8	7	7	11
	Other biochemical	2			2
Neurotransmitters	Cholinesterase	2	7	3	11
	Dopamine and metabolites		1		1
	Other neurotransmitters	2	2	1	2
Oxidative stress	Antioxidant activity	1	10	4	12
	Lipid peroxidation byproduct	7		4	11
	Protein oxidation	2		1	2
	ROS	2		2	4

*Interactive figure and additional study details in Tableau® (https://public.tableau.com/app/profile/ntp.visuals/viz/Fluoride_Animal_SelectMechanisms_2021/FigureA5-2). This figure displays study counts for low risk-of-bias studies, as these counts are most relevant to the text in this section. Counts for high risk-of bias studies or all studies combined can be accessed in the interactive figure in Tableau®. Study counts are tabulated by significance—statistically significant increase (↑), statistically significant decrease (↓), or not significant (NS). For example, the "↑" column displays numbers of unique studies with at least one endpoint in the mechanistic subcategory with significantly increasing results at fluoride exposure levels of ≤20 ppm. These columns are not mutually exclusive (i.e., a study may report on multiple endpoints with varying results within a single mechanistic subcategory and therefore may be reflected in the counts for the "↑", "↓", and NS columns, but would only be counted once in the Grand Total column). Endpoints, species, strain, sex, and exposure duration are available for each study in the interactive figure in Tableau®.

U.S. DEPARTMENT OF HEALTH AND HUMAN SERVICES

FOREWORD

The National Toxicology Program (NTP), established in 1978, is an interagency program within the Public Health Service of the U.S. Department of Health and Human Services. Its activities are executed through a partnership of the National Institute for Occupational Safety and Health (part of the Centers for Disease Control and Prevention), the Food and Drug Administration (primarily at the National Center for Toxicological Research), and the National Institute of Environmental Health Sciences (part of the National Institutes of Health), where the program is administratively located. NTP offers a unique venue for the testing, research, and analysis of agents of concern to identify toxic and biological effects, provide information that strengthens the science base, and inform decisions by health regulatory and research agencies to safeguard public health. NTP also works to develop and apply new and improved methods and approaches that advance toxicology and better assess health effects from environmental exposures.

NTP conducts literature-based evaluations to determine whether exposure to environmental substances (e.g., chemicals, physical agents, and mixtures) may be associated with adverse health effects. These evaluations result in hazard conclusions or characterize the extent of the evidence and are published in the NTP Monograph series, which began in 2011. NTP Monographs serve as an environmental health resource to provide information that can used to make informed decisions about whether exposure to a substance may be of concern for human health.

NTP conducts these health effects evaluations following pre-specified protocols that apply the general methods outlined in the "Handbook for Conducting a Literature-Based Health Assessment Using the OHAT Approach for Systematic Review and Evidence Integration."[1] The protocol describes project-specific procedures tailored to each systematic review in a process that facilitates evaluation and integration of scientific evidence from published human, experimental animal, and mechanistic studies.

The key feature of the systematic review approach is the application of a transparent framework to document the evaluation methods and the basis for scientific judgements. This process includes steps to comprehensively search for studies, select relevant evidence, assess individual study quality, rate confidence in bodies of evidence across studies, and then integrate evidence to develop conclusions for the specific research question. Draft monographs undergo external peer review prior to being finalized and published.

NTP Monographs are available free of charge on the NTP website and cataloged in PubMed, a free resource developed and maintained by the National Library of Medicine (part of the National Institutes of Health). Data for these evaluations are included in the Health Assessment and Workspace Collaborative.

For questions about the monographs, please email NTP or call 984-287-3211.

[1] OHAT is the abbreviation for Office of Health Assessment and Translation, which is within the Division of the National Toxicology Program at the National Institute of Environmental Health Sciences.

ABSTRACT

Background: The overall objective of this evaluation was to undertake a systematic review of published literature to reach conclusions concerning the potential for exposure to fluoride to affect neurodevelopment and cognition. The review only addresses whether exposure to fluoride could present a potential hazard (i.e., has the potential to cause harm, at any exposure level, including exposures that are higher than those typically encountered from consuming fluoridated drinking water in the United States). Benefits of fluoride with respect to oral health are not addressed in this monograph.

Previous reviews of epidemiological studies, including a 2006 evaluation by the National Research Council (NRC), found support for an association between consumption of high levels of naturally occurring fluoride in drinking water and adverse neurological effects in humans and recommended further investigation (NRC 2006). Most of the evidence reviewed was from dental and skeletal fluorosis-endemic regions that have higher levels of naturally occurring fluoride than the fluoride concentrations historically added to water in community water fluoridation programs (0.8–1.2 mg/L). For community water systems that add fluoride, the Public Health Service now recommends a fluoride concentration of 0.7 mg/L.

NTP previously published a systematic review of the evidence from experimental animal studies of the effects of fluoride on learning and memory (NTP 2016). The systematic review found a low-to-moderate level of evidence that learning and memory deficits occur in non-human mammals exposed to fluoride. Studies in animals generally used fluoride drinking water concentrations that far exceeded the levels used in water fluoridation, and the lack of studies at lower fluoride concentrations was identified as a data gap. The evidence for effects on learning and memory was strongest (moderate) in animals exposed as adults, and evidence was weaker (low) in animals exposed during development. Since the publication of the NTP (2016) systematic review of the animal evidence, additional animal studies have been published, many examining the effects of perinatal exposures. In addition, the number of studies examining cognitive and neurobehavioral effects of fluoride in humans has grown considerably since the NRC (2006) review, including several recent prospective cohort studies evaluating prenatal fluoride exposures.

Objective: To conduct a systematic review of the human, experimental animal [extending (NTP 2016) report], and mechanistic literature to evaluate the evidence and develop hazard conclusions about whether fluoride exposure is associated with neurodevelopmental and cognitive effects.

Method: A systematic review protocol was developed and utilized following the Office of Health Assessment and Translation (OHAT) approach for conducting literature-based health assessments.

Results: The literature search and screening process identified 159 published human studies, 339 published experimental animal studies, and 60 in vitro/mechanistic studies relevant to the objective. Ninety-two of the 159 human studies evaluated the association between fluoride exposure and neurodevelopmental or cognitive effects, and the remaining human studies evaluated thyroid effects or other potential mechanistic data. The majority of the experimental animal studies were mechanistic studies, which were not assessed in the NTP (2016) report. Since the NTP (2016) systematic review (through April 2019), 35 experimental animal studies evaluating effects on learning and memory and/or motor activity and sensory effects of fluoride were identified.

Supported by a meta-analysis, the human body of evidence provides a consistent and robust pattern of findings that higher fluoride exposure (e.g., >1.5 mg/L in drinking water) is associated with adverse effects on neurocognitive development, including lower intelligence quotient (IQ) in children. There is a moderate level of evidence from cognitive neurodevelopmental studies in children based on five prospective cohort studies and 14 cross-sectional studies where exposure was identified as occurring prior to outcome. The evidence for cognitive effects in adults is limited, coming from two cross-sectional studies, and is inadequate to evaluate whether fluoride exposure in adults is associated with cognitive effects. The assessment of the new animal data focuses on evaluating a deficiency identified during the prior NTP (2016) review concerning the difficulty in distinguishing potential effects of fluoride on motor and sensory functions from effects specifically on learning and memory functions. Further examination of the animal data, including studies carried out at the NTP, has not resolved this issue. Because of this and other deficiencies related to overall study quality, the animal body of evidence is now considered inadequate to inform conclusions on whether fluoride exposure is associated with cognitive effects (including cognitive neurodevelopmental effects) in humans. While the animal data provide evidence of effects of fluoride on neurodevelopment, the human evidence base is primarily focused on cognitive neurodevelopmental effects, and these human data are the primary basis of conclusions.

Conclusions: Because the majority of available studies evaluated cognitive neurodevelopmental effects in children, the focus of the hazard conclusions is on cognitive neurodevelopmental effects, primarily IQ. When focusing on findings from studies with exposures in ranges typically found in drinking water in the United States (0.7 mg/L for optimally fluoridated community water systems)[2] that can be evaluated for dose response, effects on cognitive neurodevelopment are inconsistent, and therefore unclear. However, when considering all the evidence, including studies with exposures to fluoride levels higher than 1.5 mg/L in water, NTP concludes that fluoride is *presumed to be a cognitive neurodevelopmental hazard to humans*. This conclusion is based on a moderate level of evidence that shows a consistent and robust pattern of findings in human studies across several different populations demonstrating that higher fluoride exposure (e.g., >1.5 mg/L in drinking water) is associated with lower IQ and other cognitive effects in children. Limited and weaker evidence is considered to provide an inadequate level of evidence that fluoride is associated with cognitive effects in adults. The evidence from animal studies is inadequate to inform conclusions on cognitive effects, and the mechanisms underlying fluoride-associated cognitive neurodevelopmental effects are not well characterized.

[2]As of April 2020, 1.08% of persons living in the United States (~ 3.5 million people) were served by community water systems (CWS) containing ≥ 1.1 mg/L naturally occurring fluoride. CWS supplying water with ≥ 1.5 mg/L naturally occurring fluoride served 0.59% of the U.S. population (~ 1.9 million people), and systems supplying water with ≥ 2 mg/L naturally occurring fluoride served 0.31% of the U.S. population (~1 million people) (https://www.cdc.gov/fluoridation/data-tools/reporting-system.html).

INTRODUCTION

The NTP's Office of Health Assessment and Translation (OHAT) conducted a systematic review to evaluate the evidence that exposure to fluoride is associated with neurodevelopmental or cognitive effects. This review was initiated in response to a nomination from the Fluoride Action Network. There are numerous human and animal studies reporting neurodevelopmental and cognitive health effects of exposure to excess fluoride. As noted by the National Research Council (NRC) in their 2006 report, although the studies lacked sufficient detail to fully assess their quality and relevance to the U.S. populations, the consistency of the results suggesting that fluoride may be neurotoxic warrants additional research (NRC 2006).

Fluoride salts are added to community water systems and dental products in the United States (e.g., toothpaste, mouth rinses, and supplements) for the prevention of dental caries. Approximately 67% of the U.S. population receives fluoridated water through a community drinking water system (CDC 2013). In other countries fluoride supplementation has been achieved by fluoridating food products such as salt, or milk. Fluoride supplementation has been recommended to prevent bone fractures (Jones *et al.* 2005). Fluoride also can occur naturally in drinking water. Other sources of human exposure include other foods and beverages, industrial emissions, pharmaceuticals, and pesticides (e.g., cryolite, sulfuryl fluoride). Soil ingestion is another source of fluoride exposure in young children (US EPA 2010).

The U.S. Public Health Service (PHS) first recommended communities add fluoride to drinking water in 1962. PHS guidance is advisory, not regulatory, which means that while PHS recommends community water fluoridation as a public health intervention, the decision to fluoridate water systems is made by state and local governments.[3] For community water systems that add fluoride, PHS now recommends a fluoride concentration of 0.7 milligrams/liter (mg/L) (equal to 0.7 parts per million [ppm]). Under the Safe Drinking Water Act, the U.S. Environmental Protection Agency (EPA) sets maximum exposure level standards for drinking water quality. The current enforceable drinking water standard for fluoride, or the maximum contaminant level goal (MCLG, a concentration at which no adverse health effects are expected), is 4.0 mg/L. This is the maximum amount of fluoride contamination (naturally occurring not from water fluoridation) that is allowed in water from public water systems; it is set to protect against increased risk of skeletal fluorosis, a condition characterized by pain and tenderness of the major joints. EPA also has a non-enforceable secondary drinking water standard of 2.0 mg/L, which is recommended to protect children against the tooth discoloration and/or pitting that can be caused by severe dental fluorosis during the formative period prior to eruption of the teeth. Although the secondary standard is not enforceable, EPA does require that public water systems notify the public if the average levels exceed it (NRC 2006). As of April 2020, 1.08% of persons living in the United States (~ 3.5 million people) were served by community water systems (CWS) containing ≥ 1.1 mg/L naturally occurring fluoride. CWS supplying water with ≥ 1.5 mg/L naturally occurring fluoride served 0.59% of the U.S. population (~ 1.9 million people), and systems supplying water with ≥ 2 mg/L naturally occurring fluoride served 0.31% of the U.S. population (~1 million people) (https://www.cdc.gov/fluoridation/data-tools/reporting-system.html).

Controversy over community water fluoridation stems from concerns about the potential harmful effects of fluoride and the ethics of water fluoridation. Commonly cited health concerns related to

[3] For many years, most fluoridated community water systems used fluoride concentrations ranging from 0.8 to 1.2 mg/L (US DHHS 2015).

fluoride are bone fractures and skeletal fluorosis, lower intelligence quotient (IQ) and other neurological effects, cancer, and endocrine disruption. Effects on neurological function, endocrine function (e.g., thyroid, parathyroid, pineal), metabolic function (e.g., glucose metabolism), and carcinogenicity were assessed in the 2006 NRC report Fluoride in Drinking Water: A Scientific Review of EPA's Standards (NRC 2006). The NRC review considered adverse effects of water fluoride, focusing on a range of concentrations (2–4 mg/L) above the current 0.7-mg/L recommendation for community water fluoridation (NRC 2006). The NRC report concluded that the current MCLG should be lowered to protect against severe enamel fluorosis and to reduce the risk of bone fractures associated with skeletal fluorosis (NRC 2006). Other than severe fluorosis, the NRC did not find sufficient evidence of negative health effects at fluoride levels below 4.0 mg/L; however, the NRC concluded that the consistency of the results of IQ deficits in children exposed to fluoride at 2.5 to 4 mg/L in drinking water from a few epidemiological studies of Chinese populations appeared significant enough to warrant additional research on the effects of fluoride on intelligence. The NRC report noted several challenges to evaluating the literature, citing deficiencies in reporting quality, lack of consideration of all sources of fluoride exposure, incomplete consideration of potential confounding, selection of inappropriate control subject populations in epidemiological studies, absence of demonstrated clinical significance of reported endocrine effects, and incomplete understanding of the biological relationship between histological, biochemical, and molecular alterations with behavioral effects (NRC 2006).

In 2016, NTP conducted a systematic review of the evidence from experimental animal studies on the potential effects of fluoride exposure on learning and memory (NTP 2016). The NTP (2016) systematic review found a low-to-moderate level of evidence that learning and memory deficits occur in experimental animals exposed to fluoride. Based on the findings in NTP (2016), NTP decided to conduct additional animal studies before carrying out a full systematic review to incorporate human, animal, and potentially relevant mechanistic evidence in order to reach hazard identification conclusions for fluoride and learning and memory effects. As the NTP (2016) report on the experimental animal evidence focused on learning and memory and developed confidence ratings for bodies of evidence by life stage of exposure (i.e., exposure during development or adulthood), this report also evaluates two different age groups in humans (i.e., children and adults) with a focus on cognitive neurodevelopmental effects in children and cognitive effects in adults in order to address potential differences in the health impact based on timeframe of exposure (i.e., during development or during adulthood). This evaluation has been conducted separately from the 2016 experimental animal assessment, but like the 2016 assessment, it has assessed mainly learning and memory effects in experimental animal studies to determine whether the findings inform the assessment of cognitive neurodevelopmental effects in children and cognitive effects in adults. The September 6, 2019 draft of this monograph was reviewed by a committee convened by the National Academy of Sciences, Engineering, and Medicine (NASEM). The current document incorporates changes in response to that review.

OBJECTIVE AND SPECIFIC AIMS

Objective

The overall objective of this evaluation is to undertake a systematic review to develop NTP hazard identification conclusions on the association between exposure to fluoride and neurodevelopmental and cognitive effects based on integrating levels of evidence from human and non-human animal studies with consideration of the degree of support from mechanistic data.

Specific Aims

- Identify literature that assessed neurodevelopmental and cognitive health effects, especially outcomes related to learning, memory, and intelligence, following exposure to fluoride in human, animal, and relevant in vitro/mechanistic studies.
- Extract data on potential neurodevelopmental and cognitive health effects from relevant studies.
- Assess the internal validity (risk of bias) of individual studies using pre-defined criteria.
- Assess effects on thyroid function to help evaluate potential mechanisms of impaired neurological function.
- Summarize the extent and types of health effects evidence available.
- Describe limitations of the systematic review, limitations of the evidence base, identify areas of uncertainty, as well as data gaps and research needs for neurodevelopmental and cognitive health effects of fluoride.

Dependent on the extent and nature of the available evidence:

- Synthesize the evidence using a narrative approach or meta-analysis (if appropriate) considering limitations on data integration such as study design heterogeneity.
- Rate confidence in the body of evidence for human and animal studies separately according to one of four statements: High, Moderate, Low, or Very Low/No Evidence Available.
- Translate confidence ratings into level of evidence of health effects for human and animal studies separately according to one of four statements: High, Moderate, Low, or Inadequate.
- Combine the level of evidence ratings for human and animal data to reach one of five possible hazard identification conclusions: Known, Presumed, Suspected, Not classifiable, or Not identified to be a hazard to humans.

METHODS

Problem Formulation and Protocol Development

The research question and specific aims stated above were developed and refined through a series of problem formulation steps including:

(1) receipt of nomination from the public in June 2015 to conduct analyses of fluoride and developmental neurobehavioral toxicity;

(2) analysis of the extent of evidence available and the merit of pursuing systematic reviews, given factors such as the extent of new research published since previous evaluations and whether these new reports address or correct the deficiencies noted in the literature (NRC 2006, OEHHA 2011, SCHER 2011);

(3) request for information in a Federal Register notice (dated October 7, 2015);

(4) consideration of comments providing a list of studies to review through Federal Register notice and public comment period from October 7, 2015 to November 6, 2015;

(5) release of draft concept titled *Proposed NTP Evaluation on Fluoride Exposure and Potential for Developmental Neurobehavioral Effects* in November 2015;

(6) presentation of draft concept at the NTP Board of Scientific Counselors (BSC) meeting on December 1−2, 2015;

(7) consideration of comments on NTP's draft concept from the NTP BSC meeting in December 2015; and

(8) consideration of input on the draft protocol from review by technical advisors.

NTP published a systematic review of the animal evidence on the effects of fluoride on learning and memory (NTP 2016). NTP has conducted additional studies in animals to assess the effect of fluoride exposure on learning and memory. The results from this experimental animal work were published (McPherson *et al.* 2018) and are incorporated into the current review, which considers the epidemiological, animal, and mechanistic evidence in its conclusions. The protocol used to conduct this systematic review was posted in June 2017 with updates posted in May 2019 and September 2020 (https://ntp.niehs.nih.gov/go/785076).[4] A brief summary of the methods is presented below.

NASEM Review

The September 6, 2019 draft of this monograph was peer reviewed by a committee convened by NASEM. The current draft reflects clarifications and changes in response to that review (NASEM 2020), including the addition of meta-analyses of the IQ studies in children.

PECO Statements

PECO (**P**opulation, **E**xposure, **C**omparators and **O**utcomes) statements were developed as an aid to identify search terms and inclusion/exclusion criteria as appropriate for addressing the overall research question (effects on neurodevelopmental or cognitive function and thyroid associated with fluoride exposure) for the systematic review (Higgins and Green 2011).The PECO statements are listed below for human, animal, and in vitro/mechanistic studies (see **Table 1**, **Table 2**, and **Table 3**).

Using the PECO statements, the evaluation searched for evidence of neurodevelopmental or cognitive function, and thyroid effects associated with fluoride exposure from human studies, controlled exposure animal studies, and mechanistic/in vitro studies. Mechanistic data can come from a wide variety of studies that are not intended to identify a disease phenotype. This source of experimental data includes in vitro and in vivo laboratory studies directed at cellular, biochemical, and molecular mechanisms that attempt to explain how a substance produces particular adverse health effects. The mechanistic data were first organized by general categories (e.g., biochemical effects in the brain and neurons, neurotransmitters, oxidative stress, etc.) to evaluate the information available. Categories focused on were those with more robust data at levels of fluoride more relevant to human exposure. The intent was not to develop a mechanism for fluoride induction of learning and memory effects, but to evaluate whether a plausible series of mechanistic events exists to support effects observed in the low-dose

[4] NTP conducts systematic reviews following pre-specified protocols that describe the review procedures selected and applied from the general methods outlined in the OHAT Handbook for Conducting a Literature-Based Health Assessment (http://ntp.niehs.nih.gov/go/38673). The protocol describes project-specific procedures tailored to each systematic review.

region (below approximate drinking water equivalent concentrations of 20 ppm) that may strengthen the hazard conclusion.

Table 1. Human PECO (Population, Exposure, Comparator and Outcome) Statement	
PECO Element	**Evidence**
Population	Humans without restriction as to age or sex, geographic location, or life stage at exposure or outcome assessment
Exposure	Exposure to fluoride based on administered dose or concentration, biomonitoring data (e.g., urine, blood, other specimens), environmental measures (e.g., air, water levels), or job title or residence. Relevant forms are those used as additives for water fluoridation: • Fluorosilicic acid (also called hydrofluorosilicate; CASRN 16961-83-4) • Sodium hexafluorosilicate (also called disodium hexafluorosilicate or sodium fluorosilicate; CASRN 16893-85-9) • Sodium fluoride (CASRN 7681-49-4) • Other forms of fluoride that readily dissociate into free fluoride ions (e.g., potassium fluoride, calcium fluoride, ammonium fluoride)
Comparators	Comparable populations not exposed to fluoride or exposed to lower levels of fluoride (e.g., exposure below detection levels)
Outcomes	Neurodevelopmental outcomes including learning, memory, intelligence, other forms of cognitive behavior, other neurological outcomes (e.g., anxiety, aggression, motor activity), and biochemical changes in the brain or nervous system tissue; or measures of thyroid function, biochemical changes, or thyroid tissue

Table 2. Animal PECO Statement	
PECO Element	**Evidence**
Population	Non-human mammalian animal species (whole organism)
Exposure	Exposure to fluoride based on administered dose or concentration, and biomonitoring data (e.g., urine, blood, other specimens). Relevant forms are those used as additives for water fluoridation: • Fluorosilicic acid (also called hydrofluorosilicate; CASRN 16961-83-4) • Sodium hexafluorosilicate (also called disodium hexafluorosilicate or sodium fluorosilicate; CASRN 16893-85-9) • Sodium fluoride (CASRN 7681-49-4) • Other forms of fluoride that readily dissociate into free fluoride ions (e.g., potassium fluoride, calcium fluoride, ammonium fluoride)
Comparators	Comparable animals that were untreated or exposed to vehicle-only treatment
Outcomes	Neurodevelopmental outcomes including learning, memory, intelligence, other forms of cognitive behavior, other neurological outcomes (e.g., anxiety, aggression, motor activity), and biochemical changes in the brain or nervous system tissue; or measures of thyroid function, biochemical changes, or thyroid tissue

Table 3. In Vitro/Mechanistic PECO Statement	
PECO Element	**Evidence**
Population	Human or animal cells, tissues, or biochemical reactions (e.g., ligand binding assays)
Exposure	Exposure to fluoride based on administered dose or concentration. Relevant forms are those used as additives for water fluoridation: • Fluorosilicic acid (also called hydrofluorosilicate; CASRN 16961-83-4) • Sodium hexafluorosilicate (also called disodium hexafluorosilicate or sodium fluorosilicate; CASRN 16893-85-9) • Sodium fluoride (CASRN 7681-49-4) • Other forms of fluoride that readily dissociate into free fluoride ions (e.g., potassium fluoride, calcium fluoride, ammonium fluoride)
Comparators	Comparable cells or tissues that were untreated or exposed to vehicle-only treatment
Outcomes	Endpoints related to neurological and thyroid function, including neuronal electrophysiology; mRNA, gene, or protein expression; cell proliferation or death in brain or thyroid tissue/cells; neuronal signaling; synaptogenesis, etc.

Literature Search

Main Literature Search

Search terms were developed to identify all relevant published evidence on developmental neurobehavioral toxicity or thyroid-related health effects potentially associated with exposure to fluoride by reviewing Medical Subject Headings for relevant and appropriate neurobehavioral and thyroid-related terms, and by extracting key neurological and thyroid-related health effects and

developmental neurobehavioral terminology from reviews and a sample of relevant primary data studies. A combination of relevant subject headings and keywords were subsequently identified. A test set of relevant studies was used to ensure the search terms retrieve 100% of the test set. Six electronic databases were searched (see **Main Literature Database Search**) using a search strategy tailored for each database (specific search terms used for the PubMed search are presented in **Appendix 1**; the search strategy for other databases are available in the protocol (https://ntp.niehs.nih.gov/go/785076). A search of PubChem indicated that sodium fluoride was not found in either the Tox21 or ToxCast databases; therefore, these databases were not included in the search. No language restrictions or publication year limits were imposed. These six databases were searched in December 2016 and the search was regularly updated during the review process through April 1, 2019.

Evaluations must include cut-off dates for the literature search to enable synthesis and development of conclusions. Following the NASEM committee peer review in November 2019 (NASEM 2020), an additional search was conducted on May 1, 2020, where only primary human epidemiology studies were prioritized during screening. The review of the 2020 search results focused on the human studies because they formed the basis of the conclusions in the September 6, 2019 draft. A supplemental literature search of Chinese-language databases (described below) was also conducted.

Publications identified in these searches are categorized as "references identified through database searches" in **Figure 4.** Studies identified from other sources or manual review that might impact conclusions were considered under "references identified through other sources" in **Figure 4**. Literature searches for this systematic review were conducted independently from the literature search conducted for NTP (2016). The current literature search strategy was based on the search terms used for NTP (2016) and refined for the current evaluation, including the addition of search terms to identify human studies. Although the review process identified studies prior to 2015, the current assessment did not evaluate the studies published prior to 2015 and relied on the NTP (2016) assessment. The focus of the literature searches for this systematic review was to identify and evaluate relevant animal studies that were published since completion of the literature searches for the NTP (2016) assessment in addition to the human and mechanistic data that were not previously evaluated.

Supplemental Chinese Database Literature Search

Following NASEM committee peer review in November 2019 (NASEM 2020), additional searches were developed for non-English-language databases to systematically search for studies that were previously identified from other resources (e.g., Chinese-language studies from the Fluoride Action Network website). Non-English-language databases with the greatest potential to contain relevant non-English publications that were not previously identified through database searches were selected. Multiple non-English language databases were explored before finding two databases (CNKI and Wanfang) that covered studies previously identified from other sources. These two Chinese electronic databases were searched in May 2020 with no language restrictions or publication year limits. Search terms from the main literature search were refined to focus on human epidemiology studies. The CNKI and Wanfang databases have character limits in the search strings; therefore, key terms were prioritized using text analytics to identify the most prevalent terms from neurodevelopmental or cognitive human epidemiology studies previously identified as relevant. Search strings were designed to capture known relevant studies that were previously identified from searching other resources without identifying large numbers of non-relevant studies [the search strategy for both databases are available in the protocol (https://ntp.niehs.nih.gov/go/785076)]. Publications retrieved were compared to publications retrieved from the main literature search and duplicates were removed. The remaining relevant publications are categorized as "references identified through database searches" in **Figure 4**. New animal and

mechanistic references retrieved were scanned for evidence that might extend the information currently in the September 6, 2019 draft. Although additional studies were identified, data that would materially advance the animal and mechanistic findings were not identified; therefore, these studies were not extracted nor were they added to the draft. Newly-retrieved human references were reviewed to identify studies that might impact conclusions with priority given to identifying and translating null studies that may have been missed using previous approaches. Null studies that were identified were translated and included.

Databases Searched

Main Literature Database Search

- BIOSIS (Thomson Reuters)
- EMBASE
- PsycINFO (APA PsycNet)
- PubMed (NLM)
- Scopus (Elsevier)
- Web of Science (Thomson Reuters, Web of Science indexes the journal Fluoride)

Supplemental Chinese Database Literature Search

- CNKI
- Wanfang

Searching Other Resources

The reference lists of all included studies; relevant reviews, editorials and commentaries; and the Fluoride Action Network website (http://fluoridealert.org/) were manually searched for additional relevant publications. Following NASEM committee peer review in November 2019 (NASEM 2020), the Fluoride Action Network website was again searched for relevant references and contacted to identify null or no effect studies.

Unpublished Data

Unpublished data were eligible for inclusion provided the owner of the data was willing to have the data made public and peer reviewed (see protocol for more details https://ntp.niehs.nih.gov/go/785076). No unpublished data were identified during the literature search.

Study Selection

Evidence Selection Criteria

In order to be eligible for inclusion, studies had to satisfy eligibility criteria that reflect the PECO statement in **Table 1**, **Table 2**, and **Table 3**. The following additional exclusion criteria were applied (see protocol for additional details; https://ntp.niehs.nih.gov/go/785076):

(1) Case studies and case reports.

(2) Articles without original data (e.g., reviews, editorials, or commentaries). Reference lists from these materials, however, were reviewed to identify potentially relevant studies not identified from the database searches. New studies identified were assessed for eligibility for inclusion.

(3) Conference abstracts or reports.

Screening Process

References retrieved from the literature search were independently screened by two trained screeners at the title and abstract level to determine whether a reference met the evidence selection criteria. Screening procedures following the evidence selection criteria in the protocol were pilot-tested with experienced contract staff overseen by NTP. For citations with no abstract or non-English abstracts, articles were screened based on title relevance (title would need to indicate clear relevance); number of pages (articles ≤ 2 pages were assumed to be conference reports, editorials, or letters unlikely to contain original data); and/or PubMed Medical Subject Headings (MeSH). Using this approach, literature was manually screened for relevance and eligibility against the evidence selection criteria using a structured form in SWIFT-Active Screener. While the human screeners review studies, SWIFT-Active Screener aids in the process by employing a machine-learning software program used to priority-rank studies for screening (Howard *et al.* 2020). SWIFT-Active Screener also refines a statistical model that continually ranks the remaining studies according to their likelihood for inclusion. In addition, SWIFT-Active Screener employs active learning to continually incorporate user feedback during title and abstract screening to predict the total number of included studies, thus providing a statistical basis for a decision about when to stop screening (Miller *et al.* 2016). Title and abstract screening was stopped once the statistical algorithm in SWIFT-Active Screener estimated that 98% of the predicted number of relevant studies were identified.

Studies that were not excluded during the title and abstract screening were further screened for inclusion with a full-text review by two independent reviewers using DistillerSR® by Evidence Partners, a web-based, systematic-review software program with structured forms and procedures to ensure standardization of the process. Screening conflicts were resolved through discussion and consultation with technical advisor(s), if necessary. During full-text review, studies that were considered relevant were tagged to the appropriate evidence streams (i.e., human, animal, and/or in vitro). Studies tagged to human or animal evidence streams were also categorized by outcome as primary neurodevelopmental or cognitive outcomes (learning, memory, and intelligence); secondary neurobehavioral outcomes (anxiety, aggression, motor activity, or biochemical); or related to thyroid effects. In vitro data were tagged as being related to neurological effects or thyroid effects. Translation assistance was sought to assess the relevance of non-English studies. Following full-text review, the remaining studies were "included" and used for the evaluation.

Screening of the May 2020 Literature Search Update

Following the NASEM committee peer review in November 2019 (NASEM 2020), an additional search was conducted on May 1, 2020, where only primary human epidemiology studies were identified. The study screening and selection process was focused on the human studies with primary outcomes for the evaluation because they form the basis of the conclusions. Animal in vivo, human secondary outcome-only, and human and animal mechanistic references were identified as part of the screening process. These studies were then scanned for evidence that might extend the information in the September 6, 2019 draft. Studies from the May 2020 literature search update will be listed in an appendix; however, data from the studies were not extracted unless it was believed they would materially advance the findings.

Data Extraction

Data were collected (i.e., extracted) from included studies by one member of the evaluation team and checked by a second member of the team for completeness and accuracy. Any discrepancies in data extraction were resolved by discussion or consultation with a third member of the evaluation team.

Data extraction was completed using the Health Assessment Workspace Collaborative (HAWC), an open source and freely available web-based interface application.[5] Data extraction elements are listed separately for human, animal, and in vitro studies in the protocol (https://ntp.niehs.nih.gov/go/785076). Data for primary and secondary outcomes as well as thyroid hormone level data were extracted from human studies. Studies evaluating only goiters or thyroid size were not extracted. All primary outcomes and functional neurological secondary outcomes (e.g., motor activity) were extracted from animal studies identified since the NTP (2016) report. For animal mechanistic data, studies were tiered based on exposure dose (with preference given to fluoride drinking water equivalent exposures, which were calculated using the method described in the NTP (2016) report) of 20 ppm or less as deemed most relevant to exposures in humans), exposure duration or relevant time window (i.e., developmental), exposure route (with preference given to oral exposures over injection exposures), and commonality of mechanism (e.g., inflammation, oxidative stress, changes in neurotransmitters, and histopathological changes were considered pockets of mechanistic data). Data were not extracted from in vitro studies; however, these studies were evaluated for biological plausibility of the human and animal results. Thyroid data were also reviewed but not extracted. The data extraction results for included studies are publicly available and can be downloaded in Excel format through HAWC (https://hawcproject.org/assessment/405/). Methods for transforming and standardizing dose levels and results from behavioral tests in experimental animals are detailed in the protocol (https://ntp.niehs.nih.gov/go/785076).

In 2016, NTP conducted a systematic review of the evidence from experimental animal studies on the potential effects of fluoride exposure on learning and memory (NTP 2016). The literature searches for the current assessment identified and evaluated relevant animal studies published since the 2016 assessment and also included human and mechanistic data that were not previously evaluated. Although literature search activities for the current assessment identified experimental animal studies prior to 2015, the current assessment did not re-evaluate studies published prior to 2015, but relied on the NTP (2016) assessment.

Quality Assessment of Individual Studies

Risk of bias was assessed for individual studies using a tool developed by OHAT that outlines a parallel approach to evaluating risk of bias from human, animal, and mechanistic studies to facilitate consideration of risk of bias across evidence streams with common terms and categories. The risk-of-bias tool is comprised of a common set of 11 questions that are answered based on the specific details of individual studies to develop risk-of-bias ratings for each question. Study design determines the subset of questions used to assess risk of bias for an individual study (see **Table 4**).

Assessors were trained with an initial pilot phase undertaken to improve clarity of rating criteria and to improve consistency among assessors. Studies were independently evaluated by two trained assessors who answered all applicable risk-of-bias questions with one of four options in **Table 5** following pre-specified criteria detailed in the protocol (https://ntp.niehs.nih.gov/go/785076). The criteria describe aspects of study design, conduct, and reporting required to reach risk-of-bias ratings for each question

[5] HAWC (Health Assessment Workspace Collaborative): A Modular Web-based Interface to Facilitate Development of Human Health Assessments of Chemicals (https://hawcproject.org/portal/).

and specify factors that can distinguish among ratings (e.g., what separates “definitely low” from “probably low” risk of bias).

Key Risk-of-bias Questions

In the OHAT approach, some risk-of-bias questions or elements are considered potentially more important when assessing studies because there is more empirical evidence that these areas of bias have a greater impact on estimates of the effect size or because these issues are generally considered to have a greater effect on the credibility of study results in environmental health studies (Rooney *et al.* 2016). There were three Key Questions for observational human studies: confounding, exposure characterization, and outcome assessment. There were also three Key Questions for experimental animal studies: randomization, exposure characterization, and outcome assessment. In addition, for animal developmental studies, failure to consider the litter as the unit of analysis was also a key risk-of-bias concern. When there was not enough information to assess the potential bias for a risk-of-bias question and authors did not respond to an inquiry for further information, a conservative approach was followed, and the studies were rated probably high risk of bias for that question.

Table 4. OHAT Risk-of-bias Questions and Applicability by Study Design

Risk-of-bias Questions	Experimental Animal*	Human Controlled Trials**	Cohort	Case-Control	Cross-Sectional***	Case Series
1. Was administered dose or exposure level adequately randomized?	X	X				
2. Was allocation to study groups adequately concealed?	X	X				
3. Did selection of study participants result in the appropriate comparison groups?			X	X	X	
4. Did study design or analysis account for important confounding and modifying variables?			X	X	X	X
5. Were experimental conditions identical across study groups?	X					
6. Were research personnel blinded to the study group during the study?	X	X				
7. Were outcome data complete without attrition or exclusion from analysis?	X	X	X	X	X	
8. Can we be confident in the exposure characterization?	X	X	X	X	X	X
9. Can we be confident in the outcome assessment (including blinding of outcome assessors)?	X	X	X	X	X	X
10. Were all measured outcomes reported?	X	X	X	X	X	X
11. Were there no other potential threats to internal validity?	X	X	X	X	X	X

*Experimental animal studies are controlled exposure studies. Non-human animal observational studies can be evaluated using the design features of observational human studies such as cross-sectional study design.

**Human Controlled Trials are studies in humans with controlled exposure (e.g., Randomized Controlled Trials, non-randomized experimental studies)

***Cross-sectional studies include population surveys with individual data (e.g., NHANES) and surveys with aggregate data (i.e., ecological studies).

Any discrepancies in ratings between assessors were resolved by a senior technical specialist and through discussion when necessary to reach the final recorded risk-of-bias rating for each question along with a statement of the basis for that rating. Members of the evaluation team were consulted for assistance if additional expertise was necessary to reach final risk-of-bias ratings based on specific aspects of study design or performance reported for individual studies. Study procedures that were not reported were assumed not to have been conducted, resulting in an assessment of "probably high" risk of bias. Authors were queried by email to obtain missing information and responses received were used to update risk-of-bias ratings.

Table 5. The Four Risk-of-bias Rating Options	
Answers to the risk-of-bias questions result in one of the following four risk-of-bias ratings	
++	***Definitely Low*** *risk of bias*: There is direct evidence of low risk-of-bias practices
+	***Probably Low*** *risk of bias*: There is indirect evidence of low risk-of-bias practices **OR** it is deemed that deviations from low risk-of-bias practices for these criteria during the study would not appreciably bias results, including consideration of direction and magnitude of bias
– NR	***Probably High*** *risk of bias*: There is indirect evidence of high risk-of-bias practices (indicated with "-") **OR** there is insufficient information provided about relevant risk-of-bias practices (indicated with "NR" for not reported). Both symbols indicate probably high risk of bias.
––	***Definitely High*** *risk of bias*: There is direct evidence of high risk-of-bias practices

Organizing and Rating Confidence in Bodies of Evidence

Health Outcome Categories for Neurodevelopmental and Cognitive Effects

After data were extracted from all studies, the health effects results within the category of neurodevelopmental or cognitive effects were grouped across studies to develop bodies of evidence or collections of studies with data on the same or related outcomes. The grouping of health effect results was not planned a priori. The vast majority of the human studies evaluated intelligence quotient (IQ) in children as the single outcome; therefore, the discussion of cognitive neurodevelopmental effects in children focuses on IQ studies with supporting information from data on other endpoints. Cognitive function in adults was evaluated separately. Consistent with the NTP (2016) assessment, the primary focus within the animal study body of evidence was on animal studies with endpoints related to learning and memory.

Considerations for Pursuing a Narrative or Quantitative Evidence Synthesis

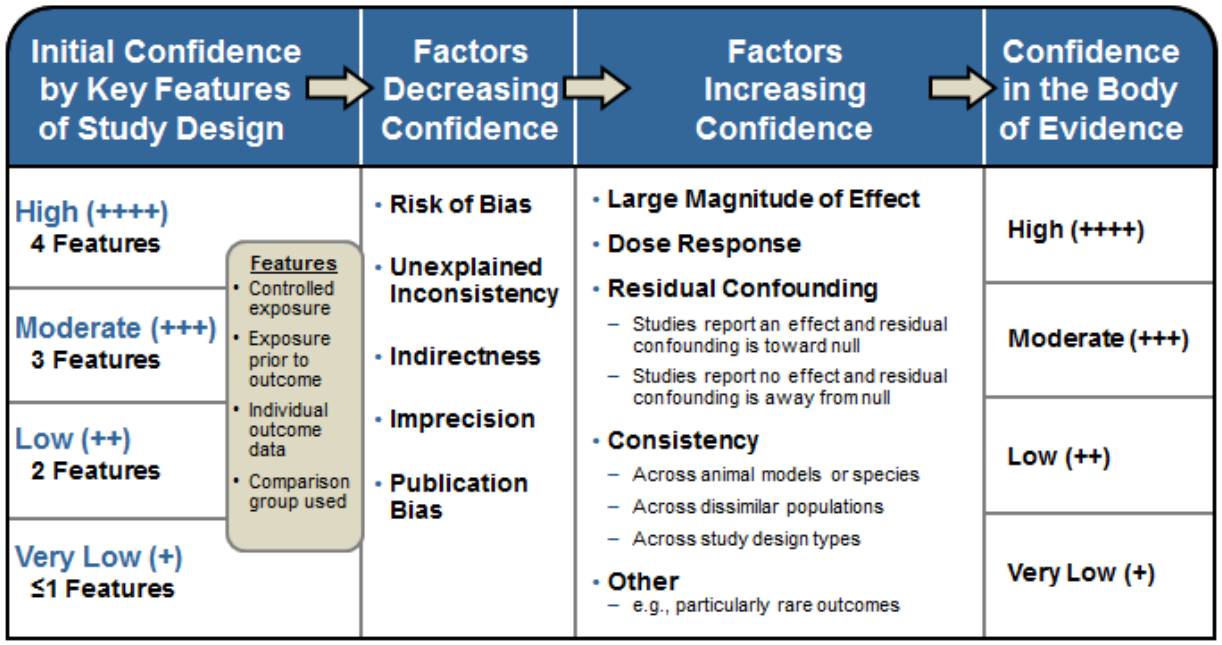
Heterogeneity within the available evidence was used to determine which type of evidence integration was appropriate—a quantitative synthesis (meta-analysis) or narrative approach for evidence integration. Choi *et al.* (2012) and Duan *et al.* (2018) conducted meta-analyses and found that high fluoride exposure was associated with lower IQ scores. Choi *et al.* (2012) was able to determine a risk ratio for living in an endemic fluorosis area but was unable to develop a dose-response relationship. Duan *et al.* (2018) suggested a significant non-linear dose-response relationship between fluoride dose and intelligence with the relationship stated to be most evident with exposures from drinking water

containing above 4 mg/L (or 4 ppm). Duan *et al.* (2018) found similar results as Choi *et al.* (2012) for the standardized mean difference; however, the majority of the available studies in both analyses compare populations with high fluoride exposure to those with lower fluoride exposure (with the lower exposure levels frequently in the range of drinking water fluoridation in the United States). After evaluating the available data, NTP determined that a narrative review—not a meta-analysis or other quantitative assessment—was appropriate for evidence integration due to heterogeneity in dose among the available human evidence, and because a hazard conclusion could be reached without conducting a meta-analysis. However, in the November 2019 review of the September 6, 2019 draft monograph (NASEM 2020), NASEM recommended that a meta-analysis be conducted. In response, NTP performed a meta-analysis of IQ studies in children. The meta-analysis protocol can be found with the revised systematic review protocol posted in September 2020 (https://ntp.niehs.nih.gov/go/785076).

Confidence Rating: Assessment of Body of Evidence

The quality of evidence for neurodevelopmental and cognitive function outcomes was evaluated using the GRADE system for rating the confidence in the body of evidence (Guyatt *et al.* 2011, Rooney *et al.* 2014). More detailed guidance on reaching confidence ratings in the body of evidence as "high," "moderate," "low," or "very low" is provided in the OHAT Handbook for Conducting a Literature-Based Health Assessment (http://ntp.niehs.nih.gov/go/38673, see STEP 5). In brief, available human and animal studies on a particular health outcome were initially grouped by key study design features, and each grouping of studies was given an initial confidence rating by those features. Starting at this initial rating (see column 1 of **Figure 1**), potential downgrading of the confidence rating was considered for factors that decrease confidence in the results (see column 2 of **Figure 1** [risk of bias, unexplained inconsistency, indirectness or lack of applicability, imprecision, and publication bias]); and potential upgrading of the confidence rating was considered for factors that increase confidence in the results (see column 3 of **Figure 1** [large magnitude of effect, dose response, consistency across study designs/populations/animal models or species, consideration of residual confounding, and other factors that increase our confidence in the association or effect]). Consideration of consistency across study designs, human populations, or animal species is not included in the GRADE guidance (Guyatt *et al.* 2011); however, it is considered in the modified version of GRADE used by OHAT (Rooney *et al.* 2014, NTP 2015).

Figure 1. Assessing Confidence in the Body of Evidence

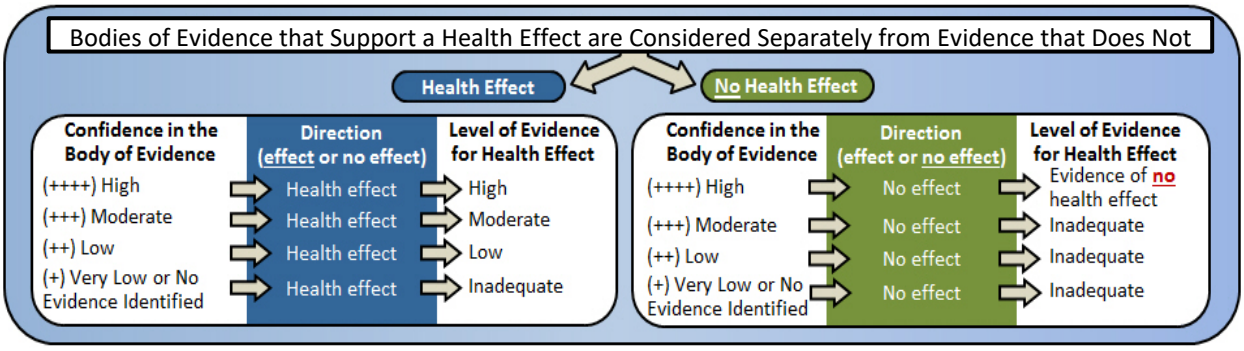


Confidence ratings were assessed by the evaluation team for accuracy and consistency, and discrepancies were resolved by consensus and consultation with technical advisors as needed. Confidence ratings for the primary outcomes are summarized in evidence profile tables for each outcome.

Preparation of Level of Evidence Conclusions

The confidence ratings were translated into level of evidence of health effects for each type of health outcome separately according to one of four statements: (1) High, (2) Moderate, (3) Low, or (4) Inadequate (see **Figure 2**). The descriptor “evidence of no health effect” is used to indicate confidence that the substance is not associated with a health effect. Because of the inherent difficulty in proving a negative, the conclusion “evidence of no health effect" is only reached when there is high confidence in the body of evidence.

Figure 2. Translate Confidence Ratings into Evidence of Health Effect Conclusions



Evidence Descriptors	Definition
High Level of Evidence	There is high confidence in the body of evidence for an association between exposure to fluoride and the health outcome(s).
Moderate Level of Evidence	There is moderate confidence in the body of evidence for an association between exposure to fluoride and the health outcome(s).
Low Level of Evidence	There is low confidence in the body of evidence for an association between exposure to fluoride and the health outcome(s), or no data are available.
Inadequate Evidence	There is insufficient evidence available to assess if exposure to fluoride is associated with the health outcome(s).
Evidence of No Health Effect	There is high confidence in the body of evidence that exposure to fluoride is not associated with the health outcome(s).

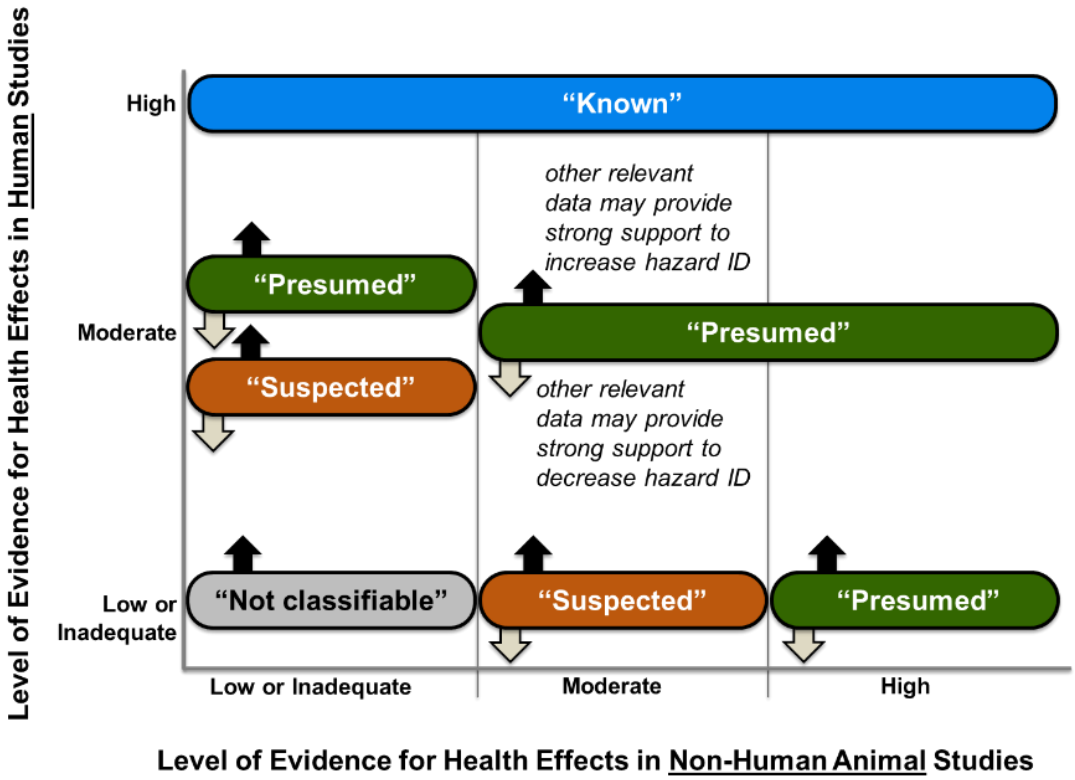
Integrate Evidence to Develop Hazard Identification Conclusions

Finally, the levels of evidence ratings for human and animal data were integrated with consideration of in vitro/mechanistic data to reach one of five possible hazard identification categories: (1) Known, (2) Presumed, (3) Suspected, (4) Not classifiable, or (5) Not identified to be a neurodevelopmental hazard to humans (see **Figure 3**).

Consideration of Human and Animal Data

Initial hazard identification conclusions were attempted by integrating the highest level-of-evidence conclusion for neurodevelopmental effects in children and cognitive effects in adults for the human and the animal evidence streams. The level-of-evidence conclusion for human data for neurodevelopmental or cognitive effects were considered with the level of evidence for non-human animal data to reach one of four initial hazard identification conclusions: Known, Presumed, Suspected, or Not classifiable. When either the human or animal evidence stream was characterized as "Inadequate Evidence," then conclusions were based on the remaining evidence stream alone (which is equivalent to treating the missing evidence stream as "Low" in **Figure 3**). If a moderate level-of-evidence conclusion for human data was reached with "Inadequate or Low Evidence" for the animal evidence stream, a hazard identification conclusion of either "suspected to be a hazard to humans" or "presumed to be a hazard to humans" could be reached based on scientific judgement as to the robustness of the body of evidence that supports moderate confidence in the human data and consideration of the potential impact of additional studies (NTP 2019).

Figure 3. Hazard Identification Scheme for Neurodevelopmental or Cognitive Effects



Consideration of Mechanistic Data

There is no requirement to consider mechanistic or mode-of-action data to reach a hazard identification conclusion regarding neurodevelopmental or cognitive health effects. However, when available, this and other relevant supporting types of evidence may be used to raise (or lower) the category of the hazard identification conclusion. Mechanistic data can come from a wide variety of studies that are not intended to identify a disease phenotype. This source of experimental data includes in vitro and in vivo laboratory studies directed at cellular, biochemical, genetic, and molecular mechanisms that attempt to explain how a chemical produces particular adverse effects.

For the evaluation of toxicity associated with fluoride exposure, NTP was interested in mechanistic or in vitro measures that comprise a coherent biological process that may support the plausibility of corresponding neurological outcomes reported from in vivo studies in animals or humans. The PECO statement in **Table 3** provides the specific endpoints considered including neuronal electrophysiology; mRNA, gene, or protein expression; cell proliferation or death in brain or thyroid tissue/cells; neuronal signaling; or synaptogenesis. In general, the mechanisms for fluoride-associated neurodevelopmental or cognitive effects are not well understood at this time, and mechanistic events identified in studies of animals receiving high fluoride exposures may not reflect biological processes occurring in humans at lower exposure levels. Mechanistic data from in vivo studies were used when feasible to examine the biological plausibility of the primary health outcomes considered in developing a hazard conclusion.

The factors outlined for increasing or decreasing confidence that the mechanistic data support biological plausibility are conceptually similar to those used to rate confidence in bodies of evidence for human or

animal in vivo studies are listed below and described in depth in the protocol (https://ntp.niehs.nih.gov/go/785076). Four factors were considered that contribute to increased confidence: potency, dose response, consistency in terms of cellular events observed at the same or lower doses than in vivo health effects, and consistency across cellular targets on the same functional pathway. Three factors were considered that contribute to decreased confidence: unexplained inconsistency across studies of the same endpoint, indirectness/applicability of the pathway for human health or concentrations for human exposure, and publication bias. Evaluations of the strength of evidence provided by mechanistic data were made on an outcome-specific basis based on discussion by the evaluation team and consultation with technical advisors as needed.

- If mechanistic data provided strong support for biological plausibility of the relationship between exposure and the health effect, the hazard identification conclusion may be upgraded (indicated by black "up" arrows in **Figure 3**) from that initially derived by considering the human and non-human animal evidence together.
- If mechanistic data provided strong opposition for biological plausibility of the relationship between exposure and the health effect, the hazard identification conclusion may be downgraded (indicated by gray "down" arrows in **Figure 3**) from that initially derived by considering the human and non-human animal evidence together.

Although it is envisioned that strong evidence for a relevant neurological effect from mechanistic data alone could indicate a potential that the substance is a neurodevelopmental hazard to humans, for this evaluation the mechanistic data were only considered to inform the biological plausibility of observed outcomes from in vivo exposure studies in humans or animals because of a general lack of understanding of the mechanistic basis for neurological outcomes.

RESULTS AND EVIDENCE SYNTHESIS

Literature Search Results

Literature Search Results Counts and Title and Abstract Screening

The electronic database searches retrieved 25,524 unique references in total (20,883 references during the initial search conducted in December 2016, 3,733 references during the literature search updates [including the final updated search conducted for the primary epidemiology studies on May 1, 2020], and 908 references from the supplemental Chinese database searches); 15 additional references were identified by technical advisors or from reviewing reference lists in published reviews and included studies. As a result of title and abstract screening, 1,038 references were moved to full-text review, 11,478 were excluded during manual title and abstract screening for not satisfying the PECO criteria, and an additional 13,023 were not screened and excluded based on the SWIFT algorithm.

Full-text Review

Among the 1,038 references that underwent full-text review, 499 references were excluded during the full-text review with reasons for exclusion documented at this stage; 332 references were excluded for not satisfying the PECO criteria; and 167 references from the May 2020 searches (main literature search update and supplemental Chinese database searches) were excluded for not including information that would materially advance the human, animal in vivo, or mechanistic findings (see the Literature Search Section for a description of the methodology). These screening results are outlined in a study selection diagram that reports numbers of studies excluded for each reason at the full text review stage (see **Figure 4**) [using reporting practices outlined in Moher *et al.* (2009)]. After full-text review, 539 studies were considered relevant with primary neurological outcomes, secondary neurological outcomes, and/or outcomes related to thyroid function (see **Appendix 2**). A few studies assessed data for more than one evidence stream (human, non-human mammal, and/or in vitro), and several human and animal studies assessed more than one type of outcome (e.g., primary and secondary outcomes). The number of included studies is summarized below. There are:

- 159 human studies (78 primary only; 13 secondary only; 5 primary and secondary; 6 primary and thyroid; 2 secondary and thyroid; and 55 thyroid only);
- 339 non-human mammal studies (7 primary only; 186 secondary only; 67 primary and secondary; 6 primary, secondary, and thyroid; 4 secondary and thyroid; and 69 thyroid only); and,
- 60 in vitro/mechanistic studies (48 neurological and 12 thyroid).

One publication contained human, experimental non-human mammal, and in vitro data. Three publications contained both human and experimental non-human mammal data. Fourteen publications contained data relevant to both experimental non-human mammal studies and in vitro studies.

Evaluation of SWIFT-Active Screener Results

During the initial title and abstract screening of 20,883 references using SWIFT-Active Screener, approximately 38%[6] of the 20,883 studies were manually screened in duplicate to identify an estimated 98.6% of the predicted number of relevant studies using the statistical algorithm in SWIFT-Active Screener (13,023 references were not screened). SWIFT-Active Screener predicted that there were 739 relevant studies during the initial title and abstract screening, of which 729 studies were identified and moved to full-text review. The SWIFT-Active statistical algorithm predicted that 10 relevant studies at the title and abstract level (10 represents 1.4% × 739 predicted relevant studies; or 739 predicted relevant studies minus 729 identified relevant studies during screening) were not identified by not screening the remaining 13,023 studies.

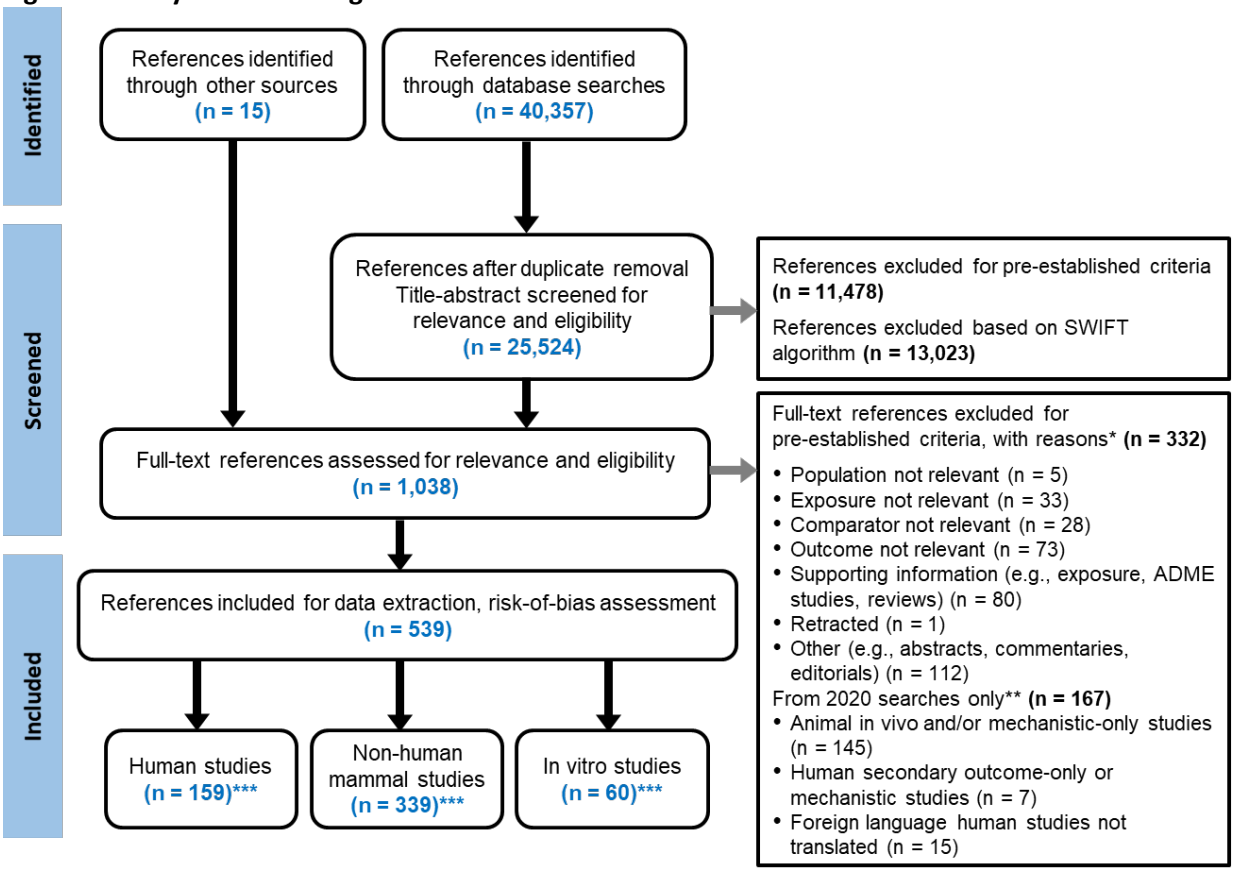
To further consider the impact of using SWIFT-Active Screener for this systematic review, NTP evaluated the SWIFT-Active screening results to gain a better understanding of the relevance of the last group of studies that were screened before 98% predicted recall was satisfied. The goal was to determine the likelihood of having missed important studies by not screening all of the literature. To do this, NTP evaluated subsets of studies screened in SWIFT-Active for trends and followed those studies through to full-text review for a final determination of relevance and potential impact (i.e., whether the studies had data on primary outcomes). Based on this evaluation, NTP estimates that the use of Swift-Active Screener may have resulted in missing 1–2 relevant human studies and 1–2 relevant animal studies with primary neurodevelopmental or cognitive outcomes.

Supplemental Chinese Database Searches and Human Epidemiology Studies

Following the NASEM committee peer review in November 2019 (NASEM 2020), supplemental searches were conducted in non-English language databases (CNKI and Wanfang). One focus of the screening of these supplemental search results was to identify null or no-effect studies that evaluated primary neurodevelopmental or cognitive outcomes (learning, memory, and intelligence) that may have been missed in previous approaches or may have been absent from the Fluoride Action Network website. Of the 908 references that were identified in the supplemental Chinese database searches, 16 relevant studies with primary neurological outcomes were identified (which were not identified through the main literature searches). Among these 16 studies, Kang *et al.* (2011) was the only null study with primary neurological outcomes that was identified through the supplemental Chinese database searches. NTP had the study translated to English, and the study was included. Note that Kang *et al.* (2011) is also identified by the Fluoride Action Network as a null study, but their website does not include an English translation of the study. The other 15 relevant studies contained results that would likely add to the body of evidence showing a negative association between fluoride exposure and primary neurological outcomes. Because this body of evidence is already so large, and because time was a factor in the revision of the monograph, these studies were not translated or included as this information would likely not materially advance the human findings.

[6] Howard *et al.* (2020) evaluated the performance of the SWIFT-Active Screener methods for estimating total number of relevant studies using 26 diverse systematic review datasets that were previously screened manually by reviewers. The authors found that on average, 95% of the relevant articles were identified after screening 40% of the total reference list when using SWIFT-Active Screener. In the document sets with 5,000 or more references, 95% of the relevant articles were identified after screening 34% of the available references, on average, using SWIFT-Active Screener.

Figure 4. Study Selection Diagram



* Studies may have been excluded for more than one reason; the first reason identified by the screener was recorded.

** Animal in vivo, human secondary outcome-only, and human and animal mechanistic references from the 2020 database searches were scanned for evidence that might strengthen the information in the September 6, 2019 draft monograph. Although 145 additional animal in vivo and/or mechanistic studies and 7 additional human secondary outcome-only or mechanistic-only studies were identified, information that would materially advance the human, animal in vivo, and mechanistic findings was not identified; therefore, these studies were not included. Additionally, 15 human primary outcome studies from the 2020 Chinese database search were excluded based on English abstracts and google translations because information that would materially advance the human findings was not identified; 1 null publication from the 2020 Chinese database search (Kang *et al.* 2011) was identified, translated, and included.

*** One publication contained human, experimental non-human mammal, and in vitro data. Three publications contained both human and experimental non-human mammal data. Fourteen publications contained data relevant to both experimental non-human mammal studies and in vitro studies.

Neurodevelopmental and Cognitive Health Effects Results

All the neurodevelopmental and cognitive data were initially considered and evaluated, with more in-depth analysis where similar endpoints were evaluated across multiple studies (e.g., IQ). Hazard conclusions were developed separately for two different age groups (i.e., children and adults) to address potential differences in the health impact based on exposure during development compared to adulthood. Although the data cover a wide array of endpoints (see **Figure 5**), the hazard conclusion covers a single category for each age group. The largest bodies of evidence were for IQ (n = 71 studies), learning and memory (n = 8 studies), as well as other cognitive development effects (e.g., total

neurobehavioral scores and total mental capacity index in children and cognitive impairment in adults; n = 14 studies)[7]. Due to heterogeneity in the endpoints examined and the limited number of human or animal studies, congenital neurological malformations and neurological complications of fluorosis were not evaluated because the body of evidence was inadequate to evaluate these potential effects. These health outcomes are not further discussed in this assessment. To the extent possible, human and animal data were grouped into similar categories (e.g., IQ in humans was considered comparable to learning and memory in animals). NTP had previously assessed animal data related to effects on learning and memory associated with fluoride exposure (NTP 2016). Therefore, to update the conclusions of the NTP (2016) systematic review, only more recent animal studies were evaluated in this assessment. Although the previous NTP (2016) report was conducted through January 14, 2016, the current assessment included studies published from 2015 through April 2019 and considered studies from the NTP (2016) report. Thirty-five animal studies have been identified that met these criteria, including 23 studies with learning and memory endpoints and 12 studies with only motor and sensory endpoints. Consistent with the NTP (2016) assessment, only learning and memory studies have been considered in the development of hazard identification conclusions. The additional motor and sensory studies have been considered, along with information on motor and sensory effects reported in the learning and memory studies, to provide evidence of possible indirectness related to the learning and memory assessments.

Risk-of-bias Considerations

Risk-of-bias ratings for each individual study for all risk-of-bias questions are available in **Appendix 3**. The risk of bias of individual studies in the body of evidence was considered in developing confidence ratings. The key risk-of-bias questions (i.e., confounding, exposure characterization, and outcome assessment for human studies and randomization, exposure characterization, and outcome assessment for experimental animal studies) are discussed in the consideration of the body of evidence. For this assessment, the key risk-of-bias questions, if not addressed appropriately, are considered to potentially have the greatest impact on the results. In addition, for developmental studies in animals, controlling for potential litter effects (i.e., adjusting for similarities in responses between littermates) was also a key risk-of-bias concern. The other risk-of-bias questions were also taken into consideration and were used to identify any other risk-of-bias concerns that may indicate serious issues with the studies. No study was excluded based on concerns for risk of bias; however, confidence conclusions were considered with and without higher risk-of-bias studies (i.e., studies rated probably high risk of bias for at least two key risk-of-bias questions or definitely high for any single question) to assess the impact of the higher risk-of-bias studies. The remaining studies (i.e., other than the higher risk-of-bias studies) were considered lower risk of bias. Based on NASEM recommendations (NASEM 2020), **Appendix 4** was created for the lower risk-of-bias studies to describe strengths and limitations of the studies identified during the assessment and to clarify why they are considered to pose lower risk of bias.

Human Neurodevelopmental and Cognitive Data

While there were several neurodevelopmental and cognitive endpoints assessed (see **Figure 5**), most of the available studies evaluated intelligence (e.g., IQ) in children. Other measures of neurodevelopment or cognitive function in children were also assessed, including general cognitive index (GCI), mental capacity, mental development index (MDI), or neonatal behavioral neurological assessment (NBNA). However, because the majority of studies evaluated intelligence, the discussion focuses primarily on IQ in children with separate discussions on other measures of cognitive function and neurobehavioral

[7]Some studies are included in more than endpoint category (e.g., IQ and other cognitive developmental effects); therefore, these counts are not mutually exclusive.

effects in children and cognitive effects in adults. The available body of literature that evaluates the association between fluoride exposure and neurodevelopmental and cognitive effects is relatively robust (n = 92) and confidence considerations in the body of evidence and hazard conclusions are focused on the studies with the least potential for bias (n = 31). Studies with higher potential for bias (n = 61) have also been evaluated and determined to have little impact on the confidence and hazard conclusions. A subgroup analysis within the meta-analysis (described in detail in **Appendix 5**) demonstrated that results were robust to the exclusion of higher risk-of-bias studies (see **Appendix 5**, **Figure A5-6**). All evaluated studies can be found in **Appendix 2**.

This section is organized to present and explain NTP's two confidence ratings in the bodies of evidence from epidemiological studies that fluoride exposure is associated with cognitive neurodevelopmental effects in children and cognitive effects in adults. These confidence ratings were determined as described in **Figure 1**.

Summary: There is moderate confidence in the body of evidence that fluoride exposure is associated with cognitive neurodevelopmental effects in children, and low confidence in the body of evidence that fluoride exposure is associated with cognitive effects in adults. The moderate confidence rating is supported by consistent evidence from the available studies of an association between high-fluoride exposure (mainly greater than the WHO Drinking Water Quality Guideline [>1.5 mg/L] (WHO 2011), but also high exposure via fluoridated salt and food) and lower IQ or cognitive function in children. There is also a recent study of lower IQ in children living in areas where drinking water fluoride concentrations are <1.5 mg/L. Specifically, a study conducted in Canada observed significantly lower IQ scores in boys and girls associated with higher estimated total maternal consumption of fluoride during pregnancy from drinking water and other water-based beverages including black and green tea. When looking at maternal urinary fluoride concentrations, the significant negative association with IQ scores was seen in in boys but not girls (Green *et al.* 2019). Another study conducted in Mexico with similar maternal urinary fluoride concentrations during pregnancy as seen in Green *et al.* (2019) observed significantly lower IQ scores in boys and girls associated with higher perinatal exposure to fluoride (Bashash *et al.* 2017). Although the body of evidence in children supports lower IQ with increased fluoride exposure, there is a lack of evidence of an association between exposure to fluoride and cognitive effects in adults (Jacqmin *et al.* 1994, Li *et al.* 2016). The body of evidence available to examine the association between exposure to fluoride and cognitive effects in adults is limited to two lower risk-of-bias cross-sectional studies; due to the limited number of studies and a lack of an observed effect, this body of evidence is considered inadequate to evaluate whether fluoride exposure is associated with cognitive effects in adults (see **Table 7**).

Most of the available epidemiological studies that evaluated the association between fluoride exposure and cognitive neurodevelopmental effects assessed IQ and other measures of cognitive function in children (see **Figure 5**). Confidence conclusions are based on those studies with the lowest potential for bias (n = 28; 26 in children and 2 in adults) (see **Table 6**). Most of these studies measured fluoride levels in drinking water or urine. All but two of the studies were conducted in infants or children. The two studies in adults were conducted in older adult populations (≥60 years old; one in France and the other in a fluorosis-endemic area of China) to evaluate the effects of fluoride on cognitive impairment.

The studies in children were conducted in multiple populations. Of the 26 studies in children:

- 12 were conducted in 6 areas of China based on 8 study populations (1 study with both IQ and other neurodevelopmental outcomes, 9 studies with IQ only, and 2 studies with other neurodevelopmental outcomes);
- 6 were conducted in 4 areas of Mexico based on 5 study populations (1 study with both IQ and other neurodevelopmental outcomes, 2 studies with IQ only, and 3 studies with other neurodevelopmental outcomes);
- 4 were conducted in Canada using 2 separate cohorts (2 studies with IQ only and 2 studies with other neurodevelopmental outcomes);
- 3 were conducted in 3 areas of India (all IQ studies); and
- 1 was conducted in Iran (IQ study).

The IQ studies used many different tests to measure IQ. The IQ tests used often differed by population as not all IQ tests are appropriate for all populations (e.g., western vs. Asian populations). In some cases, different IQ tests were used to study similar populations. Overall, studies used IQ or cognitive tests appropriate for the population and were age appropriate. Other neurodevelopmental outcomes assessed in some studies included neurobehavioral effects (in infants), learning and memory impairment, and learning disabilities such as attention deficit hyperactivity disorder (ADHD). The different tests conducted and the populations on which the tests were conducted are indicated in **Table 6**.

The lower risk-of-bias studies (i.e., studies not meeting criteria for higher risk of bias) showing associations with cognitive neurodevelopmental effects in children include 5 prospective cohort studies from 3 study populations (Bashash *et al.* 2017, Valdez Jimenez *et al.* 2017, Green *et al.* 2019, Bashash *et al.* 2018, Till *et al.* 2020) and 21 cross-sectional studies from 16 study populations (Li *et al.* 2004 [translated in Li *et al.* 2008a], Choi *et al.* 2015, Rocha-Amador *et al.* 2007, Rocha-Amador *et al.* 2009, Saxena *et al.* 2012, Seraj *et al.* 2012, Xiang *et al.* 2003a, Xiang *et al.* 2011, Zhang *et al.* 2015b, Ding *et al.* 2011, Barberio *et al.* 2017b, Yu *et al.* 2018, Cui *et al.* 2018, Cui *et al.* 2020, Wang *et al.* 2020b, Wang *et al.* 2020a, Wang *et al.* 2012, Soto-Barreras *et al.* 2019, Sudhir *et al.* 2009, Trivedi *et al.* 2012, Riddell *et al.* 2019) (see **Figure D1** through **Figure D12**). One limitation of the 21 cross-sectional studies was the lack of direct evidence that exposure to fluoride occurred prior to the development of the neurodevelopmental outcomes. However, several studies from different study populations (n = 5) indicated that a large portion of the exposed children had dental fluorosis (ranging from 43–100%) at the time of the assessment (Choi *et al.* 2015, Ding *et al.* 2011, Seraj *et al.* 2012, Yu *et al.* 2018, Sudhir *et al.* 2009). Because dental fluorosis occurs when fluoride is consumed during enamel formation usually during the first 6–8 years of life, the presence of dental fluorosis suggests that exposures to fluoride occurred prior to the outcome assessment. Ten studies from seven study populations (including Yu *et al.* (2018), Wang *et al.* (2012) listed above) excluded subjects that had not lived in the study area for a specified period of time, sometimes since birth (Rocha-Amador *et al.* 2007, Rocha-Amador *et al.* 2009, Saxena *et al.* 2012, Yu *et al.* 2018, Wang *et al.* 2020b, Wang *et al.* 2012, Xiang *et al.* 2011, Xiang *et al.* 2003a, Soto-Barreras *et al.* 2019, Sudhir *et al.* 2009). Another study evaluated fluoride exposure in mothers and included urine levels just prior to birth and assessed children a few days after birth (Li *et al.* 2004 [translated in Li *et al.* 2008a]). Because these areas were generally known to be fluoride-endemic areas for long periods of time, it can generally be assumed that in these 14 cross-sectional studies from 11 study populations, exposure occurred prior to the outcome. These exposure concerns were not an issue for the prospective studies because fluoride levels were measured prenatally. Therefore, the moderate confidence in the body of evidence in children is primarily based on the consistency of findings across different populations in the 5 lower risk-of-bias prospective cohort studies and the 14

cross-sectional studies where exposure is considered to have occurred prior to the outcome with initial and final ratings of moderate confidence.

Children-IQ Studies					
China					
Choi *et al.* (2015)	Cross-sectional Mianning County/1st grade children [51]	Drinking water GM: 2.20 mg/L Children's urine GM: 1.64 mg/L Severity of fluorosis (Dean Index)	Children (ages 6–8 years)	IQ: WISC-IV (square root block design and digit span)	Compared to normal/ questionable fluorosis, moderate/severe fluorosis significantly associated with lower total (adjusted β = −4.28; 95% CI: −8.22, −0.33) and backward digit span scores (adjusted β = −2.13; 95% CI: −4.24, −0.02); linear correlation between fluoride in urine (adjusted β = −1.67; 95% CI: −5.46, 2.12) and in drinking water (adjusted β = −1.39; 95% CI: −6.76, 3.98) with total digit span was observed but not significant; other outcomes not significantly associated with fluoride exposure Adjusted for child's age, child's gender, parity, illness before 3 years old, household income last year, and caretaker's age and education
Cui *et al.* (2018)	Cross-sectional Tianjin City (districts Jinghai and Dagang)/school children [323]	Children's urine Range (log-transformed): −1.2–2.2	Children (ages 7–12 years)	IQ: Combined Raven's Test for Rural China	Significant correlation between IQ score and urinary fluoride (adjusted β = −2.47) Adjusted for child age, mother's education, family member smoking, stress, and anger
Cui *et al.* (2020)	Cross-sectional Tianjin City (all districts) /school children [498]	Children's urine <1.6–≥2.5 mg/L	Children (ages 7–12 years)	IQ: Combined Raven's Test	No significant difference in IQ score in the three urinary fluoride exposure groups based on a one-way ANOVA <1.6 mg/L = 112.16 ± 11.50 1.6-2.5 mg/L = 112.05 ± 12.01 ≥2.5 mg/L = 110 ± 14.92 No statistical adjustment for confounders

Table 6. Studies on Neurodevelopmental and Cognitive Function in Humans[a,b]

Study	Study Design (Location/Subjects) [n]	Exposure Measures and Summary Statistics	Assessment Timing	Outcome and Methods	Neurological Outcome Summary
Zhang *et al.* (2015b)	Cross-sectional Tianjin City (Jinnan District)/school children [180]	Drinking water Mean: 0.63 (control), 1.40 (endemic fluorosis) mg/L (SD not reported) Children's urine Mean (SD): 1.1 (0.67) (control), 2.4 (1.01) (endemic fluorosis) mg/L Children's serum Mean (SD): 0.06 (0.03) (control), 0.18 (0.11) (endemic fluorosis) mg/L	Children (ages 10–12 years)	IQ: Combined Raven's Test for Rural China	Significant correlation between IQ score and serum fluoride (r = −0.47) and urinary fluoride (r = −0.45); significant difference in IQ score for high-fluoride area (>1 ppm; 102.33 ± 13.46) compared with control area (109.42 ± 13.30) Adjusted for child's age and gender, if applicable
Yu *et al.* (2018)*	Cross-sectional Tianjin City (7 towns) /children [2,886]	Drinking water Mean (SD): 0.50 (0.27) (normal), 2.00 (0.75) (high) mg/L Children's urine Mean (SD): 0.41 (0.49) (normal), 1.37 (1.08) (high) mg/L	Children (ages 7–13 years)	IQ: Combined Raven's Test for Rural China	Significant difference in mean IQ scores in high water fluoride area (>1.0 mg/L; 106.4 ± 12.3 IQ) compared to the normal area (≤1.0 ppm; 107.4 ± 13.0 IQ); distribution of the IQ scores also significantly different (p = 0.003); every 0.5-mg/L increase in water fluoride was associated with a 4.29 lower IQ score (95% CI: −8.09, −0.48) between 3.40 and 3.90 mg/L Adjusted for child's age, child's gender, maternal education, paternal education, and low birth weight
Wang *et al.* (2020b)	Cross-sectional Tianjin City (villages not specified)/school children [571]	Drinking water Mean (SD): 1.39 (1.01) mg/L Children's urine Mean (SD): 1.28 (1.30) mg/L	Children (ages 7–13 years)	IQ: Combined Raven's Test for Rural China	Significant associations between IQ and water and urine fluoride concentrations in boys and girls combined based on both quartiles and continuous measures (water: −1.587 per 1-mg/L increase; urine: −1.214 per 1-mg/L increase); there was no significant modification effect of gender Adjusted for child's age, child's gender, BMI, maternal education, paternal education, household income, and low birth weight

Table 6. Studies on Neurodevelopmental and Cognitive Function in Humans[a,b]

Study	Study Design (Location/Subjects) [n]	Exposure Measures and Summary Statistics	Assessment Timing	Outcome and Methods	Neurological Outcome Summary
Ding *et al.* (2011)	Cross-sectional Inner Mongolia (Hulunbuir City)/ elementary school children [331]	Drinking water Mean (SD): 1.31 (1.05) mg/L Children's urine Range: 0.1–3.55 mg/L	Children (ages 7–14 years)	IQ: Combined Raven's Test for Rural China	Significant association between urinary fluoride and IQ score (each 1-mg/L increase was associated with a lower IQ score of 0.59 points (95% CI: −1.09, −0.08); dose response relationship between fluoride and dental fluorosis ($p < 0.0001$) Adjusted for child's age
Xiang *et al.* (2003a)	Cross-sectional Wamiao and Xinhuai villages (Sihong County)/school children [512]	Drinking water Mean (SD): 0.36 (0.15) (control), 2.47 (0.79) (high fluoride) mg/L Children's urine Mean (SD): 1.11 (0.39) (control), 3.47 (1.95) (high fluoride) mg/L Village of residence (non-endemic v. endemic fluorosis)	Children (ages 8–13 years)	IQ: Combined Raven's Test for Rural China	Significant dose-related effect of fluoride on IQ score based on quintile levels with significantly lower IQ scores observed at water fluoride levels 1.53 mg/L or higher; Pearson correlation coefficient of -0.164 with urinary fluoride; IQ scores for children in non-endemic region (100.41 ± 13.21) significantly higher than endemic region (92.02 ± 13.00); calculated a lower-bound confidence limit benchmark concentration (BMCL) of 1.85 mg/L
Xiang *et al.* (2011)	Cross-sectional Wamiao and Xinhuai villages (Sihong County)/school children (same population as Xiang *et al.* (2003a)) [512]	Children's serum Mean (SD): 0.041 (0.009) (control), 0.081 (0.019) (high fluoride) mg/L	Children (ages 8–13 years)	IQ: Combined Raven's Test for Rural China	Significant trend on association between quartiles of serum fluoride and children's IQ score < 80 (adjusted ORs for Q1 and Q2; Q1 and Q3; and Q1 and Q4, respectively: 1; 2.22 [95% CI: 1.42, 3.47]; and 2.48 [95% CI: 1.85, 3.32]); significant effects at ≥0.05 ppm fluoride Adjusted for child's age and gender
Wang *et al.* (2012)	Cross-sectional Wamiao and Xinhuai villages (Sihong County)/school children (same population as Xiang *et al.* (2003a)) [526]	Drinking water Mean (SD): 0.36 (0.11) (control), 2.45 (0.80) (high fluoride) mg/L Children's total fluoride intake Mean (SD): 0.78 (0.13) (control), 3.05 (0.99) (high fluoride) mg/day Village of residence (non-endemic v. endemic fluorosis)	Children (ages 8–13 years)	IQ: Combined Raven's Test for Rural China	Significantly lower mean IQ in the high fluoride village (92.02 ± 13.00) compared to the control village (100.41 ± 13.21); when high exposure group was broken into 4 exposure groups, a dose-dependent decreasing IQ and increase in % with low IQ observed; significant correlation between total fluoride intake and IQ ($r = −0.332$); OR for IQ<80 per increase in total fluoride intake = 1.106; 95% CI 1.052–1.163). Adjusted for child's age and gender

Table 6. Studies on Neurodevelopmental and Cognitive Function in Humans[a,b]

Study	Study Design (Location/Subjects) [n]	Exposure Measures and Summary Statistics	Assessment Timing	Outcome and Methods	Neurological Outcome Summary
Mexico					
Rocha-Amador *et al.* (2007)	Cross-sectional Moctezuma and Salitral in San Luis Potosi State and 5 de Febrero of Durango State /elementary school children [132]	Drinking water Mean (SD): 0.8 (1.4), 5.3 (0.9), 9.4 (0.9) mg/L (3 rural areas) Children's urine Mean (SD): 1.8 (1.5), 6.0 (1.6), 5.5 (3.3) mg/L (3 rural areas)	Children (ages 6–10 years)	IQ: WISC-Revised Mexican Version	Significant associations between fluoride and IQ scores (full IQ adjusted βs of −10.2 with water and −16.9 with urine; CIs not reported); arsenic also present, but the effect was smaller (full IQ adjusted βs of −6.15 with water and −5.72 with urine; CIs not reported) Adjusted for blood lead, mother's education, SES, height-for-age z-scores, and transferrin saturation
Bashash *et al.* (2017)	Cohort (prospective) Mexico City/Early Life Exposures in Mexico to Environmental Toxicants (ELEMENT) participants [299] IQ analysis [211]	Maternal urine during pregnancy Mean (SD): 0.90 (0.35) mg/L Children's urine Mean (SD): 0.82 (0.38) mg/L	Children (ages 6–12 years)	IQ: WASI-Spanish Version	Significant effect between maternal urinary fluoride and offspring IQ score (adjusted β = −2.50; 95% CI: −4.12, −0.59); associations with children's urine not significant Adjusted for gestational age, weight at birth, child's gender, parity (being the first child), age at outcome measurement, and maternal characteristics including smoking history (ever smoked during the pregnancy vs. nonsmoker), marital status (married vs not married), age at delivery, education, IQ, and cohort

Table 6. Studies on Neurodevelopmental and Cognitive Function in Humans[a,b]					
Study	**Study Design (Location/Subjects) [n]**	**Exposure Measures and Summary Statistics**	**Assessment Timing**	**Outcome and Methods**	**Neurological Outcome Summary**
Soto-Barreras *et al.* (2019)	Cross-sectional Chihuahua/school children [161]	Drinking water Range: 0.05–2.93 mg/L Children's urine Range: 0.11–2.10 mg/L	Children (ages 9–10 years)	IQ: Raven's Colored Progressive Matrices	No significant differences in fluoride exposure level (urine fluoride [p = 0.559], exposure dose [p = 0.389], or fluorosis index [p = 0.851]) between the different IQ grades No statistical adjustment for confounders
Canada					
Green *et al.* (2019)	Cohort (prospective) 10 cities/Maternal-Infant Research on Environmental Chemicals (MIREC) [512] Non-Fluoridated [238] Fluoridated [162] Boys [248] Girls [264]	Maternal urine during pregnancy Mean (SD): 0.51 (0.36) mg/L (0.40 [0.27] mg/L in non-fluoridated areas and 0.69 [0.42] mg/L in fluoridated areas) Maternal fluoride intake during pregnancy Mean (SD): 0.54 (0.44) mg/day (0.30 [0.26] and 0.93 [0.43] mg/day, respectively) Drinking water Mean (SD): 0.31 (0.23) mg/L (0.13 [0.06] and 0.59 [0.08] mg/L, respectively)	Children (ages 3−4 years)	IQ: full scale, performance, and verbal using Wechsler Preschool and Primary Scale of Intelligence, Third Edition (WPPSI-III)	Significantly lower full-scale IQ (adjusted β = −4.49; 95% CI: −8.38, −0.60) and performance IQ (adjusted β = −4.63; 95% CI: −9.01, −0.25) per 1-mg/L increase in maternal urine in boys, but not girls (adjusted β = 2.40; 95% CI: −2.53, 7.33 and adjusted β = 4.51; 95% CI: −1.02, 10.05, respectively); significantly lower full-scale IQ (adjusted β = −3.66; 95% CI: −7.16, −0.15) per 1-mg increase in maternal fluoride intake (no sex interaction); significantly lower full-scale IQ (adjusted β = −5.29; 95% CI: −10.39, −0.19) per 1-mg/L increase in water fluoride concentration (no sex interaction); no significant changes observed in verbal IQ Adjusted for city, HOME score, maternal education, race, child's gender, and prenatal secondhand smoke exposure

Table 6. Studies on Neurodevelopmental and Cognitive Function in Humans[a,b]

Study	Study Design (Location/Subjects) [n]	Exposure Measures and Summary Statistics	Assessment Timing	Outcome and Methods	Neurological Outcome Summary
Till *et al.* (2020)	Cohort (prospective) 10 cities/ MIREC [398] Non-Fluoridated [247] Fluoridated [151] Breastfed as infants [200] Formula-fed as infants [198]	Maternal urine during pregnancy Mean (SD) breastfed: 0.42 (0.28) mg/L in non-fluoridated areas and 0.70 (0.39) mg/L in fluoridated areas formula-fed: 0.38 (0.27) mg/L in non-fluoridated areas and 0.64 (0.37) mg/L in fluoridated areas Infant fluoride intake Mean (SD) breastfed: 0.02 (0.02) mg/day in non-fluoridated areas and 0.12 (0.07) mg/day in fluoridated areas formula fed: 0.08 (0.04) mg/day in non-fluoridated areas and 0.34 (0.12) mg/day in fluoridated areas Drinking water Mean (SD) breastfed: 0.13 (0.06) mg/L in non-fluoridated areas and 0.58 (0.08) mg/L in fluoridated areas formula fed: 0.13 (0.05) mg/day in non-fluoridated areas and 0.59 (0.07) mg/L in fluoridated areas	Children (ages 3–4 years)	IQ: full-scale, performance, and verbal using Wechsler Preschool and Primary Scale of Intelligence, Third Edition (WPPSI-III)	Significantly lower performance IQ with water fluoride (−9.26 formula-fed, −6.19 breastfed) and fluoride intake from formula (−8.76); significantly lower full scale IQ with water fluoride in formula-fed (−4.40); lower full-scale IQ for water fluoride in breastfed (−1.34) and fluoride intake from formula (−2.69) were not significant; no significant changes in verbal IQ scores with fluoride exposure Adjusted for maternal education, maternal race, child's age at IQ testing, child's sex, HOME total score, and second-hand smoke status in the child's house (separate analysis also adjusted for mother's urinary fluoride)
India					
Sudhir *et al.* (2009)	Cross-sectional Nalgonda District (Andhra Pradesh)/school children [1,000]	Drinking water Level 1: <0.7 ppm Level 2: 0.7–1.2 ppm Level 3: 1.3–4.0 ppm Level 4: >4.0 ppm	Children (ages 13–15 years)	IQ: Raven's Standard Progressive Matrices	Significant increase in mean and distributions of IQ grades (i.e., increase in intellectually impaired children) with increasing drinking water fluoride levels No statistical adjustment for confounders

Table 6. Studies on Neurodevelopmental and Cognitive Function in Humans[a,b]

Study	Study Design (Location/Subjects) [n]	Exposure Measures and Summary Statistics	Assessment Timing	Outcome and Methods	Neurological Outcome Summary
Saxena *et al.* (2012)	Cross-sectional Madhya Pradesh/school children [170]	Drinking water ≥1.5 mg/L (high fluoride group) Children's urine Range: 1.7–8.4 mg/L	Children (age 12 years)	IQ: Raven's Standard Progressive Matrices	Significant correlation between water (r = 0.534; p = 0.000) and urinary fluoride (r = 0.542; p = 0.000) levels and IQ score; no significant differences in the levels of urinary lead or arsenic in children from the different groups Confounders included in the analysis were not reported
Trivedi *et al.* (2012)	Cross-sectional Kachchh, Gujarat/school children (6th and 7th grades) [84]	Drinking water Mean (SE): 0.84 (0.38) (low), 2.3 (0.87) (high) Children's urine Mean (SE): 0.42 (0.23) (low), 2.69 (0.92) (high)	Children (age 12–13 years)	IQ: questionnaire prepared by Professor JH Shah (97% reliability rating)	Significantly lower IQ score in the high fluoride (92.53 ± 3.13) compared to the low fluoride (97.17 ± 2.54) areas in boys and girls combined (as well as separately) No statistical adjustment for confounders
Iran					
Seraj *et al.* (2012)	Cross-sectional Makoo/school children [293]	Drinking water Mean (SD): 0.8 (0.3) (normal), 3.1 (0.9) (medium), 5.2 (1.1) (high) mg/L	Children (ages 6–11 years)	IQ: Raven's Colored Progressive Matrices	Significant correlation between water fluoride and IQ score (adjusted β = −3.865; CIs not reported); significantly higher IQ score in normal area (97.77 ± 18.91) compared with medium (89.03 ± 12.99) and high (88.58 ± 16.01) areas Adjusted for child's age, child's gender, child's education level, mother's education level, father's education level, and fluorosis intensity
Children-Other Neurodevelopmental Studies					
China					
Choi *et al.* (2015)	Cross-sectional Mianning County/1st grade children [51]	Drinking water GM: 2.20 mg/L Children's urine GM: 1.64 mg/L Severity of fluorosis (Dean Index)	Children (ages 6–8 years)	Learning and memory: Neuropsychological tests including WRAML Visual motor ability: WRAVMA Motor ability: Finger tapping task Manual dexterity: Grooved pegboard test	Outcomes unrelated to the IQ test not significantly associated with fluoride exposure Adjusted for child's age, child's gender, parity, illness before 3 years old, household income last year, and caretaker's age and education

Table 6. Studies on Neurodevelopmental and Cognitive Function in Humans[a,b]

Study	Study Design (Location/Subjects) [n]	Exposure Measures and Summary Statistics	Assessment Timing	Outcome and Methods	Neurological Outcome Summary
Li *et al.* (2004) [translated in Li *et al.* 2008a]	Cross-sectional Zhaozhou County, Heilongjiang Province/neonates [91]	Drinking water Range: 0.5–1.0 mg/L (control); 1.7–6.0 mg/L (high) Maternal urine during pregnancy Mean (SD): 1.74 (0.96) mg/L (control); 3.58 (1.47) mg/L (high)	Neonates (24–72 hours after delivery)	Neurodevelopmental: Neonatal behavioral neurological assessment (NBNA)	Significant differences in neurobehavioral assessment total scores between high-fluoride (36.48 ± 1.09) and control groups (38.28 ± 1.10); significant differences in total score of behavioral capability that includes measures of non-biological visual orientation reaction and biological visual and auditory orientation reaction between the two groups (11.34 ± 0.56 in controls compared to 10.05 ± 0.94 in high-fluoride group) No statistical adjustment for confounders
Wang *et al.* (2020a)	Cross-sectional Tongxu County/school children [325]	Children's urine Mean (SD): 1.54 (0.89) mg/L	Children (ages 7–13 years)	ADHD and behavior measures: Conners' Parent Rating Scale-Revised (Chinese version) (CPRS-48)	Significant association between psychosomatic problems and urinary fluoride level (per 1-mg/L increase β=4.01; 95% CI 2.74, 5.28; OR for T-score >70=1.97; 95% CI 1.19, 3.27) Adjusted for child's age, child's gender, child's BMI, urinary creatinine, mother migrated and father migrated
Mexico					
Rocha-Amador *et al.* (2009)	Cross-sectional Durango/elementary school children [80]	Children's urine GM (SD): 5.6 (1.7) mg/L	Children (ages 6–11 years)	Visuospatial organization and visual memory: Rey-Osterrieth Complex Figure Test, children's version	Significant correlation between urinary fluoride and visuospatial organization (r = −0.29) and visual memory scores (r = −0.27); no significant correlation with arsenic Adjusted for age
Valdez Jimenez *et al.* (2017)	Cohort (Prospective) Durango City and Lagos de Moreno/infants [65]	Drinking water Range: 0.5–12.5 mg/L (all trimesters) Maternal urine Range: 0.16–8.2 mg/L (all trimesters)	Infants (ages 3–15 months)	Mental development index (MDI): Bayley Scales of Infant Development II (BSDI-II)	Significant correlation between maternal urinary fluoride and MDI score during first trimester (adjusted β = −19.05; SE = 8.9) and second trimester (adjusted β = −19.34; SE = 7.46) Adjusted for gestational age, child's age, marginality index, and type of drinking water

Table 6. Studies on Neurodevelopmental and Cognitive Function in Humans[a,b]

Study	Study Design (Location/Subjects) [n]	Exposure Measures and Summary Statistics	Assessment Timing	Outcome and Methods	Neurological Outcome Summary
Bashash *et al.* (2017)	Cohort (prospective) Mexico City/Early Life Exposures in Mexico to Environmental Toxicants (ELEMENT) participants [299] GCI analysis [287]	Maternal urine during pregnancy Mean (SD): 0.90 (0.35) mg/L Children's urine Mean (SD): 0.82 (0.38) mg/L	Children (age 4 years)	General cognitive index (GCI): McCarthy Scales of Children's Abilities (MSCA)	Significant effect between maternal urinary fluoride and offspring GCI score (adjusted β = −3.15; 95% CI: −5.42, −0.87); associations with children's urine not significant Adjusted for gestational age, weight at birth, child's gender, parity (being the first child), age at outcome measurement, and maternal characteristics including smoking history (ever smoked during the pregnancy vs. nonsmoker), marital status (married vs not married), age at delivery, IQ, education, and cohort
Bashash *et al.* (2018)	Cohort (prospective) Mexico City/Early Life Exposures in Mexico to Environmental Toxicants (ELEMENT) participants [210]	Maternal urine during pregnancy Mean 0.85 (95% CI: 0.81, 0.90) mg/L	Children (ages 6–12 years)	ADHD: Conners' Rating Scales-Revised (CRS-R)	Significant associations between maternal urinary fluoride and CRS-R scores including Cognitive Problems + Inattention Index (adjusted β = 2.54; 95% CI: 0.44, 4.63), DSM-IV Inattention Index (adjusted β = 2.84; 95% CI: 0.84, 4.84), DSM-IV ADHD Total Index (adjusted β = 2.38; 95% CI: 0.42, 4.34), and ADHD Index (adjusted β = 2.47; 95% CI: 0.43, 4.50) Adjusted for gestational age, birth weight, child's gender, parity, age at outcome measurement, and maternal characteristics including smoking history (ever smoked vs. nonsmoker), marital status (married vs. not married), education, socioeconomic status, and cohort

Study	**Study Design (Location/Subjects) [n]**	**Exposure Measures and Summary Statistics**	**Assessment Timing**	**Outcome and Methods**	**Neurological Outcome Summary**
Canada					
Barberio *et al.* (2017b)	Cross-sectional General population/ Canadian Health Measures Survey (Cycles 2 and 3) [2,221]	Children's urine Mean Cycle 2: 32.06 (95% CI: 29.65, 34.46) µmol/L Mean Cycle 3: 26.17 (95% CI: 22.57, 29.76) µmol/L	Children (ages 3–12 years)	Learning disability, ADHD (Cycle 2 only): Parent or child self-report	Significant increase in adjusted OR for learning disability (adjusted OR = 1.02; 95% CI: 1.00, 1.03) only when Cycle 2 and 3 were combined using unadjusted urinary fluoride (associations no longer significant once adjusted for creatinine and specific gravity); no significant associations found between urinary fluoride and ADHD (only evaluated in Cycle 2) Adjusted for child's age, child's gender, household income adequacy, and highest attained education in the household
Riddell *et al.* (2019)	Cross-sectional General population/ Canadian Health Measures Survey (Cycles 2 and 3) [3,745]	Children's urine Mean (SD): 0.61 (0.39) mg/L; non-fluoridated water-0.46 (0.32) mg/L, fluoridated water-0.82 (0.54) Drinking water Mean (SD): 0.23 (0.24) mg/L; non-fluoridated water-0.04 (0.06) mg/L, fluoridated water-0.49 (0.22)	Children (ages 6–17 years)	Hyperactivity/inattention: Strengths and Difficulties Questionnaire (SDQ) ADHD: parent or self-reported physician diagnosis	Significantly increased risk of ADHD with fluoride in tap water (adjusted OR = 6.10 per 1-mg/L increase; 95% CI: 1.60, 22.8) or community water fluoridation status (1.21; 95% CI: 1.03, 1.42), but not with urinary fluoride; similar results observed with attention symptoms based on the SDQ scores Adjusted for child's age, child's gender, child's BMI, ethnicity, parental education, household income, blood lead, and smoking in the home

Table 6. Studies on Neurodevelopmental and Cognitive Function in Humans[a,b]

Study	Study Design (Location/Subjects) [n]	Exposure Measures and Summary Statistics	Assessment Timing	Outcome and Methods	Neurological Outcome Summary
Adult Studies					
Jacqmin *et al.* (1994)	Cross-sectional France (Gironde and Dordogne)/elderly adults [3,490]	Drinking water Range: 0.03–2.03 mg	Adults (ages ≥ 65 years)	Cognitive function: Mini-Mental State (MMS) Examination	No significant increase in the prevalence of cognitive impairment with increasing fluorine quartiles No statistical adjustment for confounders
Li *et al.* (2016)	Cross-sectional China (Inner Mongolia)/adults [511]	Drinking water intake and urinary fluoride Mean (SD) levels reported for a subset of subjects with normal scores (2.23 [2.23] mg and 1.46 [1.04] mg/L, respectively) and subjects with cognitive impairment (3.62 [6.71] mg and 2.47 [2.88] mg/L, respectively)	Adults (ages ≥ 60 years)	Cognitive function: MMS Examination	Results suggested that degree of fluoride exposure was consistent with severity of skeletal fluorosis, and fluoride exposure may be a risk factor for cognitive impairment; however, neither water fluoride intake (adjusted ORs = 0.94 [95% CI: 0.85, 1.04] and 0.86 [95% CI: 0.69, 1.06] in the moderate and severe cognitive impairment groups, respectively) nor urinary fluoride levels (adjusted ORs = 1.12 [95% CI: 0.89, 1.42] and 1.25 [95% CI: 0.87, 1.81] in the moderate and severe cognitive impairment groups, respectively) were significantly correlated with cognitive impairment Adjusted for sex, age, education, marital status (married vs. not married), alcohol consumption (non-drinkers, light drinkers, moderate to heavy drinkers), smoking history (never smoker, ex-smoker, light smoker, heavy smoker), and serum homocysteine levels

*Three additional publications based on subsample (i.e., 50–60 children) of the larger Yu *et al.* (2018) cohort were identified (Zhao *et al.* 2020, Zhou *et al.* 2019, Zhao *et al.* 2019); however, these publications focused on mechanistic considerations and are not included in the study totals for IQ because the main study by Yu *et al.* (2018) is considered a better representation of the IQ results.

[a]Includes lower risk-of-bias studies.

[b]Definitions: **ADHD**: attention-deficit/hyperactivity disorder; **GCI**: General Cognitive Index; **GM**: geometric mean; **HOME**: Home Observation Measurement of the Environment; **IQ**: intelligence quotient; **MSCA**: McCarthy Scales of Children's Abilities; **WASI**: Wechsler Abbreviated Scale of Intelligence (Spanish version); **WISC-IV**: Wechsler Intelligence Scale for Children-Revised; **WRAML**: Wide Range Assessment of Memory and Learning; **WRAVMA**: Wide Range Assessment of Visual Motor Ability.

Overall Risk-of-bias Discussion of the Body of Evidence

The confidence rating for the body of evidence in humans was based on studies with the lowest potential for bias (i.e., studies rated probably low or definitely low risk of bias for at least two of the three key risk-of-bias questions). Each of these 28 studies (including 26 studies in children and 2 in adults) had little or no risk-of-bias concerns, and confidence in the body of evidence was not

downgraded for risk of bias. However, the remaining studies in the human body of evidence were rated as probably high or definitely high risk of bias for at least two key risk-of-bias questions or had other major concerns. Risk-of-bias ratings for individual studies for all questions are available in **Figure A3-1** and **Figure A3-3**. Among the studies with lower potential for bias (see **Figure A3-1** and **Figure A3-2**), the key risk-of-bias question with the most potential for bias was the potential for confounding. Potential confounding was a concern for 5 of the 26 lower risk-of-bias studies in children (see *Confounding* for further discussion). Among the studies with higher overall potential for bias, there were a number of risk-of-bias concerns, including potential confounding, poor exposure characterization, poor outcome assessment, and, in many cases, potential concern with participant selection (see **Figure A3-3** and **Figure A3-4**). Many of the studies (n = 32) included in the entire human body of evidence were initially published in a foreign language (mainly Chinese) and were either translated and published in volume 41 of the journal *Fluoride* (n = 19) or were translated by the Fluoride Action Network (n = 13) (http://fluoridealert.org/researchers/translations/complete_archive/). Most of these studies were considered to have high potential for bias due to lack of information across many key risk-of-bias questions. Therefore, in order to assess if the lack of information relevant to key risk-of-bias concerns was the result of a loss in translation, the original Chinese publications and the translated versions of the five studies that had the most potential for being included in the lower risk-of-bias group of studies were reviewed to determine if any of the risk-of-bias concerns could be addressed (An *et al.* 1992, Chen *et al.* 1991 [translated in Chen *et al.* 2008], Du *et al.* 1992 [translated in Du *et al.* 2008], Guo *et al.* 1991 [translated in Guo *et al.* 2008a], Li *et al.* 2009). For all five studies, the translations were determined to be accurate and there was no impact on the key risk-of-bias concerns.

Confounding

Potential confounding variables and/or effect modifiers that were considered key for all studies, populations, and outcomes included child's age, child's sex, and socioeconomic status (e.g., maternal education, household income, marital status, crowding). Additional potential confounding variables and/or effect modifiers considered important for this evaluation depending on the study population and outcome included race/ethnicity; maternal demographics (e.g., maternal age, body mass index [BMI]); parental behavioral and mental health disorders (e.g., ADHD, depression); smoking (e.g., maternal smoking status, secondhand tobacco smoke exposure); reproductive factors (e.g., parity); nutrition (e.g., BMI, growth, anemia); iodine deficiency/excess; minerals and other chemicals in water associated with neurotoxicity (e.g., arsenic, lead); maternal and paternal IQ; and quantity and quality of caregiving environment (e.g., Home Observation Measurement of the Environment [HOME] score). To be assigned a rating of probably low risk of bias for the key risk-of-bias question regarding confounding, studies were not required to address every potential confounder listed; however, studies were required to address the three key covariates for all studies, the potential for co-exposures if applicable (e.g., arsenic and lead, both of which could affect cognitive function), and any other potential confounders considered important for the specific study population and outcome. For example, studies of populations in China, India, and Mexico, where there is concern for exposures to high fluoride and high arsenic, were required to address arsenic, and smoking needed to be addressed in studies of adults when dementia was evaluated. In order to identify areas of China, India, and Mexico where arsenic is a concern, groundwater quality maps were evaluated (https://www.gapmaps.org/Home/Public#) (Podgorski and Berg 2020). If no arsenic measurements were available for the area, the arsenic groundwater quality predictions from the global arsenic 2020 map were used (Podgorski and Berg 2020). If an area had less than 50% probability of having arsenic levels greater than 10 µg/L (the WHO guideline concentration), the area was considered not to have an issue with arsenic that needed to be addressed by the study authors.

Among studies with lower risk-of-bias concerns, 21 of the 26 studies were considered to have lower potential for bias due to confounding. Relative to confounders considered key for all studies and populations (i.e., age, sex, and SES), one study did not address age, one study did not address sex, and two studies did not account for indicators of SES (e.g., parental education, household income). Nine of the 26 lower risk-of-bias studies accounted for maternal or family member smoking. Potential confounding related to co-exposure to arsenic was not accounted for in five lower risk-of-bias studies and was the main potential concern in these studies; however, three of these studies (Xiang *et al.* 2011, Wang *et al.* 2012, Xiang *et al.* 2003a) were still considered low risk of bias for confounding due to the fact that arsenic was observed in the low fluoride areas (which would bias the effect toward the null), but an effect was still observed. The other two studies did not address arsenic and were in areas that had potential for arsenic exposure to occur (Soto-Barreras *et al.* 2019, Valdez Jimenez *et al.* 2017). Seven studies did not consider co-exposures to lead; however, for all of these studies this co-exposure was considered unlikely to have an impact in these study populations as there was no evidence that lead was prevalent or occurring in relation to fluoride.

Although there is variability in the potential confounders considered and differences in populations evaluated, the consistency of the results among the lower risk-of-bias studies indicates that confounding is not a major concern in this body of evidence. Even though 5 of 26 lower risk-of-bias studies in children are considered to have higher potential for bias due to confounding that could not be ruled out for that specific population and outcome (see **Figure 6**), results were consistent across multiple populations; all but two of the lower risk-of-bias studies in children reported an association between higher fluoride exposure and lower IQ or another cognitive effect. Seven of the lower risk-of-bias studies confirmed the robustness of the results by conducting sensitivity analyses (Bashash *et al.* 2018, Bashash *et al.* 2017, Green *et al.* 2019, Yu *et al.* 2018, Wang *et al.* 2020a, Wang *et al.* 2020b, Till *et al.* 2020). None of the sensitivity analyses adjusting for additional confounders found meaningful shifts in the association between fluoride exposure and IQ or other measures of cognitive function. Bashash *et al.* (2017) found that adjusting for HOME score increased the association between maternal urinary fluoride and children's IQ. Bashash *et al.* (2018) examined several potential confounders in sensitivity analyses involving subsets of participants, including HOME scores, child contemporaneous fluoride exposure measured by child urinary fluoride adjusted for specific gravity, and maternal lead and mercury exposures. The authors reported that no sensitivity analyses indicated appreciable changes in the fluoride-related association with behaviors related to ADHD, nor did they find evidence of effect modification between sex and maternal urinary fluoride. Green *et al.* (2019) found that adjusting for lead, mercury, manganese, perfluorooctanoic acid, and arsenic concentrations did not substantially alter the associations with IQ. Sensitivity analyses by Yu *et al.* (2018) that adjusted for covariates (including age, sex, and socioeconomic status) did not find differences in the results compared to the primary analyses. Both Wang *et al.* (2020a) and Wang *et al.* (2020b) found the results of the sensitivity analysis to be the same as the results from the preliminary analysis. Till *et al.* (2020) found that adjusting for maternal urinary fluoride levels had little effect on the results.

As previously mentioned, most of the higher risk-of-bias studies in the human body of evidence did not address the potential confounders of greatest concern. Many of these studies conducted only simple statistical analyses without accounting for any potential confounders (50 of 61 higher risk-of-bias studies), and many studies did not report whether the study subjects were from areas of similar socioeconomic status or environmental conditions (n = 20 higher risk-of-bias studies). Potential confounding related to important co-exposures (e.g., arsenic and lead) was often not addressed in higher risk-of-bias studies. In studies where there was high exposure to fluoride via drinking water with high naturally-occurring fluoride or from the use of coal-containing fluoride, most researchers did not

account for potential exposures to arsenic, which is commonly found in coal and drinking water in fluoride-endemic areas of China and Mexico. In general, researchers did not account for potential exposures to lead; however, studies reporting lead levels in fluoride-endemic areas, including areas in China, often reported low levels of lead (Xiang *et al.* 2011, Choi *et al.* 2012, Seraj *et al.* 2012, Choi *et al.* 2015, Yu *et al.* 2018, Saxena *et al.* 2012, Xiang *et al.* 2003b). Therefore, lead is not assumed to be a common exposure in fluoride-endemic areas. Most of the studies did not account for smoking or socioeconomic status, nor did they provide information to lessen the risk-of-bias concern (e.g., list of study characteristics indicating no significant differences between comparison groups). However, as noted for the lower risk-of-bias studies, given the consistency of the evidence, confounding among higher risk-of-bias studies is likely less of a concern for the body of evidence as a whole than for any individual study.

Figure 6. Potential Confounders Considered in Lower Risk-of-bias Studies Conducted in Children

Notes:

[1]Includes all lower risk-of-bias studies in children. Studies are organized as those with an overall risk-of-bias rating for confounding as probably low (green) followed by those with an overall risk-of-bias rating for confounding as probably high (yellow).

[2]Potential confounding factors and/or effect modifiers represented here are those considered important for this evaluation. See study details provided in HAWC for information on additional confounders.

Factors outlined in blue (subject age, subject sex, arsenic, SES) are considered key confounders.

A √ indicates that a factor was considered (and may or may not have been adjusted for in final model). For 'Other Exposures', a √ might also be used when a co-exposure was not expected to be an issue because there is no evidence to indicate that the co-exposure was prevalent or occurring in relation to fluoride. See risk-of-bias explanations in HAWC for details. A hyphen (–) indicates that the factor was not considered.

[3]See the "Notes" column for additional details.

[4]Extent of reported effects varies by study. "Yes" indicates that study authors reported one or more significant effects on IQ or other cognitive functions associated with fluoride exposure.

Exposure assessment

Exposure was assessed using a variety of methods in the human body of evidence. Studies provided varying levels of details on the methods used and employed different exposure characterization methods to group study subjects into exposed and reference groups. Exposure metrics included spot urine (from children or mothers during at least one trimester), serum, individual drinking water, intake from infant formula, estimated total exposure dose, municipal drinking water (with residence information), area of residence (endemic versus a non-endemic fluorosis area with or without individual validation of exposure), burning coal (with or without fluoride), and occupation type. Analytical methods to measure fluoride in biological or water samples also varied, some of which included atomic absorption, ion selective electrode methods, colorimetric methods, or the hexamethyldisiloxane microdiffusion method. Individual-level measures of exposure were generally considered more accurate than group-level measures; however, using group-level measures (e.g., endemic versus non-endemic area) in an analysis was less of a concern if the study provided water or urine fluoride levels from some individuals to verify that there were differences in the fluoride exposure between groups. Studies that provided results by area but also reported individual urinary or serum fluoride concentrations or other biochemical measures, including dental fluorosis in the children or urinary levels in mothers during pregnancy, were considered to have probably low risk of bias.

In general, there were few or no risk-of-bias concerns regarding exposure assessment in the lower risk-of-bias studies. Many of the lower risk-of-bias studies used individual urine or water measures with appropriate analyses. Urinary fluoride levels include all ingested fluoride and are considered a valid measure to estimate fluoride exposure (Villa *et al.* 2010, Watanabe *et al.* 1995); however, some concerns exist. Urinary fluoride is thought to reflect recent exposure but can be influenced by the timing of exposure (e.g., when water was last consumed, when teeth were last brushed). When compared to 24-hour urine samples, spot urine samples are more prone to these influences and can also be affected by differences in dilution; however, many studies attempted to account for dilution either using urinary creatinine or specific gravity. Good correlations between 24-hour samples and urinary fluoride concentrations from spot samples adjusted for urinary dilution have been described (Zohouri *et al.* 2006). Despite potential issues with spot urine samples, if authors made appropriate efforts to reduce the concern for bias, studies that used this metric were generally considered to have probably low risk of bias for exposure.

Although there are concerns related to using maternal urine samples, many studies provide evidence to suggest that urinary fluoride is a reasonable measure of exposure. Using three methods to account for urine dilution, Till *et al.* (2018) reported that adjusted risk estimates did not differ from unadjusted estimates. Analyzing the same study population as Till *et al.* (2018), Green *et al.* (2019) found that adjusting for time of urine collection or time of collection since last void during pregnancy did not substantially affect associations with IQ results in either boys or girls. In addition, adjusting the maternal urinary fluoride for creatinine did not substantially alter the association observed (Green *et al.* 2019). To provide a more accurate and sensitive measurement of maternal urinary fluoride than a single measurement provides, Green *et al.* (2019) only included participants with valid fluoride measurements at each trimester in their analysis. Several other studies also measured urinary fluoride multiple times throughout pregnancy (Bashash *et al.* 2018, Bashash *et al.* 2017, Green *et al.* 2019, Valdez Jimenez *et al.* 2017). Other studies demonstrated correlations between the urinary fluoride and fluoride in the drinking water, fluorosis, or estimated dose based on water (Green *et al.* 2019, Saxena *et al.* 2012, Zhang *et al.* 2015b, Ding *et al.* 2011, Choi *et al.* 2015, Yu *et al.* 2018). Till *et al.* (2018) demonstrated that there was a linear association between urinary fluoride concentrations in pregnant women and drinking water fluoride concentrations regardless of method to correct for urine dilution or whether or not

adjustments were made for dilution. Bashash *et al.* (2017) excluded exposure outliers but found that doing so did not change the results in a meaningful way. Taken together, these studies suggest that urinary fluoride is a reasonable measure of exposure despite some of the potential issues.

A frequent critical limitation among the higher risk-of-bias studies was lack of information regarding exposure or poor exposure characterization. Many of the higher risk-of-bias studies only compared subjects living in two regions with differing levels of fluoride exposure, and while most of them did provide some differentiation in levels of fluoride between the areas, limited or no individual exposure information was reported. Among studies that provided drinking water levels of fluoride in two areas being compared, sufficient information to determine if the individual study subjects were exposed to these levels was often not reported. Some studies also lacked information on fluoride analysis methods and timing of the exposure measurements. In some cases (n = 3), study areas that were considered endemic for dental and/or skeletal fluorosis were compared to non-endemic areas, or high-fluoride areas were compared to low-fluoride areas, with no other information provided on fluoride levels in the areas (Sun *et al.* 1991, Li *et al.* 2003 [translated in Li *et al.* 2008c], Ren *et al.* 1989 [translated in Ren *et al.* 2008]). While living in an area endemic for fluorosis could be an indicator of exposure, these studies did not specify if the study subjects themselves had fluorosis. Another study used only dental fluorosis as a measure of fluoride exposure in subjects that were all from an endemic area with similar drinking water fluoride levels (Li *et al.* 2010).

Outcome assessment

Studies included in this evaluation used a wide variety of methods to measure IQ and other cognitive effects. Measures of IQ were generally standardized tests of IQ; however, for these standardized methods to be considered low potential for bias they needed to be conducted in the appropriate population or modified for the study population. Because results of these tests can be subjective, it was important that the outcome assessors were blind to the fluoride exposure when evaluating the results of the tests. If the study reported that the assessor was blind to the exposure, this was assumed to mean that the outcome assessor did not have any knowledge of the exposure, including whether the study subjects were from high-fluoride communities.

The lower risk-of-bias studies have few concerns regarding outcome assessment. Four studies (Barberio *et al.* 2017b, Riddell *et al.* 2019, Sudhir *et al.* 2009, Wang *et al.* 2020a) had concerns for potential bias in the outcome assessment and that was due to either the use of self-reported of outcomes or the lack of accounting for blinding at the time of the outcome assessment in cases where there was potential concern. The remainder of the studies used appropriate measures of IQ or other cognitive effects for the study population. Seventeen of the studies reported blinding of the outcome assessors or correspondence with the study authors indicated that it was not likely an issue. For the remainder of the studies, it was assumed that the outcome assessors were most likely blind because exposure was assessed via urine or drinking water obtained at the same time as the outcome assessment.

Among the studies with higher risk of bias, the main limitation in the outcome assessment was the lack of reporting on whether the outcome was assessed without knowledge of exposure. Although there is little concern that the children's knowledge of their own exposure would bias the way they took the IQ tests, there is potential for bias if the tests were administered by an interviewer, or if the scoring of results could be subjective (e.g., drawing tests), and the interviewer or scorer had knowledge of the children's exposure. Most of the studies did not provide sufficient information on the person scoring or administering the tests or other information on the assessment methods to alleviate concerns for potential interviewer or reviewer bias. In some cases, the outcomes were not considered sensitive

measures (e.g., Seguin Form Board Test to test for IQ), or the test was not considered appropriate for the study population (e.g., a test validated in a western population was used on a rural Chinese population).

IQ in Children

The results from 17 studies (3 prospective cohort and 14 cross-sectional studies from 13 different study populations) with lower potential for bias that evaluated IQ in children (Bashash *et al.* 2017, Choi *et al.* 2015, Ding *et al.* 2011, Rocha-Amador *et al.* 2007, Saxena *et al.* 2012, Seraj *et al.* 2012, Xiang *et al.* 2003a, Xiang *et al.* 2011, Zhang *et al.* 2015b, Yu *et al.* 2018, Green *et al.* 2019, Cui *et al.* 2018, Wang *et al.* 2020b, Wang *et al.* 2012, Sudhir *et al.* 2009, Till *et al.* 2020, Trivedi *et al.* 2012) provide consistent evidence that exposure to fluoride is associated with lower IQ scores (see **Figure D1** through **Figure D7**); however, the analyses performed and the specific results varied by study. Consistent results between increased fluoride levels and lower IQ scores were seen across studies using different exposure measures [e.g., single serum samples (Xiang *et al.* 2011, Zhang *et al.* 2015b), single spot urine samples in children (Xiang *et al.* 2003a, Rocha-Amador *et al.* 2007, Ding *et al.* 2011, Saxena *et al.* 2012, Zhang *et al.* 2015b, Cui *et al.* 2018, Yu *et al.* 2018, Wang *et al.* 2020b), and prenatal maternal urinary measures (Bashash *et al.* 2017, Green *et al.* 2019)] (see **Figure D6** and **Figure D7**). The consistency also occurs across different study designs and study populations. There were two studies with lower potential for bias (Cui *et al.* 2020, Soto-Barreras *et al.* 2019) that did not provide evidence of an association between fluoride exposure and IQ, but evaluating the association between fluoride and IQ levels was not the primary focus in either of these studies.

The three prospective cohort studies all found an association between increasing fluoride exposure and lower IQ in children. Two of the studies (Green *et al.* 2019, Till *et al.* 2020) were based on the same study population but evaluated fluoride exposure differently. Bashash *et al.* (2017) observed a significant inverse association between children's IQ and maternal urinary fluoride during pregnancy (measured during all three trimesters and included if at least one measurement was available; an increase of 0.5 mg/L of maternal urinary fluoride was associated with a 2.5-point lower IQ score [95% CI: −4.12, −0.59]) in boys and girls combined (see **Figure D7**); however, the association between IQ level and children's urinary fluoride levels, while inverse, was not significant (single spot urine sample; an increase of 0.5 mg/L of child urinary fluoride was associated with a 0.89-point lower IQ score [95% CI: −2.63, 0.85]) (Bashash *et al.* 2017). Green *et al.* (2019) also observed a significantly lower IQ for boys associated with maternal urinary fluoride averaged across trimesters (a significant 4.49-point lower IQ score [95% CI: −8.38, −0.60] in IQ per 1-mg/L increase in maternal urinary fluoride); results were not significant in girls (2.40-point increase [95% CI: −2.53, 7.33] in IQ) or in boys and girls combined (1.95-point lower IQ score per 1-mg/L increase; 95% CI: −5.19, 1.28). Other measures of prenatal exposure (maternal fluoride intake or water fluoride concentrations) were associated with lower IQ scores in boys and girls combined although the authors did not report boys and girls separately, as they found no significant effect measure modification between child sex and fluoride exposure in these analyses (Green *et al.* 2019). Specifically, when evaluating the association between estimated maternal fluoride intake based on maternal water and beverage consumption during pregnancy and IQ in children, a 1-mg increase in daily maternal consumption of fluoride during pregnancy was associated with a significantly lower IQ score of 3.66 points in boys and girls combined (95% CI: −7.16, −0.15). Similarly, water fluoride concentrations for pregnant women from fluoridated areas (mean water fluoride levels of 0.59 ± 0.08 mg/L) versus pregnant women from non-fluoridated areas (mean water fluoride levels of 0.13 ± 0.06 mg/L) were associated with a significant 5.29-point lower IQ score per 1-mg/L increase in fluoride in both boys and girls combined (95% CI: −10.39, −0.19) (Green *et al.* 2019). Using the same study population as Green *et al.* (2019), but using fluoride intake from formula or water concentrations in

formula-fed versus breastfed infants, Till *et al.* (2020) observed a significantly lower performance IQ scores regardless of the comparison used. They did not observe any effect on verbal IQ, and full-scale IQ was only significantly lower in formula-fed infants using water fluoride concentrations as the exposure measure. All other comparisons showed negative associations but were not significant.

Cross-sectional studies also demonstrated a consistent association between fluoride and lower IQ scores. Rocha-Amador *et al.* (2007) observed significant negative correlations between IQ and both water and children's single spot urinary fluoride levels in a population in Mexico (adjusted β = −10.2 per log fluoride increase [CIs not reported] and −16.9 per log fluoride increase [CIs not reported], respectively) (see **Figure D7**). The authors also observed a significant inverse association between IQ and children's drinking water and single spot urinary arsenic levels (adjusted β = −6.15 [CIs not reported] and −5.72 [CIs not reported], respectively). Because fluoride and arsenic were highly correlated in the study area, the authors were not able to adjust for exposure to arsenic when evaluating the effects of fluoride exposure (Rocha-Amador *et al.* 2007). Ding *et al.* (2011) reported a negative dose-response relationship between children's single spot urinary fluoride levels and IQ (see **Figure D4**); after adjusting for age, using multiple linear regression, they found a 0.59-point lower IQ score (95% CI: −1.09, −0.08) per 1-mg/L increase in urinary fluoride (p-value < 0.0001) (see **Figure D7**). Cui *et al.* (2018) observed a significant association between log-transformed children's single spot urine fluoride and lower IQ scores (2.47-point lower IQ scores [95% CI: −4.93, −0.01] per unit increase in urinary fluoride), and the association was the strongest in subjects with the TT polymorphism in the dopamine receptor D2 gene which, according to the authors, probably results in a reduced D2 receptor density (12.31-point lower IQ score [95% CI: −18.69, −5.94] per unit increase in urinary fluoride) (Cui *et al.* 2018).

Although Green *et al.* (2019) observed a significant negative association between maternal fluoride levels and IQ scores in boys but not girls in a Canadian population, sex differences were not observed in a cross-sectional study conducted using children spot urine fluoride concentrations in China (Wang *et al.* 2020b). Wang *et al.* (2020b) evaluated boys and girls combined and separately and observed significant decreasing trends in the sexes both combined and alone by urinary fluoride quartiles. When evaluated as a continuous variable, spot urinary fluoride levels (per 1-mg/L increase) were significantly associated with lower IQ scores in both girls (−1.379 [95%CI: −2.628, −0.129]) and boys (−1.037 [95% CI: −2.040, −0.035]), as well as, combined (−1.214 [95%CI: −1.987, −0.442]). Green *et al.* (2019) did not find any sex difference when using water fluoride concentrations, but Wang *et al.* (2020b) found that based on water fluoride quartiles there was a significant trend in girls and in boys and girls combined but not in boys alone. While there was a decreasing trend in boys, the results did not achieve statistical significance (p = 0.077). However, when water fluoride levels were evaluated as a continuous variable (per 1 mg/L increase), there were significant associations between lower IQ scores in both girls (−1.649 [95%CI: −3.201, −0.097] and boys (−1.422 [95%CI: −2.792, −0.053], as well as, combined (−1.587 [95%CI: −2.607, −0.568]).

Other cross-sectional studies also observed consistent results across populations, but there were some slight variations based on exposure measurement, level of exposure, or based on the outcome measured. Choi *et al.* (2015) conducted a pilot study with 51 children in an area of China with a wide range of fluoride concentrations in the drinking water. Aside from observing no association between the square root block design test score and fluoride exposure from drinking water, the authors observed consistent negative associations between IQ measures and fluoride in children's single spot urine or drinking water and significant associations between specific tasks from an omnibus IQ test (i.e., significantly lower WISC-IV backward and total digit span scores) and fluoride exposure based on moderate or severe dental fluorosis in children (see **Figure D7**). While observing no association between

IQ and low children's single spot urinary fluoride levels (0.01–1.60 mg/L), Yu *et al.* (2018) observed significant negative associations (p values not reported) between IQ and median children's urinary fluoride levels (1.60–2.50 mg/L)—with an IQ score 2.67 points lower (95% CI: −4.67, −0.68) for every 0.5-mg/L increment of urinary fluoride—and high children's urinary fluoride levels at 2.50–5.54 mg/L with an IQ score of 0.84 points lower (95% CI: −2.18, 0.50) for every 0.5-mg/L increment of urinary fluoride (see **Figure D7**). The authors also reported a significant negative association between drinking water fluoride levels at 3.40–3.90 mg/L (4.29-point lower IQ score [95% CI: −8.09, −0.48] for every 0.5-mg/L increment of water fluoride); a 0.04-point lower IQ score (95% CI: −0.33, 0.24) was observed for 0.5-mg/L increments of water fluoride at levels of 0.20–3.40 mg/L. When comparing water fluoride concentrations of >1 mg/L to ≤1 mg/L, there was an increased risk (adjusted OR = 1.25; 95% CI: 0.69, 2.26) for marginal intelligence (i.e., IQ score = 70–79) and a decreased risk (adjusted OR = 0.47; 95% CI: 0.32, 0.71) of excellent intelligence (i.e., IQ score ≥ 130) (see **Figure D4**). Similar results were observed using children's urinary fluoride levels (adjusted OR for marginal intelligence = 1.44; 95% CI: 0.72, 2.91; adjusted OR for excellent intelligence = 0.49; 95% CI: 0.26, 0.93) (Yu *et al.* 2018).

Two lower risk-of-bias studies (Cui *et al.* 2020, Soto-Barreras *et al.* 2019) did not observe a significant association between fluoride and IQ in children; however, both studies only performed simple comparisons between IQ and fluoride exposure. Cui *et al.* (2020) studied children in the same region as Cui *et al.* (2018)—and possibly included some of the same subjects but over a longer timeframe—and did not observe a significant change in IQ score with increasing urinary fluoride levels. Although there was a 2-point drop in IQ between the lowest fluoride exposure group (i.e., spot urine fluoride < 1.6 mg/L) and the highest fluoride exposure group (i.e., ≥ 2.5 mg/L), the difference in IQ (112.16 ± 11.50 versus 110.00 ± 14.92) was not significant (p = 0.58). However, this study did not account for age in the analysis, even though they reported a significant difference in IQ score based on age (p < 0.001). Soto-Barreras *et al.* (2019) also did not find an association between various fluoride exposure metrics (water, spot urine, exposure dose, and fluorosis index) and IQ grade. However, this study only compared fluoride exposure levels within the 5 IQ grades and did not adjust for any potential confounders.

The results from 47 studies with higher potential for bias that evaluated IQ in children provide consistent supporting evidence of decrements in IQ associated with exposures to fluoride. Forty-one of the 47 studies reported an association between high fluoride exposure and lower IQ scores in children.

Meta-analysis

In response to the recommendations of the NASEM review of the September 6, 2019 draft monograph (NASEM 2020), a two-part meta-analysis was conducted. The first part was an update to two previous meta-analyses (Choi *et al.* 2012, Duan *et al.* 2018) of group-level exposures from studies that reported a comparison of the mean IQ score between two or more exposure groups. The second part was a new meta-analysis and included studies with more precise individual-level exposures (e.g., urine, water, fluoride intake). The meta-analysis protocol can be found with the revised systematic review protocol posted in September 2020 (https://ntp.niehs.nih.gov/go/785076).

Group-level exposures

For the group-level exposure meta-analysis, a comparison on the mean outcome measure (IQ score) was conducted across two exposure groups ("exposed" and "reference"). If there were more than two exposure groups, the highest exposure group was designated the exposed group and the lowest exposure group was designated the reference group. For studies that had more than one exposed group (n = 17), a sensitivity analysis was performed to evaluate the impact of using any exposed group compared to the reference group. Using mean IQ levels with measures of uncertainty (95% confidence

interval [CI], standard error [SE], and sample size [N]) for exposed versus reference groups, the standardized mean difference (SMD) and corresponding 95% CI were calculated for each study. Given the heterogeneity of the studies, random effects models were used to obtain the pooled effect estimate, calculated as a weighted SMD with a corresponding 95% CI. These methods are consistent with both the Choi *et al.* (2012) and Duan *et al.* (2018) meta-analyses. More detailed methods are provided in **Appendix 5** and in the meta-analysis protocol, which can be found with the revised systematic review protocol posted in September 2020 (https://ntp.niehs.nih.gov/go/785076).

Characteristics of the 46 studies that compared mean IQ scores between groups of children with different levels of fluoride exposure are shown in **Table A-1**. One study was conducted in New Zealand, 1 study was conducted in Mexico, 4 studies were conducted in Iran, 9 studies were conducted in India, and the remaining 31 studies were performed in China (**Table A-1**). Five study populations were exposed to fluoride from coal burning (Guo *et al.* 1991 [translated in Guo *et al.* 2008a], Li *et al.* 1994 [translated in Li *et al.* 2008b], Li *et al.* 1995, Li *et al.* 2009, Bai *et al.* 2014); otherwise, it is assumed that study populations were exposed to fluoride through drinking water. Measures of fluoride exposure included water fluoride (n = 28), dental fluorosis (n = 7), and other non-drinking water sources of exposure to fluoride (e.g., fluoride exposure from coal burning [n = 11]). Thirteen studies presented results for males and 12 studies reported results for females; 9 studies examined children < 10 years old and 11 studies examined children ≥ 10 years old. The CRT-RC was used to measure children's IQ in 23 studies. Other measures of IQ included Wechsler intelligence tests (Ren *et al.* 1989 [translated in Ren *et al.* 2008], Wang *et al.* 1996 [translated in Wang *et al.* 2008b], An *et al.* 1992, Broadbent *et al.* 2015), the Binet IQ test (Guo *et al.* 1991 [translated in Guo *et al.* 2008a], Xu *et al.* 1994), the Raven's test (Yao 1997, Yao *et al.* 1996, Seraj *et al.* 2006, Seraj *et al.* 2012, Eswar *et al.* 2011, Poureslami *et al.* 2011, Shivaprakash *et al.* 2011, Khan *et al.* 2015, Sebastian and Sunitha 2015, Mondal *et al.* 2016), the Raymond B Cattell test (Karimzade *et al.* 2014), the Japan IQ test (Sun *et al.* 1991, Zhang *et al.* 1998), the Index of Mental Capacity (Li *et al.* 1994 [translated in Li *et al.* 2008b]), the Sequin Form Board test (Nagarajappa *et al.* 2013), and other tests using a doctor-prepared questionnaire (Trivedi *et al.* 2012, Trivedi *et al.* 2007). This meta-analysis includes 27 studies that were also included in Choi *et al.* (2012) and 25 studies that were also included in Duan *et al.* (2018). Also included in this meta-analysis were an additional 3 studies published since the Duan *et al.* (2018) publication and 11 studies that were not captured in either of the previous meta-analyses. Overall, the updated group-level results were highly consistent with these previous meta-analyses (Choi *et al.* 2012, Duan *et al.* 2018) (**Table A5-1**).

The random-effects pooled SMD estimated from the 46 studies included in the meta-analysis was −0.50 (95% CI: −0.61, −0.39) (**Table A5-1**, **Figure A5-1)**. There was evidence of heterogeneity (I^2 = 89%, p < 0.001, **Table A5-1**) and publication bias (funnel plot and Egger's p < 0.001, Begg's p = 0.08; **Figure A5-2**, **Figure A5-3**). Eliminating publication bias through trim-and-fill analysis supports the results with an adjusted pooled effect estimate of – 0.42 (95% CI: −0.54, 0.30) (**Figure A5-4**). Among the 46 studies, all but two showed SMD estimates that indicated an inverse association, ranging from −5.34 (95% CI: −6.34, −4.34) to −0.04 (95% CI: −0.45, 0.36). The studies with a positive association (Broadbent *et al.* 2015) reported an SMD estimate of 0.01 (95% CI: −0.19, 0.22) to 0.13 (95% CI: −0.16, 0.42). Three studies (Aravind *et al.* 2016, Kundu *et al.* 2015, Razdan *et al.* 2017) were excluded from the main analysis due to uncertainties about the way the intelligence assessment for children was performed, but sensitivity analyses that included these studies did not reveal any substantial changes in the pooled SMD estimate (−0.57 [95% CI: −0.69, −0.45]) (see **Figure A-35**).

Several subgroup analyses, discussed in **Appendix 5** and outlined in the meta-analysis protocol (found with the revised systematic review protocol posted in September 2020

[https://ntp.niehs.nih.gov/go/785076]), included risk of bias, gender, age group, country, outcome assessment type, and exposure assessment type. Among the lower risk-of-bias studies (n = 9), the random-effects pooled SMD was −0.31 (95% CI: −0.52, −0.10) with an I^2 of 87% and heterogeneity test p-value < 0.001 (**Table A5-1** and **Figure A5-6**). There was no evidence of publication bias (funnel plot and Egger's p = 0.72, **Figure A5-7** and **Figure A5-8**). Among the higher risk-of-bias studies (n = 37), the random-effects pooled SMD was −0.56 (95% CI: −0.68, −0.43) with an I^2 of 88% and heterogeneity test p-value < 0.001 (**Table A5-1** and **Figure A5-6**). There was evidence of publication bias among the higher risk-of-bias studies (funnel plot and Egger's p < 0.001, **Figure A5-7** and **Figure A5-8**); eliminating publication bias through trim-and-fill analysis supports the results with an adjusted pooled SMD estimate of −0.35 (95% CI: −0.50, −0.21) (**Figure A5-7** and **Figure A5-9**).

Subgroup analyses by gender, age group, country, outcome assessment type, and exposure assessment type further support the consistent and robust pattern of results (**Table A5-1**). Except for the subgroup analysis of the four studies from Iran, heterogeneity remained at an I^2 of ≥ 70% when the analyses were restricted by subgroup. Sensitivity analyses that removed an outlier (Khan *et al.* 2015) or compared all exposed groups versus the reference (i.e., exposed groups were combined if a study reported more than one exposed group) also did not appreciably change the results (**Figure A-45**, **Table A5-1**, and **Figure A-25**).

Individual-level exposures

The individual-level exposure meta-analysis included 6 studies with individual-level exposures that reported effect estimates as beta coefficients and included a 95% CI or SE. Characteristics of the studies with individual-level exposures are shown on **Table B-1**. All studies included in this meta-analysis were considered lower risk of bias. Adjusted effect estimates were used, and if results from multiple models were reported within a single study, the most adjusted results were selected. (For more details, see the meta-analysis protocol, which can be found with the revised systematic review protocol posted in September 2020 [https://ntp.niehs.nih.gov/go/785076].) To ensure consistent units across studies, units of fluoride exposure were transformed to 1 mg/L. For Bashash *et al.* (2017), Yu *et al.* (2018), and Till *et al.* (2020), units of exposure were transformed from 0.5 mg/L to 1 mg/L. For Cui *et al.* (2018), units of exposure were transformed from 1 log mg/L to 1 mg/L. Cui *et al.* (2018) reported an association between IQ and log transformed exposure. A sensitivity analysis was performed to evaluate the impact of using Cui *et al.* (2018), since the relationship between IQ and exposure evaluated in this study was not linear (as was the case among the other studies included). Yu *et al.* (2018) reported estimates from piecewise linear regression models and provided three ranges for urinary fluoride exposure (low 0.01–1.60 mg/L, medium 1.60–2.50 mg/L, high 2.50–5.54 mg/L) and two ranges for water fluoride (low 0.20–3.40 mg/L and high 3.40–3.90 mg/L). Since these piecewise effect estimates are likely correlated, the study-specific pooled effect estimates were used for urine and water fluoride exposures for the overall effect meta-analysis. A sensitivity analysis was performed to evaluate the impact of using pooled estimates rather than piecewise estimates from Yu *et al.* (2018).

For studies with overlapping populations (i.e., multiple studies that used the same cohort), results were selected considering the following factors: most appropriate exposure metric, exposure range, exposure period, number of subjects, and statistical adjustment for potential confounders. In the overall effect analysis, for studies reporting multiple measures of fluoride exposure, the results associated with measured or estimated individual-level exposures, biomarker levels (such as urinary fluoride), or fluoride intake levels were prioritized over water fluoride concentrations (revised protocol posted in September 2020 [https://ntp.niehs.nih.gov/go/785076]); however, subgroup analyses by exposure metric (urinary fluoride, fluoride intake, and water fluoride) were also performed. Yu *et al.* (2018) and

Wang *et al.* (2020b) used the same study cohort of children recruited in 2015 from the rural areas of Tianjin City, China. Since Wang *et al.* (2020b) (n = 571) used a subset of the original study sample from Yu *et al.* (2018) (n = 2,668), only results from Yu *et al.* (2018) were included in the meta-analysis. A sensitivity analysis was performed to evaluate the impact of using the effect estimate from Wang *et al.* (2020b) rather than the pooled effect estimate from Yu *et al.* (2018). Green *et al.* (2019) and Till *et al.* (2020) used the same Maternal-Infant Research on Environmental Chemicals (MIREC) cohort that reported drinking tap water in 10 Canadian cities with the studies overlapping for 398 mother-child pairs. Both studies reported effect estimates for maternal urinary fluoride (MUF) and water fluoride concentrations. In the Green *et al.* (2019) study, 512 mother-child pairs had MUF data (and all covariates) compared to 398 pairs in Till *et al.* (2020). Water fluoride levels were available for 420 pairs in Green *et al.* (2019) compared to 398 pairs in Till *et al.* (2020). Both studies reported effect estimates adjusted for maternal education, maternal race, child's sex, HOME total score, and secondhand smoke status in the child's home. In addition, Till *et al.* (2020) adjusted for child's age at IQ testing (the age range for all children was 3–4 years old). Because of the larger sample size and covariate adjustments were similar, results from Green *et al.* (2019) were included in the main analysis. However, because of the more adjusted estimates from Till *et al.* (2020) compared to Green *et al.* (2019), a sensitivity analysis was performed using the water fluoride result for formula-fed children and the MUF result from Till *et al.* (2020). For fluoride from intake, the estimates from both studies were used since they represent total fluoride intake (Green *et al.* 2019) and infant fluoride intake from formula (Till *et al.* 2020).

The overall pooled effect estimate based on 6 lower risk-of-bias studies with individual-level measures of exposure shows that a 1-mg/L increase in urinary fluoride was associated with a statistically significant lower IQ score of 1.40 (95% CI: −2.33, −0.47) points. Studies with individual-level urinary fluoride measures had evidence of moderate heterogeneity (I^2 = 46%, p = 0.101; **Table A5-2**, **Figure A5-16**). Eliminating publication bias through trim-and-fill analysis supports the conclusion that a 1-mg/L increase in individual-level exposure to urinary fluoride was associated with lower IQ, with an adjusted pooled effect estimate of −0.82 (95% CI: −1.81, 0.17) (**Figure A5-19**). Fluoride intake and water fluoride were also significantly associated with an IQ score of 3.31 points lower (95% CI: −6.12, −0.50) and 4.77 points lower (95% CI: −9.10, −0.45), respectively (**Table A5-2**); however, the results for both metrics were based on two studies each and should be interpreted with caution.

No substantial changes in the pooled effect estimates were seen in sensitivity analyses to evaluate the following scenarios: using the piecewise estimates from Yu *et al.* (2018) (−1.37, 95% CI: −2.38, −0.37) (**B-1**); using effect estimates from Wang *et al.* (2020b) rather than Yu *et al.* (2018) (−1.24, 95% CI: −1.94, −0.54) (**Figure B-6**); and using the water fluoride result for formula-fed children and MUF result from Till *et al.* (2020) rather than effect estimates from Green *et al.* (2019) (−1.50, 95% CI: −2.44, −0.57) (**Figure B-11**).

Other Neurodevelopmental or Cognitive Effects in Children

Among the studies with lower potential for bias, the results from three prospective cohort studies (Bashash *et al.* 2017, Valdez Jimenez *et al.* 2017, Bashash *et al.* 2018) and six cross-sectional studies (Li *et al.* 2004 [translated in Li *et al.* 2008a], Rocha-Amador *et al.* 2009, Choi *et al.* 2015, Barberio *et al.* 2017b, Wang *et al.* 2020a, Riddell *et al.* 2019) based on seven study populations provide mostly consistent results for associations of fluoride exposure with cognitive impairment in children other than decrements in IQ, such as hand-eye coordination, neurobehavioral assessment, behavioral capacity, and learning disabilities (see **Figure D8** through **Figure D10**). Because IQ cannot be assessed in infants, other neurodevelopmental tests were conducted. Two studies (Li *et al.* 2004 [translated in Li *et al.* 2008a],

Valdez Jimenez *et al.* 2017), based in China and Mexico, evaluated neonates (within 3 days of birth) or infants (3–15 months) (see **Figure D8** and **Figure D10**).

In neonates, the high fluoride group (based on a single maternal urine fluoride level just prior to birth [3.58 ± 1.47 mg/L] compared to controls [1.74 ± 0.96 mg/L]) had significant lower ($p < 0.05$) total neurobehavioral assessment scores (38.28 ± 1.10 in controls compared to 36.48 ± 1.09 in high fluoride group) and total behavioral capacity scores (11.34 ± 0.56 in controls compared to 10.05 ± 0.94 in high fluoride group) as measured by a standard neonatal behavioral neurological assessment (NBNA) method (Li *et al.* 2004 [translated in Li *et al.* 2008a]). In infants, the Mental Development Index (MDI)—which measures functions including hand-eye coordination, manipulation, understanding of object relations, imitation and early language development—was significantly negatively correlated with maternal urinary fluoride in both the first and second trimesters (adjusted βs = −19.05 with standard error of 8.9 for first trimester and −19.34 with standard error of 7.46 for second trimester) (Valdez Jimenez *et al.* 2017). This study did not find an association between maternal fluoride during any trimester and Psychomotor Developmental Index (PDI), which measures gross motor development (adjusted βs = 6.28 and 5.33 for first and second trimesters, respectively; no variance provided) (Valdez Jimenez *et al.* 2017). The General Cognitive Index (GCI) of the McCarthy Scales of Children's Abilities (MSCA) in 4-year-old children was significantly negatively associated with maternal creatinine-adjusted urinary fluoride levels during pregnancy (collected during each trimester) even after adjusting for maternal bone lead (adjusted β = −3.15 [95% CI: −5.42, −0.87] in a model adjusting for main covariates (e.g., gestational age, weight at birth, sex, maternal smoking, and indicators of socioeconomic status); adjusted β = −5.63 [95% CI: −8.53, −2.72] in a model limited to a subset of cases who had data on maternal bone lead and adjusted for main covariates and maternal bone lead) (Bashash *et al.* 2017) (see **Figure D10**). Choi *et al.* (2015), however, evaluated cognitive function endpoints in addition to IQ and found no significant associations between concurrent water or urinary fluoride levels and Wide Range Assessment of Visual Motor Ability (WRAVMA) scores, finger tapping, and the grooved pegboard test although there were some significant associations based on degree of fluorosis (see **Figure D10**). Another study using construction and memory scores in children 6–11 years old observed statistically significant lower scores with increasing concurrent child single spot urinary fluoride even after adjusting for age ($p < 0.05$; −0.29 and −0.27 for copy and immediate recall, respectively [CIs not reported]); however, scores were not significantly associated with urinary arsenic levels (−0.05 and 0.02 for copy and immediate recall, respectively [CIs not reported]) (Rocha-Amador *et al.* 2009) (see **Figure D9**).

Barberio *et al.* (2017b) evaluated learning disabilities in children 3–12 years of age, including ADHD, attention deficit disorder (ADD), and dyslexia, as part of the Canadian Health Measures Survey and found a small but significantly increased risk in self-reported (children 12 years of age) or parent- or guardian-reported (children 3–11 years of age) learning disabilities associated with higher spot urinary fluoride levels in children (adjusted OR = 1.02; 95% CI: 1.00, 1.03) (see **Figure D11**); however, significant associations were not observed in analyses using creatinine- or specific gravity-adjusted urinary fluoride (Barberio *et al.* 2017b). Barberio *et al.* (2017b) also reported no associations between single spot urinary fluoride and ADHD in children ages 3 to 12 years. Riddell *et al.* (2019) used the same Canadian Health Measured Survey, but evaluated children 6–17 years old. Riddell *et al.* (2019) found a significantly increased risk for ADHD diagnosis with both tap water fluoride (adjusted OR per 1-mg/L increase = 6.10; 95% CI: 1.60, 22.8) and community water fluoridation status (adjusted OR = 1.21; 95% CI: 1.03, 1.42). A similar increase in hyperactivity-inattention symptoms score based on the Strengths and Difficulties Questionnaire was observed with both tap water fluoride (adjusted β per 1-mg/L increase = 0.31; 95% CI: 0.04, 0.58) and community fluoridation status (adjusted β = 0.11; 95% CI: 0.02, 0.20). As was observed with Barberio *et al.* (2017b), Riddell *et al.* (2019) did not observe an association with either

ADHD diagnosis (adjusted OR per 1-mg/L increase = 0.96; 95% CI: 0.63, 1.46) or hyperactivity-inattention symptoms (adjusted β = 0.31; 95% CI: −0.04, 0.66) and specific-gravity-adjusted spot urinary fluoride concentrations. Bashash *et al.* (2018) evaluated behaviors associated with ADHD in children ages 6–12 years using the Conners' Rating Scales-Revised (CRS-R) and observed significant associations between maternal urinary fluoride (measured during each trimester) and ADHD-like symptoms, particularly those related to inattention (an increase in 0.5 mg/L of maternal urinary fluoride was associated with a 2.84-point increase [95% CI: 0.84, 4.84] in the DSM-IV Inattention Index and a 2.54-point increase [95% CI: 0.44, 4.63] in the Cognitive Problems and Inattention Index). These two scales contributed to the global ADHD Index and the DSM-IV ADHD Total Index, which were also associated with higher levels of prenatal fluoride exposure (an increase of 0.5 mg/L in maternal urinary fluoride was associated with a 2.38-point increase [95% CI: 0.42, 4.34] in the DSM-IV ADHD Total Index and a 2.47-point increase [95% CI: 0.43, 4.50] in the ADHD Index) (see **Figure D10**). Significant associations were not observed between maternal urinary fluoride concentrations during pregnancy and child performance on measures of hyperactivity nor were there any significant results in children using the Connors' Continuous Performance Test (CPT-II, 2nd Edition), a computerized test of sustained attention and inhibitory control (Bashash *et al.* 2018). Wang *et al.* (2020a) also used a Connors' Parent Rating Scale (Chinese version), but only found a significant association between spot urinary fluoride concentrations (model adjusted for creatinine) and psychosomatic problems (adjusted OR for T-score > 70 = 1.97; 95% CI: 1.19, 3.27 and adjusted β = 4.01; 95% CI: 2.74, 5.28). No associations were found between spot urinary fluoride and ADHD index or other behavioral measures.

Higher risk-of-bias studies (n = 5) also provide some evidence of associations of fluoride exposure with neurodevelopmental or cognitive effects in children other than effects on IQ, but the results are inconsistent with heterogeneous outcomes (Li *et al.* 1994 [translated in Li *et al.* 2008b], Shannon *et al.* 1986, Malin and Till 2015, Morgan *et al.* 1998, Mustafa *et al.* 2018).

Cognitive Effects in Adults

Results from two lower risk-of-bias studies in adults did not find consistent evidence for an association between cognitive impairment (based on the Mini-Mental State Examination) and exposure to fluoride (Jacqmin *et al.* 1994, Li *et al.* 2016). Jacqmin *et al.* (1994) did not find an association between drinking water fluoride and cognitive impairment in populations in France (n = 3,490) and found prevalence rates of cognitive impairment to be the same regardless of fluoride exposure (see **Figure D12**). In an analysis of 38 cognitively-impaired cases and 38 controls matched for several confounders including age, gender, education, alcohol consumption, and smoking, Li *et al.* (2016) did find significantly higher urinary fluoride levels and skeletal fluorosis scores in the cognitively-impaired group compared with the control group; however, the authors found no significant correlation between cognitive impairment and total daily water fluoride intake (adjusted ORs = 0.94 [95% CI: 0.85, 1.04] and 0.86 [95% CI: 0.69, 1.06] in the moderate and severe cognitive impairment groups, respectively) or urinary fluoride levels (adjusted ORs = 1.12 [95% CI: 0.89, 1.42] and 1.25 [95% CI: 0.87, 1.81] in the moderate and severe cognitive impairment groups, respectively) in subjects from fluorosis-endemic areas of China (n = 511).

Higher risk-of-bias studies (n = 7) provide some evidence of cognitive impairment in adults associated with exposure to fluoride. In aluminum factory workers (exposed to gaseous and particular fluoride emissions during the production of aluminum metal), significant decreases in IQ (Duan *et al.* 1995), diminished performance on several neurobehavioral core battery tests (NCTBs) (Guo *et al.* 2001 [translated in Guo *et al.* 2008b]), and impaired psychomotor performance and memory were observed (Yazdi *et al.* 2011). One study conducted on adult subjects with fluorosis (dental and skeletal) from a fluorosis-endemic area compared with healthy subjects from a non-endemic area observed significant

differences for some cognitive function tests (i.e., tests of speech fluency, recognition, and working memory) but not others and generally did not observe a significant change in IQ except in the operation scores (Shao 2003). One prospective cohort study evaluated exposure to fluoride in children at age of 5 years based on whether or not the children resided in areas with community water fluoridation or used fluoride toothpaste or fluoride tablets, and found no clear differences in IQ scores of the subjects at age 38 years (Broadbent *et al.* 2015). One additional study suggested that populations living in areas with higher drinking water fluoride had lower levels of dementia (Still and Kelley 1980); however, the study was not focused on effects of fluoride, but rather if fluoride was able to reduce the risk associated with aluminum by competing with aluminum and reducing the aluminum bioavailability. Therefore, the study was considered inadequate to evaluate the effects of fluoride on dementia (Still and Kelley 1980). A more recent study in Scotland evaluated dementia rates associated with aluminum and fluoride drinking water concentrations and observed an increase in dementia only in the highest quartile of fluoride (56.3 µg/L) compared to the lowest quartile (<44.4 µg/L), but found a significant increase with all quartiles of aluminum compared with the reference group (Russ *et al.* 2019). In addition to studies that reported on cognitive impairment and exposure to fluoride, two studies were identified that reported effects on motor and sensory function (Rotton *et al.* 1982) and a higher prevalence of self-reported headaches, insomnia, and lethargy (Sharma *et al.* 2009).

Mechanistic Data in Humans

Eight lower risk-of-bias studies were available that evaluated mechanistic data in humans associated with fluoride exposure that was considered potentially relevant to neurological effects, including effects on thyroid hormones in children (Singh *et al.* 2014, Zhang *et al.* 2015b, Kumar *et al.* 2018), adults (Kheradpisheh *et al.* 2018b, Kheradpisheh *et al.* 2018a, Malin *et al.* 2018), or children and adults combined (Barberio *et al.* 2017a). In addition, some studies evaluated self-reported thyroid conditions in children and adults combined (Barberio *et al.* 2017a) and thyroid diseases in adults (Kheradpisheh *et al.* 2018b, Peckham *et al.* 2015) (see **Figure A3-5** and **Figure A3-6**). Although the lower risk-of-bias studies provide some evidence of mechanistic effects (primarily changes in thyroid stimulating hormone [TSH] levels in children), the studies were too heterogeneous or limited in number to make any determination on mechanism (see **Figure 7**).

Among the seven lower risk-of-bias studies that reported on changes in thyroid hormones, three studies were conducted in children (Zhang *et al.* 2015b, Singh *et al.* 2014, Kumar *et al.* 2018) and reported increases in TSH levels. Zhang *et al.* (2015b) reported significant increases in TSH in children from a fluorosis-endemic area (median fluoride drinking water concentration = 1.40 mg/L; interquartile range = 1.23–1.57 mg/L) compared with a non-fluorosis-endemic area (median fluoride drinking water concentration = 0.63 mg/L; interquartile range = 0.58–0.68 mg/L), while 3,5,3'-triiodothyronine (T_3) or thyroxine (T_4) were not significantly different between the two groups. Similarly, Singh *et al.* (2014) observed significantly higher TSH levels in children without dental fluorosis who lived in a fluorosis-endemic area (fluoride drinking water concentrations of 1.6–5.5 mg/L) compared with children without dental fluorosis who lived in a non-fluorosis-endemic area (fluoride drinking water concentrations of 0.98–1.00 mg/L). Higher TSH levels in children with dental fluorosis from the fluorosis-endemic area compared with children without dental fluorosis from the non-fluorosis-endemic area were observed but did not reach statistical significance. Significant differences in T_4 or T_3 were not observed between groups (Singh *et al.* 2014). Kumar *et al.* (2018) also observed a significant increase in TSH levels in children from a fluorosis endemic area (1.5–5.8 mg/L fluoride) compared with a control area (0.94–1.08 mg/L fluoride). There were also decreases in T_3 and T_4, but results were not statistically significant.

Barberio *et al.* (2017a) evaluated fluoride effects on TSH levels in children and adults combined and found no relationship between fluoride exposure (measures in urine and tap water) and TSH levels. In the one study that evaluated thyroid hormone levels in adults but not children, Kheradpisheh *et al.* (2018b) found a significant increase in TSH associated with higher fluoride concentrations in drinking water in both adults with and without thyroid diseases such as hypothyroidism, hyperthyroidism, thyroid nodules, or thyroid cancer. Significant increases in T_3 were associated with higher fluoride in drinking water in adults without thyroid diseases, but increases in T_3 were not significant in adults with thyroid diseases. A significant association between T_4 and higher fluoride in drinking water was not observed in adults with or without thyroid diseases (Kheradpisheh *et al.* 2018b).

Other than changes in hormone levels, there is limited evidence of fluoride-related mechanistic effects in the three lower risk-of-bias studies that evaluated thyroid-related effects. Barberio *et al.* (2017a) found no relationship between fluoride exposure and self-reported thyroid conditions in children and adults (children were older than 12). Kheradpisheh *et al.* (2018b) also found no association between fluoride exposure and hypothyroidism in an adult population in Iran. One study found a significantly higher prevalence of hypothyroidism in areas with higher fluoride concentrations in drinking water (>0.7 mg/L) compared with areas with lower fluoride drinking water concentrations (≤0.7 mg/L) (Peckham *et al.* 2015).

Several higher risk-of-bias studies were available that evaluated potential mechanistic data in humans associated with fluoride exposure, including effects on thyroid hormones mostly in children (n = 11 studies); catecholamines in adults (Michael *et al.* 1996) or in subjects of unknown ages (Chinoy and Narayana 1992); acetylcholinesterase (AChE) or serotonin levels in children (Singh *et al.* 2013, Lu *et al.* 2019); brain histopathology or biochemistry in aborted fetuses (Du *et al.* 1992 [translated in Du *et al.* 2008], Yu *et al.* 1996 [translated in Yu *et al.* 2008]); and mitochondrial fission/fusion molecules in children (Zhao *et al.* 2019). Similar to the lower risk-of-bias studies, the higher risk-of-bias studies provide some evidence of mechanistic effects (primarily changes in TSH levels in children); however, the data are insufficient to identify a clear mechanism by which fluoride causes neurodevelopmental or cognitive effects in humans.

Among higher risk-of-bias studies (see **Figure A3-7** and **Figure A3-8**), varying results were reported in 11 studies that evaluated fluoride exposure and effects on thyroid hormones, and a few of these studies (Lin *et al.* 1991, Yang *et al.* 1994 [translated in Yang *et al.* 2008], Wang *et al.* 2001) were complicated by high or low iodine in the high fluoride area. When considering fluoride effects on each of the hormones individually, similar to results from lower risk-of-bias studies, the most consistent evidence of fluoride-associated effects on a thyroid hormone was reported as changes in TSH levels in children, although there was some variation in the direction of effect. Six of the nine higher risk-of-bias studies that evaluated changes in TSH levels in children reported increases in TSH levels with higher fluoride (Lin *et al.* 1991, Susheela *et al.* 2005, Wang *et al.* 2001, Yang *et al.* 1994 [translated in Yang *et al.* 2008], Yao *et al.* 1996, Yasmin *et al.* 2013). Two of the nine higher risk-of-bias studies reported decreases in TSH levels in children with higher fluoride (Khandare *et al.* 2017, Khandare *et al.* 2018). One of the nine studies found no significant alterations in TSH levels in children from fluorosis-endemic areas (Hosur *et al.* 2012) (see **Figure 8**).

When considering fluoride-associated effects on TSH, T_3, and T_4 levels together, studies that evaluated changes in all three thyroid hormones reported varying combinations of increases, decreases, or no changes in levels across the three hormones, although among the eight lower and higher risk-of-bias studies that evaluated the effects of fluoride exposure on TSH, T_3, and T_4 levels and reported increases

in TSH levels in children, seven of the eight studies found no alterations in T_3 levels (one study found an increase in T_3), and six of the eight studies found no alterations in T_4 levels (two studies found an increase in T_4). Studies also displayed variation by age in fluoride-associated effects on TSH, T_3, and T_4. Due to the dynamic relationship between the thyroid gland, the pituitary gland, and the production and clearance of TSH, T_3, and T_4, the variations in results are not unexpected and do not eliminate the possibility of a mechanistic link between thyroid effects and neurodevelopmental or cognitive effects; however, the data do not support a clear indication that thyroid effects are a mechanism by which fluoride causes these effects in humans.

In addition to evaluating thyroid hormone levels, a few higher risk-of-bias studies evaluated other mechanistic data associated with fluoride exposure; however, the data are insufficient to identify a clear mechanism by which fluoride might cause neurodevelopmental or cognitive effects in humans. Serum epinephrine and norepinephrine were significantly increased in a fluoride-endemic region (not reported whether subjects were children or adults) compared to a non-endemic region (Chinoy and Narayana 1992). Serum adrenaline and noradrenaline were significantly increased in adults in a fluoride-endemic area (fluoride in the drinking water ranged from 1.0–6.53 ppm) compared to a control area (fluoride in the drinking water ranged from 0.56–0.72 ppm) (Michael *et al.* 1996). Serum AChE was significantly reduced in children from a high fluoride region compared to a lower fluoride region (Singh *et al.* 2013). Serum serotonin was significantly increased in children from Turkey who were drinking water containing 2.5 mg/L of fluoride compared to children drinking bottled water or water containing <0.5 mg/L of fluoride (Lu *et al.* 2019). Aborted fetuses from high fluoride areas in China were found to have histological changes in the brain and significant changes in neurotransmitter levels compared to a control area (Du *et al.* 1992 [translated in Du *et al.* 2008], Yu *et al.* 1996 [translated in Yu *et al.* 2008]).

There are also two more recent lower risk-of-bias studies that evaluated polymorphisms in dopamine-related genes; however, a determination on mechanism cannot be made at this time due to the limited number of studies. For children (10–12 years old) with a Val158Met polymorphism in the *COMT* gene (i.e., catechol-O-methyltransferase), which results in slower degradation and greater availability of dopamine within the brain, a stronger association between increasing urinary fluoride levels and decreasing IQ was reported (Zhang *et al.* 2015b). For children (7–12 years old) with a dopamine receptor-2 (DRD2) Taq 1A polymorphism (which is involved in reduced D2 receptor density and availability) and the TT (variant) genotype, a significant inverse relationship between log urine fluoride and IQ was observed; however, this significant relationship was not observed in children with the CC (wild-type) or CT (hybrid) genotypes (Cui *et al.* 2018).

Figure 7. Number of Lower Risk-of-bias Studies that Evaluated Thyroid Hormones in Children and Adults by Endpoint and Direction of Effect*

Endpoint	Direction of Effect ↑	NS	Grand Total
serum T3	1	3	4
serum T4		4	4
serum TSH	5	2	7
self-reported thyroid condition		1	1
thyroid disease		1	1
hypothyroidism prevalence	1		1

*Interactive figure and additional study details in Tableau® (https://public.tableau.com/profile/ntp.visuals#!/vizhome/Fluoride_EpiThyroid_UPDATE/Figures6and7). This figure displays study counts for lower risk-of-bias studies in both children and adults, as these counts are most relevant to the summary of fluoride-related mechanistic effects in lower risk-of-bias studies. Counts for higher risk-of bias studies and studies by age (i.e., children, adults, or children/adults combined) can also be accessed in the interactive figure in Tableau®. Study counts are tabulated by significance (unless if study footnotes in Tableau indicate that statistical significance was not tested)—statistically significant increase (↑), statistically significant decrease (↓), or not significant (NS). For example, the "↑" column displays numbers of unique studies with significantly increased results.

Figure 8. Number of Higher Risk-of-bias Studies that Evaluated Thyroid Hormones in Children by Endpoint and Direction of Effect*

Endpoint	Direction of Effect ↑	↓	NS	Grand Total
serum T3	1	1	6	8
serum T4	3		5	8
serum TSH	6	2	1	9

*Interactive figure and additional study details in Tableau® (https://public.tableau.com/profile/ntp.visuals#!/vizhome/Fluoride_EpiThyroid_UPDATE/Figures6and7). This figure displays study counts for higher risk-of-bias studies in children, as these counts are most relevant to the summary of fluoride-related effects on thyroid hormones in higher risk-of-bias studies. Counts for lower risk-of bias studies, studies in adults, or all studies combined, can also be accessed in the interactive figure in Tableau®. Study counts are tabulated by significance (unless if study footnotes in Tableau indicate that statistical significance was not tested)—statistically significant increase (↑), statistically significant decrease (↓), or not significant (NS). For example, the "↑" column displays numbers of unique studies with significantly increased results.

Animal Learning and Memory Data

[Note: An earlier version of the monograph underwent NASEM committee peer review in November 2019 (NASEM 2020). In this earlier review the committee criticized this section primarily over concerns that the NTP's risk-of-bias evaluations failed to adequately capture a number of important threats to internal validity that are specific to neurobehavioral outcomes in animal tests. The committee found

several examples of studies cited in the monograph where national or international guidelines for performance or statistical analyses were not followed or descriptions of methods were insufficient to evaluate their adequacy. Additionally, the committee took issue with a conclusion of the prior peer reviewed systematic review of the experimental animal literature (NTP 2016) concerning the degree to which motor activity deficits might compromise neurobehavioral assessments, affecting the directness of applicability of deficits in animal learning and memory to support the plausibility of IQ deficits in exposed children.

The NTP generally does not take issue with the NASEM peer review comments and acknowledges that further efforts to disentangle the potential for motor activity deficits to influence tests of learning and memory in the fluoride literature are warranted. The NTP agrees with the comments of the NASEM committee concerning the overall poor quality of the experimental animal database, with many studies suffering from major reporting deficiencies. NTP also found these to be general issues with the experimental animal database and were identified as deficiencies that led to the inadequate conclusion. However, the following experimental animal study section remains largely unchanged from the initial version of the monograph reviewed by NASEM in November 2019. The reasons for this are: (1) because a more critical risk-of-bias assessment would result in fewer relevant animal studies judged to be of high quality; (2) because the highest quality experimental animal study reviewed for this monograph (McPherson *et al.* 2018) did not find effects of fluoride on learning, memory or motor activity in the critical $\leq$20 ppm in drinking water concentration range; and (3) because of the availability of a large number of human epidemiology studies directly addressing neurobehavioral and cognitive effects of fluoride in children, a decision was made to focus efforts to address comments on the critical human epidemiology evaluation in this revised and updated monograph. NTP acknowledges the helpful comments of the NASEM committee on the following section and refers readers to the NASEM review (NASEM 2020) when considering the information provided. For the purpose of this updated review the NTP considers that the experimental animal data remain *inadequate* to inform conclusions on whether fluoride exposure is associated with cognitive effects (including cognitive neurodevelopmental effects) in humans. NTP is aware of a number of additional relevant experimental animal studies published since the literature cutoff date for the monograph. These additional studies have not been formally reviewed and may shed further light on these issues].

In 2016, NTP conducted a systematic review of the available experimental animal studies to develop level-of-evidence conclusions on the association between fluoride exposure and neurobehavioral effects, specifically effects related to learning and memory impairment (NTP 2016). As previously discussed, the evaluation of the animal body of evidence in this assessment is an extension of the NTP (2016) systematic review and is consistent with the methodology and format used in that report.

NTP (2016) identified two main issues with the animal body of evidence related to effects of fluoride exposure on learning and memory: indirectness and concerns for risk of bias. The concern related to indirectness was based on the fact that many learning and memory tests rely on a motor response (e.g., latency to achieve the desired effect). Changes in motor function or activity levels associated with fluoride exposures could complicate the interpretation of the results on learning and memory test performance depending on the outcome measured. The directness of the measure as an indicator of learning and memory (i.e., the ability to rule out impaired motor or sensory function) was considered when addressing confidence in the data. Concerns in these studies related to risk of bias included the following factors: lack of randomization, lack of blinding or other methods to reduce potential bias at outcome, lack of exposure information, lack of control for litter effects, lack of expected response in the

control animals, and lack of reporting of other key study information such as sample size or sex of the animals.

Since the NTP (2016) report was published, additional experimental animal studies were identified that evaluated learning and memory impairment associated with fluoride exposure, including 12 developmental exposure studies (Banala and Karnati 2015, Mesram *et al.* 2016, Zhu *et al.* 2017, Sun *et al.* 2018, Wang *et al.* 2018, Ge *et al.* 2018b, McPherson *et al.* 2018, Zhao *et al.* 2019, Ge *et al.* 2018a, Chen *et al.* 2018, Bartos *et al.* 2018, Banala *et al.* 2018); 5 Morris water maze study in adults (Zheng *et al.* 2016, Niu *et al.* 2018, Dong *et al.* 2017, Sharma *et al.* 2018, Yang *et al.* 2018); and 7 other maze studies in adults (Pulungan *et al.* 2016, Shalini and Sharma 2015, Sharma *et al.* 2018, Sudhakar *et al.* 2017, Nageshwar *et al.* 2018, Yuan *et al.* 2019, Raju *et al.* 2019). In addition, 12 studies were identified that evaluated motor activity/coordination or sensory effects without evaluating learning and memory impairment (Adedara *et al.* 2017a, Nageshwar *et al.* 2017, Nkpaa and Onyeso 2018, Sudhakar *et al.* 2018b, Ahmad *et al.* 2017, Kinawy and Al-Eidan 2018, Manusha *et al.* 2019, Sudhakar *et al.* 2018a, Agustina *et al.* 2018, Lu *et al.* 2019, Jia *et al.* 2019, Li *et al.* 2019).

Although Adedara *et al.* (2017a) and Nkpaa and Onyeso (2018) evaluated exploration, the authors concluded that the track plots in the open field novel environment test were consistent with impaired locomotor activity in the fluoride-treated animals. The additional studies reviewed did not address the concern of indirectness and most included risk-of-bias concerns; however, a few of these more recent studies are notable in that they provide results on learning and memory effects that could possibly be distinguished from effects on motor activity. Bartos *et al.* (2018) used a step-down inhibitory avoidance test to evaluate short-term and long-term memory in rat offspring. Although the authors did not discuss activity in the animals, this test would be expected to result in increased latency in animals if there was decreased activity with fluoride exposure. The fluoride-treated female offspring, however, had decreased latency indicating diminished memory of the foot shock. Chen *et al.* (2018) also evaluated female rat offspring (treatment continued until the offspring were 6 months old) and observed an effect of fluoride on latency to reach the platform and the number of platform crossings in the Morris Water Maze; however, swimming speed was measured, and no changes were observed. The tracks during the spatial probe test were also very different in the two higher exposed groups (i.e., 50 and 100 mg/L NaF), suggesting that the animals did not know the location of the platform. It is not clear if litter effects were addressed in the study.

After further evaluation of the data available in NTP (2016) and in this update, it is concluded that the animal data are inadequate to evaluate the effects of fluoride on learning and memory primarily due to the inability to separate the learning and memory effects from the effects on motor activity or motor coordination. The majority of the studies that evaluated effects of fluoride on learning and memory did not also evaluate a motor activity component to determine if the learning and memory effects could be attributed to motor activity or coordination deficits. Of the studies that did evaluate both learning and memory and motor activity/coordination, studies mainly found an association between fluoride exposure and both types of neurological outcomes or found no effect of fluoride exposure on either type of neurological outcome irrespective of the dose range or duration of dosing. In addition, studies that found effects on motor activity/coordination or learning and memory often did not provide sufficient indicators of general health of the animals to reliably attribute impaired performance on a task to a specific acquisition of learning and memory or motor activity/coordination. The few studies that provided this information used different test methods or results were inconsistent. Thus, it is difficult to conclude that evidence from experimental animal studies is meaningful when considering the specific question of fluoride's potential influence on human IQ or cognitive function, particularly at

human -relevant exposure levels. Based on this consideration, the experimental animal body of evidence does not contribute to confidence in conclusions derived from human epidemiological studies with respect to effects on human IQ. Although the evidence supports an association between fluoride exposure and neurodevelopmental effects, the data are not sufficient to support the primary effect evaluated in children (i.e., IQ) nor is it sufficient to support a conclusion on cognitive effects in adults especially in the absence of additional adult human data.

Mechanistic Data in Animals

There are a wide variety of studies in animals that evaluate mechanistic effects potentially related to neurological changes following oral fluoride exposure (see **Figure 9**). Categories of mechanistic endpoints with the largest amount of available data include changes in biochemical components of the brain or neurons, neurotransmitters, oxidative stress, histopathology, and thyroid function. Limiting the data to studies with at least one exposure at or below 20 ppm fluoride drinking water equivalents (gavage and dietary exposures were back calculated into equivalent drinking water concentrations for comparison) still provided a sufficient number of studies for evaluation of these mechanistic endpoints. Neurotransmitter and biochemical changes in the brain and neurons were considered to be the mechanistic areas with the greatest potential to demonstrate effects of fluoride on the brain of animals in the lower dose range and provide evidence of changes in the brain that may relate to lower IQ in children (see **Figure 10**). Histological data can be useful in determining whether effects are occurring in the brain at lower fluoride concentrations; however, author descriptions of these effects may be limited thereby making it difficult to directly link histological changes in the brain to learning and memory effects. Oxidative stress is considered a general mechanistic endpoint that cannot be specifically linked to neurodevelopmental or cognitive effects in humans; however, like histopathology, it may help in identifying changes in the brain occurring at lower concentrations of fluoride. Although any effects in the brain or neurological tissue at lower concentrations of fluoride may support reduced IQ in humans, it may be difficult to distinguish the potential effects of fluoride on learning and memory functions from other neurological or general health outcomes.

Figure 9. Number of Animal Mechanistic Studies for Fluoride by Mechanistic Category and Exposure Level*

Mechanism	Dose Level	
	All	≤20 ppm
Biochemical (brain/neurons)	66	25
Neurotransmitters	53	23
Oxidative stress	78	25
Histopathology	67	30
Apoptosis/cell death	19	7
Inflammation	7	5
Thyroid	50	17
Other	3	2

*Interactive figure and additional study details in Tableau® (https://public.tableau.com/profile/ntp.visuals#!/vizhome/Animal_Mechanisms_All_June2019/Figure8). The number of

studies that evaluated mechanistic effects associated with at least one exposure at or below 20 ppm fluoride is tabulated in the "≤20 ppm" column. The total number of studies per mechanistic category are summarized in the "All" column.

The following sections summarize the mechanistic data by category of mechanistic endpoint. Although there is some evidence of consistency in mechanistic effects, overall these data are insufficient to increase confidence or support a change to hazard conclusions.

Neurotransmitters

Twenty of 23 neurotransmitter studies assessed changes in brain cholinesterase activity associated with fluoride exposure at or below 20 ppm fluoride. Acetylcholine is a major neurotransmitter involved in learning, memory, and intelligence (Chen 2012, Gais and Schonauer 2017). AChE is responsible for the breakdown of acetylcholine in the synapses of nerve cells. Changes in cholinesterase, acetylcholine, or AChE could be related to effects on memory. Evidence of an effect varied among the lower risk-of-bias studies that assessed changes in cholinesterase or acetylcholine (n = 11 drinking water studies) (Gao *et al.* 2009, Baba *et al.* 2014, Adedara *et al.* 2017a, Khan *et al.* 2017, Gao *et al.* 2008a, Akinrinade *et al.* 2015a, Sun *et al.* 2000 [translated in Sun *et al.* 2008], Chouhan *et al.* 2010, Mesram *et al.* 2016, Liu *et al.* 2010, Nkpaa and Onyeso 2018), with the majority of studies reporting evidence of an effect that is considered inconsistent with the phenotypic outcome. Decreases in cholinesterase will cause increases in acetylcholine, which can have a positive effect on learning and memory; however, long-term decreases in cholinesterase can lead to secondary neuronal damage occurring in the cholinergic region of the brain (Chen 2012).

Five of the 11 studies with lower risk of bias (Gao *et al.* 2009, Baba *et al.* 2014, Adedara *et al.* 2017a, Khan *et al.* 2017, Nkpaa and Onyeso 2018) found statistically significant decreases in cholinesterase or AChE in brain homogenates (with some brains dissected into specific regions prior to homogenizing) with fluoride concentrations in drinking water at or below 20 ppm, and 4 of the 5 studies found statistically significant decreases in cholinesterase or AChE below 10 ppm. The 5 studies were conducted in rats (Wistar or Sprague-Dawley) with exposure ranging from 28 days to 6 months. An additional 2 out of 11 studies (Gao *et al.* 2008a, Akinrinade *et al.* 2015a) reported decreases in brain homogenate AChE at concentrations at or below 20 ppm fluoride in drinking water, but statistical significance was not reached. These studies were also conducted in rats with exposure for 30 days or 3 months. Gao *et al.* (2008a) reported a dose-dependent decrease in brain homogenate AChE in the low (5 ppm fluoride) and high (50 ppm fluoride) treatment groups compared with the control group, but the decrease was only statistically significant in the high dose group. Similarly, Akinrinade *et al.* (2015a) observed a dose-dependent decrease in percent intensity of AChE immunohistochemistry in the prefrontal cortex associated with 2.1 and 10 ppm sodium fluoride in the drinking water, but neither result was statistically significant. Gao *et al.* (2009) found lower brain homogenate AChE levels in the 5-ppm animals compared with the 50-ppm animals; therefore, the results were not always dose dependent.

Relative to the above-mentioned studies, 2 of the 11 lower risk-of-bias studies observed opposite effects on brain cholinesterase levels. Sun *et al.* (2000) [translated in Sun *et al.* 2008] observed a significant increase in brain cholinesterase in Kunming mice associated with fluoride drinking water concentrations from 10 to 100 mg/L, but did not observe a dose response. Chouhan *et al.* (2010) did observe a dose-related increase in AChE levels in brain homogenate of Wistar rats with sodium fluoride concentrations of 1 to 100 ppm for 12 weeks and noted statistically significant results at 1, 50, and 100 ppm but not at 10 ppm.

Mesram *et al.* (2016) did not assess changes in AChE but observed a significant decrease in acetylcholine levels in cerebral cortex homogenate through 30 days of age in rats treated in utero with 20 ppm

sodium fluoride, which may suggest an increase in AChE levels. Likewise, Liu *et al.* (2010) did not assess changes in AChE, but measured nicotinic acetylcholine receptors (nAChRs) in brain homogenate of rats following drinking water fluoride exposure, which the authors stated could modulate physiological and pharmacological functions that are involved in learning and memory-related behaviors. Significant decreases in the protein expressions of nAChR subunits at 2.26 ppm fluoride were observed; however, the corresponding receptor subunit mRNAs did not exhibit any changes (Liu *et al.* 2010).

The studies that assessed other neurotransmitters of the brain and neurons were too heterogeneous or limited in number to make any determination on mechanism, even before limiting the review of the data to lower risk-of-bias studies. There were only five studies that evaluated dopamine and/or metabolites (Tsunoda *et al.* 2005, Chouhan *et al.* 2010, Reddy *et al.* 2014, Banala *et al.* 2018, Sudhakar and Reddy 2018). Four of the studies observed decreases in dopamine levels in the brain with exposures less than 20 ppm fluoride (Reddy *et al.* 2014, Chouhan *et al.* 2010, Banala *et al.* 2018, Sudhakar and Reddy 2018); however, the fifth study (Tsunoda *et al.* 2005) observed increased dopamine and metabolites at fluoride exposures below 20 ppm (with statistical significance achieved only for the metabolite homovanillic acid in one brain region). No differences from the control group were observed at levels above 20 ppm fluoride. Other neurotransmitters were evaluated at or below 20 ppm fluoride exposure, but generally only in a couple of studies.

Biochemistry (brain/neurons)

Similar to above, the endpoints measured in brain biochemistry studies were too heterogeneous or limited in number to make any determination on potential relevance of mechanism, even before limiting the review of the data to lower risk-of-bias studies (see **Figure 10**). Endpoints related to biochemical changes in the brain or neurons included carbohydrate or lipid changes, RNA or DNA changes, changes in gene expression, or changes in protein expression. For the most part, only a single study was available for any given endpoint. The largest body of evidence on biochemistry was on protein level in various brain regions. Eleven lower risk-of-bias studies were identified that evaluated protein levels; however, few studies evaluated the same proteins or areas of the brain. In the few cases where the same protein was evaluated, results were not always consistent. These data are insufficient to increase confidence or support a change to hazard conclusions.

Histopathology

Histopathology of the brain was evaluated in 31 studies with concentrations at or below 20 ppm fluoride, of which 15 studies had a lower potential for bias (Adedara *et al.* 2017b, Akinrinade *et al.* 2015a, Bhatnagar *et al.* 2002, Bhatnagar *et al.* 2011, Chouhan *et al.* 2010, Guner *et al.* 2016, Jiang *et al.* 2014, Lou *et al.* 2013, McPherson *et al.* 2018, Mesram *et al.* 2016, Niu *et al.* 2018, Pulungan *et al.* 2016, Nageshwar *et al.* 2018, Zhao *et al.* 2019, Jia *et al.* 2019). In all but one lower risk-of-bias study [Pulungan *et al.* (2016); gavage], animals were exposed to fluoride via drinking water. All lower risk-of-bias studies were conducted in rodents, and all but three studies were conducted in rats (Wistar [seven studies]; Sprague-Dawley [four studies]; Long-Evans hooded [one study]). Overall, the lower risk-of-bias studies that evaluated histopathology in the brain had low potential for bias for key questions regarding randomization and exposure characterization; however, eight studies were rated as probably high risk of bias for the key risk-of-bias question regarding outcome assessment based on lack of reporting of blinding of outcome assessors and/or inadequate description of outcome measures or lesions. Moreover, low image quality in some of the studies hampered the ability to verify the quality of the data. Further technical review of the 15 lower risk-of-bias studies was conducted by a board-certified pathologist. Based on confidence in the results for each study, the technical reviewer further categorized the lower risk-of-bias studies as studies with higher or lower confidence in the outcome

assessment, which is reflected in the following summary of the brain histopathology results. Main limitations of the histopathology data identified by the pathologist included lack of information on methods of euthanasia and fixation. Perfusion fixation is generally considered the best practice for lesions of the central nervous system in addition to complete fixation of the brain prior to its removal from the skull (Garman *et al.* 2016). Four of the lower risk-of-bias studies reported that they used this method (Bhatnagar *et al.* 2002, Bhatnagar *et al.* 2011, McPherson *et al.* 2018, Pulungan *et al.* 2016). Two of the lower risk-of-bias studies handled the brains before fixation was complete, which can produce artifacts that can resemble dead neurons (Zhao *et al.* 2019, Nageshwar *et al.* 2018). Fixation and brain removal details were inadequately described in the remaining lower risk-of-bias studies.

Although there was heterogeneity in the endpoints reported (e.g., cell size, shape, and counts; nuclei fragmentation; increased vacuolar spaces) and some variation in the consistency of the evidence based on the area of the brain evaluated, the majority of the lower risk-of-bias studies (11 of 14 drinking water studies) found some histological change in the brain of rats or mice treated with fluoride at concentrations at or below 20 ppm, of which 8 studies reported histological changes in the brain at or below 10 ppm. Histological changes in the hippocampus (one of the areas of the brain most evaluated for histological changes) associated with fluoride exposures at or below 20 ppm were reported in three of four lower risk-of-bias studies with higher confidence in the outcome assessment (Bhatnagar *et al.* 2002, Bhatnagar *et al.* 2011, Guner *et al.* 2016) and in three of four lower risk-of-bias studies with lower confidence in the outcome assessment (Jiang *et al.* 2014, Niu *et al.* 2018, Nageshwar *et al.* 2018). McPherson *et al.* (2018) was the only drinking water study (with higher confidence in the histopathology outcome assessment) that did not observe any histological changes in hippocampus at 10 or 20 ppm fluoride in male Long-Evans hooded rats exposed in utero through adulthood (>PND80). Although there are too few studies to definitively explain the inconsistency in results, McPherson *et al.* (2018) also did not observe any associations between fluoride exposure and impairments to learning and memory, which is inconsistent with the majority of developmental exposure studies that observed learning and impairments associated with fluoride exposure for other strains of rats. Similarly, histological changes in the cortex were reported in three of the four lower risk-of-bias drinking water studies with higher confidence in the outcome assessment (Chouhan *et al.* 2010, Bhatnagar *et al.* 2011, Akinrinade *et al.* 2015a) and in three of four lower risk-of-bias studies with lower confidence in the outcome assessment (Lou *et al.* 2013, Mesram *et al.* 2016, Nageshwar *et al.* 2018).

Histological changes were also consistently reported in other areas of the brain in studies with higher confidence in the outcome assessment, including the amygdala, caudate putamen, cerebellum, and hypothalamus, although each of these areas of the brain were only evaluated in one lower risk-of-bias study (Bhatnagar *et al.* 2011, Guner *et al.* 2016). Pulungan *et al.* (2016), one of two lower risk-of-bias studies with higher confidence in the outcome assessment that did not report histological changes in the brain, observed a decreasing trend in the number of pyramidal cells in the prefrontal cortex with increasing dose, but this was not changed at concentrations below 20 ppm (study administered sodium fluoride via gavage; the 5-mg/kg-day dose was considered to be equivalent to 15.3 ppm fluoride in drinking water) nor were any of the results statistically significant.

Oxidative stress

Oxidative stress in the brain was evaluated in 25 studies that examined concentrations at or below 20 ppm fluoride, of which 15 studies had lower potential for bias (Adedara *et al.* 2017a, Adedara *et al.* 2017b, Akinrinade *et al.* 2015b, Chouhan *et al.* 2010, Gao *et al.* 2008b, Guner *et al.* 2016, Mesram *et al.* 2016, Nkpaa and Onyeso 2018, Shan *et al.* 2004, Zhang *et al.* 2015a, Chouhan and Flora 2008, Gao *et al.* 2009, Khan *et al.* 2017, Bartos *et al.* 2018, Nageshwar *et al.* 2018). All of the lower risk-of-bias studies

were conducted in rats (mainly Wistar or Sprague-Dawley) and administered fluoride via drinking water with exposure durations ranging from 28 days to 7 months. Although there was heterogeneity in the endpoints reported (i.e., varying measures of protein oxidation, antioxidant activity, lipid peroxidation, and reactive oxygen species [ROS]) and some variation in the consistency of the evidence based on the endpoint, the majority of the studies (13 of 15 studies) (Adedara *et al.* 2017a, Adedara *et al.* 2017b, Akinrinade *et al.* 2015b, Gao *et al.* 2008b, Gao *et al.* 2009, Guner *et al.* 2016, Mesram *et al.* 2016, Nkpaa and Onyeso 2018, Shan *et al.* 2004, Zhang *et al.* 2015a, Khan *et al.* 2017, Nageshwar *et al.* 2018, Bartos *et al.* 2018) found evidence of oxidative stress in the brains of rats treated with fluoride at concentrations at or below 20 ppm, of which 10 studies reported oxidative stress in the brain below 10 ppm fluoride. The most consistent evidence of oxidative stress in the brain was reported through changes in antioxidant activity. Eleven of the 12 lower risk-of-bias studies that evaluated antioxidant activity reported an effect at concentrations at or below 20 ppm (Adedara *et al.* 2017a, Adedara *et al.* 2017b, Akinrinade *et al.* 2015b, Gao *et al.* 2008b, Gao *et al.* 2009, Guner *et al.* 2016, Mesram *et al.* 2016, Nkpaa and Onyeso 2018, Khan *et al.* 2017, Bartos *et al.* 2018, Nageshwar *et al.* 2018). Decreases in antioxidant activity using measures of superoxide dismutase (SOD) activity were reported in seven of eight lower risk-of-bias studies (Adedara *et al.* 2017a, Adedara *et al.* 2017b, Akinrinade *et al.* 2015b, Mesram *et al.* 2016, Nkpaa and Onyeso 2018, Khan *et al.* 2017, Nageshwar *et al.* 2018) and, among these seven studies, all that also measured changes in catalase (CAT) activity (n = 6 studies) also reported decreased activity (Adedara *et al.* 2017a, Adedara *et al.* 2017b, Mesram *et al.* 2016, Nkpaa and Onyeso 2018, Khan *et al.* 2017, Nageshwar *et al.* 2018). A decrease in total antioxidant capacity (T-AOC) as a measure of antioxidant activity was also consistently reported in two lower risk-of-bias studies (Gao *et al.* 2008b, Gao *et al.* 2009), and a decrease in glutathione peroxidase (GPx) activity was reported in two of three lower risk-of-bias studies (Adedara *et al.* 2017b, Nkpaa and Onyeso 2018).

Relative to the above-mentioned studies, 2 of the 15 lower risk-of-bias studies (Chouhan and Flora 2008, Chouhan *et al.* 2010) did not observe statistically significant effects on oxidative stress in the brain with concentrations at or below 20 ppm fluoride; however, the measure of oxidative stress evaluated in Chouhan and Flora (2008) and Chouhan *et al.* (2010) (glutathione [GSH] to oxidized glutathione [GSSG] ratio as an indication of antioxidant activity and ROS levels) were not evaluated in any other lower risk-of-bias study. Chouhan and Flora (2008) observed a dose-dependent increase in ROS levels associated with 10, 50, and 100 mg/L sodium fluoride in the drinking water; however, results were not statistically significant at any dose. In Chouhan *et al.* (2010), the levels of ROS were significantly higher at 50 ppm sodium fluoride in drinking water, but statistical significance was not met at doses below 20 ppm fluoride (1 and 10 ppm sodium fluoride) or at 100 ppm sodium fluoride; yet, hydrogen peroxide levels as a measure of ROS were found to be significantly increased at 15 ppm sodium fluoride in drinking water in studies conducted by another group of authors (Adedara *et al.* 2017a, Adedara *et al.* 2017b).

Apoptosis/cell death

Seven lower risk-of-bias studies were identified that evaluated apoptosis with concentrations at or below 20 ppm fluoride. Results from these studies were inconsistent and were insufficient for evaluating fluoride-induced apoptosis. These data are insufficient to increase confidence or support a change to hazard conclusions.

Inflammation

Five lower risk-of-bias studies were identified that evaluated potential effects of fluoride on inflammation with concentrations at or below 20 ppm. The inflammation markers were too heterogeneous or limited in number to make any determination on potential relevance of mechanism,

even before limiting the review of the data to lower risk-of-bias studies. These data are insufficient to increase confidence or support a change to hazard conclusions.

Thyroid

Seventeen studies were identified that evaluated potential effects of fluoride on the thyroid with concentrations at or below 20 ppm (see **Figure 9**). These animal thyroid data are not further described because this endpoint has been directly evaluated in a number of human studies that have failed to identify consistent evidence to suggest that thyroid effects are a requisite mechanism by which fluoride causes neurodevelopmental or cognitive effects in humans.

Figure 10. Number of Lower Risk-of-bias Animal Studies that Evaluated Biochemical, Neurotransmission, and Oxidative Stress Effects at or Below 20 ppm by Mechanism Subcategory and Direction of Effect*

Mechanism	Mechanism Subcategory	Direction of Effect ↑	↓	NS	Grand Total
Biochemistry (brain/neurons)	Carbohydrate/lipid-related		1	1	2
	Gene expression		1		1
	Protein levels associated with brain function	8	7	7	11
	Other biochemical	2			2
Neurotransmitters	Cholinesterase	2	7	3	11
	Dopamine and metabolites		1		1
	Other neurotransmitters	2	2	1	2
Oxidative stress	Antioxidant activity	1	10	4	12
	Lipid peroxidation byproduct	7		4	11
	Protein oxidation	2		1	2
	ROS	2		2	4

*Interactive figure and additional study details in Tableau® (https://public.tableau.com/profile/ntp.visuals#!/vizhome/Fluoride_Animal_SelectMechanisms_UPDATE/Figure9). This figure displays study counts for lower risk-of-bias studies, as these counts are most relevant to the text in this section. Counts for higher risk-of bias studies or all studies combined can be accessed in the interactive figure in Tableau®. Study counts are tabulated by significance—statistically significant increase (↑), statistically significant decrease (↓), or not significant (NS). For example, the "↑" column displays numbers of unique studies with at least one endpoint in the mechanistic subcategory with significantly increasing results at fluoride exposure levels of ≤20 ppm. These columns are not mutually exclusive (i.e., a study may report on multiple endpoints with varying results within a single mechanistic subcategory and therefore may be reflected in the counts for the "↑", "↓", and NS columns, but would only be counted once in the Grand Total column). Endpoints, species, strain, sex, and exposure duration are available for each study in the interactive figure in Tableau®.

In Vitro/Mechanistic Data on Neurodevelopmental or Cognitive Effects

Although in vitro data were collected as part of the systematic review process, NTP determined that the information on neurological effects obtained from these studies is too general, and results cannot necessarily be attributed to effects on learning and memory or other cognitive functions at this time. The in vitro data may help support specific mechanisms identified from in vivo mechanistic data; however, as described above, no specific mechanism has been determined for fluoride effects on learning and memory or other neurodevelopmental or cognitive outcomes.

Evidence Synthesis for Neurodevelopmental or Cognitive Effects

There is consistent evidence that exposure to fluoride is associated with cognitive neurodevelopmental effects in children. There is moderate confidence in the human data in children from 5 well-conducted

prospective studies, supported by 14 cross-sectional studies where exposure was identified as likely occurring prior to outcome. The human body of evidence in adults is considered inadequate to evaluate whether fluoride exposure is associated with cognitive effects due to low confidence in the human data in adults, a limited number of studies, and a lack of evidence of an effect (i.e., there is not sufficient evidence of an effect, but the confidence in the data is not high enough to conclude that there is no effect). The animal data are inadequate to evaluate for learning and memory effects primarily due to the uncertainty in distinguishing effects on cognitive outcomes from secondary effects on the nervous system or general health including motor activity issues; however, these data do provide evidence of other neurodevelopmental effects. There is also evidence from mechanistic studies of adverse neurological effects of fluoride in humans and animals of unknown relationship to cognition.

The initial moderate confidence is based on 19 studies where exposure occurred prior to outcome and that evaluated individual-based outcomes and used a comparison group. Factors considered for upgrading or downgrading the confidence are as follows:

- **Risk of bias**: Only studies that were considered to have lower risk of bias were included in the moderate confidence rating; therefore, there is no downgrade for risk-of-bias concerns.

- **Unexplained inconsistencies:** The data are relatively consistent and there was no downgrade for this factor. In terms of IQ data, 17 studies observed significant effects associated with fluoride, and 2 studies found no significant association but neither of these studies adjusted for confounders. Consistency among neurodevelopmental effects other than IQ was also considered; however, the conclusions are based on the IQ data so these other neurodevelopmental effects would not impact a potential adjustment in confidence. Studies measuring neurodevelopmental effects other than IQ did not show consistent effects. It is not known whether fluoride exposure would be expected to be associated with neurodevelopmental outcomes in addition to IQ or other cognitive measures.

- **Indirectness:** IQ in humans is a direct measure of effect and therefore no adjustment in confidence is warranted.

- **Imprecision:** The meta-analysis indicates that there was no reason to downgrade due to imprecision.

- **Publication bias:** While the meta-analysis that estimated the pooled SMD among 46 included studies (both higher and lower risk-of-bias) indicated that there was potential for publication bias, a subgroup analysis indicated that there was no publication bias among the lower risk-of-bias studies (see **Figure A5-8**). Among the higher risk-of-bias studies, the trim-and-fill analysis estimated that, in the absence of publication bias, the negative direction of effect and statistical significance remained (**Figure A5-9**). For the meta-analysis that calculated a pooled effect estimate among the studies with individual-level measures, the funnel plot indicated publication bias; however, the trim-and-fill analysis estimated that once adjusted for publication bias, the negative direction of effect remained (**Appendix 5**, **Figure A5-16** and **Figure A5-18**). Therefore, no downgrade was applied for publication bias.

- **Large magnitude of effect:** While some individual studies indicate a large magnitude of effect, the overall pooled effect estimate from the meta-analysis of studies with individual-level

measures does not demonstrate a large magnitude of effect (**Appendix 5**). Therefore, the overall data would not support an upgrade due to a large magnitude of effect.

- **Dose-response:** Linear dose-response models provide the best fit to the data in studies examining individual-level measures of fluoride exposure and IQ. A meta-analysis of studies that compared mean IQ scores between groups of children with different levels of fluoride exposure showed a significantly lower mean SMD at higher concentrations of fluoride (>1.5 mg/L) from water (SMD: −0.14; 95% CI: −0.19, −0.08; n = 31 studies) and urine (SMD: −0.18; 95% CI: −0.31, −0.05; n = 22 studies) (**Appendix 5**); however, the dose-response relationship at fluoride concentrations below 1.5 mg/L fluoride in urine or drinking water is less certain. The overall dose-response could be used to upgrade the confidence in the body of evidence.

- **Residual confounding:** Xiang *et al.* (2003a), Xiang *et al.* (2011), and Wang *et al.* (2012) studied the same population where arsenic occurred in the area with low fluoride, but did not occur in the area with high fluoride. This would have biased the results toward the null, but there was a significantly lower IQ scores in the area with high fluoride. The remaining studies do not provide enough information to consider residual confounding as an impactful factor for the body of evidence. Therefore, the overall data would not support an upgrade due to residual confounding.

- **Consistency:** There is consistent evidence across study populations and study designs that fluoride is associated with lower IQ scores at higher concentrations of fluoride. There is uncertainty and less of a consistent pattern at concentrations below 1.5 mg/L. There is also a lack of consistency observed with and among other types of neurodevelopmental effects. The consistency in the overall results of the data set could increase the confidence.

Summary judgement on potential upgrades or downgrades in the confidence: Although the OHAT approach for evidence integration allows for the initial confidence in the body of evidence to be increased based on consistency or dose response, the NTP judgement is that the magnitude of effect and the overall strength and quality of the human literature base provides a moderate confidence in the body of evidence that fluoride causes cognitive neurodevelopmental effects in children.

The moderate confidence in the body of evidence in children translates to a moderate level of evidence that fluoride is associated with lower IQ and other cognitive neurodevelopmental effects in children.

The limited and weaker evidence of cognitive effects in adults is considered to provide an inadequate level of evidence that fluoride is associated with cognitive effects in adults. The animal body of evidence is also considered to provide an inadequate level of evidence for cognitive effects in adults.

Integration of these level-of-evidence conclusions supports an initial hazard conclusion of *presumed to be a cognitive neurodevelopmental hazard to humans* because of the extent and consistency of effect in the available data in children. Because most of the available studies evaluated intelligence in children, the primary focus in human data was on IQ and other cognitive neurodevelopmental effects, which is the primary basis for the hazard conclusion. A separate conclusion on other neurodevelopmental effects was not reached based on limited information in humans.

The moderate level of evidence in the human data in children supports a hazard conclusion of *presumed* instead of *suspected* due to the relatively large and consistent body of evidence, especially in relation to measures of IQ (17 of 19 lower risk-of-bias studies that assessed IQ reported an association between

higher fluoride and lower IQ scores) across multiple populations. A conclusion of *presumed* is supported by a statistically significant effect observed in the meta-analysis. Furthermore, the *presumed* hazard conclusion is supported by the low expectation that new studies would decrease the hazard conclusion.

Effects in children

- **Human body of evidence:** Moderate Confidence = Moderate Level of Evidence
- **Animal body of evidence:** Overall poor quality of studies and few studies that specifically assess effects on learning and memory after exposure during developmental periods separately from other neurological effects including motor activity = Inadequate Level of Evidence
- **Initial hazard conclusion (Moderate Human x Inadequate Animal)** = Presumed to be a Cognitive Neurodevelopmental Hazard to Humans
- **Final hazard conclusion (after consideration of biological plausibility)** = Presumed to be a Cognitive Neurodevelopmental Hazard to Humans

Effects in adults

- **Human body of evidence:** Low Confidence with no discernible effect = Inadequate Level of Evidence
- **Animal body of evidence:** Overall poor quality of studies and few studies that specifically assess effects on learning and memory after exposure in adulthood separately from other neurological effects including motor activity = Inadequate Level of Evidence
- **Initial hazard conclusion (Inadequate Human x Inadequate Animal)** = Not classifiable
- **Final hazard conclusion (after consideration of biological plausibility)** = Not classifiable

Table 7. Neurodevelopmental and Cognitive Function Evidence Profile for Fluoride

INITIAL CONFIDENCE for each body of evidence (# of studies)	Factors decreasing confidence "---" if no concern; "↓" if serious concern to downgrade confidence					Factors increasing confidence "---" if not present; "↑" if sufficient to upgrade confidence				FINAL CONFIDENCE RATING

*This includes learning disabilities, neonatal behavioral neurological assessment, mental development index, memory score for copy, and immediate recall.

**This includes Mini-Mental State Examination scores, psychomotor performance, and memory.

DISCUSSION

The overall objective of this evaluation was to undertake a systematic review of published literature to reach conclusions concerning the potential for exposure to fluoride to affect neurodevelopment and cognition. This review only addresses whether exposure to fluoride could present a potential hazard (i.e., has the potential to cause harm at any exposure level, including exposures that are higher than typically encountered from consuming fluoridated drinking water in the United States). Benefits of fluoride with respect to oral health are not addressed in this monograph.

Given this context, when focusing on human epidemiology studies with exposures in ranges typically found in the water distribution systems in the United States (0.7 mg/L for optimally fluoridated community water systems)[8] that can be evaluated for dose response, effects on cognitive neurodevelopment are inconsistent and therefore unclear. However, given the totality of the data, including studies with exposures to fluoride levels higher than the WHO safe water guideline of 1.5 mg/L in water (WHO 2011), the NTP concludes that fluoride is *presumed to be a cognitive neurodevelopmental hazard to humans.* This conclusion is based on a moderate level of evidence that shows a consistent and robust pattern of findings in human studies across several different populations demonstrating that higher fluoride exposure (e.g., >1.5 mg/L in drinking water) is associated with lower IQ and other cognitive effects in children. Limited and weaker evidence is considered to provide an inadequate level of evidence that fluoride is associated with cognitive effects in adults. The primary focus of the human data was on IQ and cognitive neurodevelopmental effects; therefore, the conclusion was based on these data. After further evaluation of the experimental animal data available in NTP (2016) and in this systematic review, NTP concludes that in terms of evaluating the effects of fluoride on learning and memory to support the cognitive effects observed in humans, the animal data are inadequate. The animal data do provide evidence for effects of fluoride on neurodevelopment; however, other neurodevelopmental outcomes were not further evaluated because of the limited information in humans. Biological plausibility of effects from mechanistic studies was considered but did not significantly influence the conclusions. Although multiple categories of mechanistic data were evaluated and provide some evidence of adverse effects in the brain, a coherent series of mechanistic events to account for fluoride-associated cognitive neurodevelopmental deficits is not sufficiently understood for these findings to contribute to the overall confidence assessment.

The human body of evidence provides a consistent and robust pattern of findings that higher fluoride exposure is associated with lower IQ scores in children. The moderate level of evidence is based on 5 lower risk-of-bias prospective cohort studies and 14 lower risk-of-bias cross-sectional studies that are considered to have sufficient evidence of fluoride exposure occurring prior to the outcome. The evaluation of the animal body of evidence in this assessment is an extension of the NTP (2016) systematic review on the association between fluoride exposure and neurobehavioral effects related to learning and memory in animals, which identified a concern related to indirectness. This concern was that many of the learning and memory tests rely on a motor response (e.g., latency to achieve the desired effect). The review of animal data published since the 2016 review focused on addressing this

[8]As of April 2020, 1.08% of persons living in the United States (~ 3.5 million people) were served by CWS containing ≥ 1.1 mg/L naturally occurring fluoride. CWS supplying water with ≥ 1.5 mg/L naturally occurring fluoride served 0.59% of the U.S. population (~ 1.9 million people), and systems supplying water with ≥ 2 mg/L naturally occurring fluoride served 0.31% of the U.S. population (~1 million people) (https://www.cdc.gov/fluoridation/data-tools/reporting-system.html).

indirectness concern. Further examination of the literature has not provided clarification of this issue. Due to the inability to separate these effects from effects on general health and other effects on the nervous system, the animal body of evidence is now considered inadequate to contribute to the evaluation of cognitive effects in humans. Although the animal data are not considered sufficient to specifically support the IQ changes observed in children, the data do support possible neurodevelopmental effects.

The NTP conclusion that fluoride is *presumed to be a cognitive neurodevelopmental hazard to humans* is supported by the extent, consistency, and robustness of the effect in the available data in children. Seventeen of the 19 lower risk-of-bias studies reported an association between higher fluoride exposure and lower IQ scores in children across multiple populations. Meta-analyses conducted at the recommendation of NASEM based on their review of the September 6, 2019 draft monograph provide further support for the hazard conclusion of *presumed* (NASEM 2020). The random-effects pooled SMD estimate from the 46 studies included in the group-level meta-analysis was consistent with two previous meta-analyses reporting statistically significant associations between higher fluoride exposure and lower IQ in children. A risk-of-bias subgroup analysis demonstrated that the significant negative association remained when the meta-analysis was restricted to 9 lower risk-of-bias studies. Further subgroup analyses by gender, age group, country, outcome assessment type, and exposure assessment type support a consistent and robust pattern of results. A second meta-analysis of the individual-level data from six lower risk-of-bias studies also provided evidence of a statistically significant negative association between fluoride exposure and lower IQ in children (overall pooled effect estimate per 1-mg/L increase in urinary fluoride was associated with a 1.40-point lower IQ score [95% CI: −2.33, −0.47]). Given the evidence, there is a low expectation that new studies would change the hazard conclusion.

There are few studies in humans and numerous studies in animals that evaluate mechanistic effects related to fluoride exposure. There are sufficient mechanistic data to determine that fluoride exposure at lower concentrations has effects on the nervous system; however, for the cognitive neurodevelopmental outcome evaluated, there are insufficient data to support a specific mechanism or mode of action. Due to the large number of mechanistic studies conducted in animals, evaluation of the mechanistic data in animals focused on studies that had exposures more relevant to humans (i.e., ≤20 ppm in the drinking water). Changes in AChE, which could potentially be related to cognitive effects such as IQ, were evaluated in one study of children and several studies of animals (measured in both the blood and in areas of the brain); however, the majority of these studies, including the study of children, reported results inconsistent with the phenotypic outcome. Animal studies that evaluated changes in other neurotransmitters and other biochemical measures provide some evidence of effects in the brain, but the data are limited due to the heterogeneity of the outcomes measured. Most consistently, studies evaluating histopathology and oxidative stress demonstrated that effects can occur in the brains of animals at or below 20 ppm, which, without supporting a specific mechanism or mode of action relevant to learning and memory impairments, provides evidence of an association between exposure to lower concentrations of fluoride and neurological effects in animals. Therefore, the evidence of neurological effects at exposure levels more relevant to humans that is demonstrated in the mechanistic data supports the NTP conclusion that fluoride is *presumed to be a cognitive neurodevelopmental hazard to humans;* however, it does not provide enough evidence to increase confidence in the human body of evidence or support a higher hazard identification conclusion.

Generalizability to the U.S. Population

For many years, fluoride concentrations were adjusted to levels between 0.8 and 1.2 mg/L in fluoridated community water systems in the United States. The U.S. Public Health Service recommended an adjustment downward to a fluoride concentration of 0.7 mg/L because of evidence of an increase in dental fluorosis in children (US DHHS 2015). In April 2020, the CDC Water Fluoridation Reporting System estimated that the majority (i.e., 97.5%) of fluoride concentrations in water for U.S. children and adolescents (≤19 years old) are below 1.2 mg/L (https://www.cdc.gov/fluoridation/data-tools/reporting-system.html).

NTP's conclusion that fluoride is *presumed to be a cognitive neurodevelopmental hazard to humans* is based on consistent evidence from 26 lower risk-of-bias studies that evaluated fluoride exposure and effects on children's IQ and other cognitive effects. Although there are many studies that evaluated associations between fluoride in the drinking water and IQ in children, no studies evaluating IQ were conducted in the United States. Generalizing the results from the IQ studies in this evaluation to the U.S. population can be difficult, in part because many studies were conducted in areas with fluoride drinking water concentrations that are much higher than drinking water fluoride concentrations in the United States. Among the human body of evidence evaluated for this assessment (including lower and higher risk-of-bias studies), there are 33 studies that evaluated associations between fluoride in drinking water and IQ in children and compared a reference or low exposure group to higher fluoride-exposed groups. Of these 33 studies, only 10 studies included fluoride exposure groups with fluoride concentrations < 1.5 mg/L (i.e., fluoride exposure groups that would potentially be relevant to levels observed in the United States) (Xu *et al.* 1994, Xiang *et al.* 2003a, Qin *et al.* 1990 [translated in Qin *et al.* 2008], Kang *et al.* 2011, Broadbent *et al.* 2015, Sebastian and Sunitha 2015, Sudhir *et al.* 2009, Zhang *et al.* 2015b, Zhang *et al.* 1998, Wang *et al.* 2020b). Of these 10 studies, 4 were considered to have lower risk of bias (Zhang *et al.* 2015b, Xiang *et al.* 2003a, Wang *et al.* 2020b, Sudhir *et al.* 2009).

In addition to the four studies mentioned above, several other studies that evaluated fluoride exposure on a continuous basis could be used to assess generalizability to the United States. This includes studies that examined fluoride exposure levels below 1.5 mg/L for which a dose response could be assessed. **Table 8** provides a summary of children's IQ studies that evaluated lower fluoride exposures (<1.5 mg/L) in drinking water and/or urine (assuming, for comparison purposes, an approximate 1-to-1 equivalence between drinking water fluoride and urinary fluoride concentrations) and provided information to evaluate dose response in the lower fluoride exposure range (e.g., three or more fluoride exposure groups or dose-response curve provided). Based on review of these studies (discussed further below), there is uncertainty if IQ changes in children occur at lower fluoride levels.

Among studies with lower risk of bias for which a dose response could be assessed, four of nine studies that examined fluoride exposure levels below 1.5 mg/L (**Table 8)** (Green *et al.* 2019, Zhang *et al.* 2015b, Xiang *et al.* 2003a, Wang *et al.* 2020b) applied regression models to individual exposure outcome measures and observed a linear association between urinary fluoride levels and lower IQ in children even at the lower fluoride concentrations. However, two of these studies (Xiang *et al.* 2003a, Zhang *et al.* 2015b) did not find an association between IQ and drinking water levels below 1.5 mg/L. Xiang *et al.* (2003a) observed a significantly lower IQ in endemic versus nonendemic villages, but when they grouped children from the endemic villages by exposure level, they did not observe a significantly lower IQ score for children exposed to lower mean exposure levels of fluoride (0.75 mg/L). Although a significant difference in IQ might not be expected due to the fact that there were only nine children in this group, the difference was less than one point in IQ. Zhang *et al.* (2015b) used a simple correlation

and did not observe a significant relationship between fluoride levels in the drinking water (with concentrations up to 1.57 mg/L) and IQ. Sudhir *et al.* (2009) observed a significant increase in IQ grade (which is associated with lower IQ) at concentrations of 0.7–1.2 mg/L. The other four of nine studies do not provide a clear dose response at the lower fluoride levels. Bashash *et al.* (2017) concluded that there was no clear association between IQ scores and maternal urinary fluoride below 0.8 mg/L. Yu *et al.* (2018) observed a correlation between lower IQ in children and fluoride exposure only with concentrations in drinking water above 3.4 mg/L or with urinary fluoride concentrations of 1.6 mg/L or higher. The study authors did note a decreased probability of having an IQ above 130 (i.e., 40% fewer people with high IQ for every 0.5-mg/L increase in fluoride) with water fluoride levels between 0.20 and 1.40 mg/L, but this was not observed with higher levels of fluoride. Although Cui *et al.* (2018) noted that IQ decreased in a "roughly linear manner" with increasing urinary fluoride, this is only apparent in the results for the TT genotype; based on the dose response, the authors concluded that the "safety threshold" was 1.73 mg/L. Ding *et al.* (2011) looked at mean differences for 10 different exposure groups and found notable decreases from the mean above approximately 1 mg/L.

Although there is less confidence in the findings from higher risk-of-bias studies, six studies identified with potential dose-response information demonstrated a similar uncertainty at the lower fluoride concentrations. Surprisingly, three of the studies (Aravind *et al.* 2016, Qin *et al.* 1990 [translated in Qin *et al.* 2008], Xu *et al.* 1994) found that the lowest IQ scores were in areas with the lowest and the highest fluoride concentrations. In these studies, the lowest fluoride concentrations ranged from 0.1–0.2 mg/L fluoride in Qin *et al.* (1990) [translated in Qin *et al.* 2008] to <1.2 mg/L in Aravind *et al.* (2016). Li *et al.* (1995) and Sebastian and Sunitha (2015) only observed lower IQ scores at concentrations above 2 mg/L. Das and Mondal (2016) found a steady decline in IQ with increasing urinary fluoride levels or exposure dose.

To further examine the dose response for lower IQ in the lower exposure region (e.g., <1.5 mg/L fluoride in drinking water or urine), a meta-analysis (**Appendix 5**) using a linear mixed model to analyze mean-effect estimates was performed. Twelve observations from 9 studies were included that reported one or more IQ measurements associated with drinking water fluoride exposures of < 1.5 mg/L and a reference group. This analysis did not show a statistically significant association with the mean SMD in children's IQ scores between exposed and reference groups (SMD = 0.32; 95% CI: −0.57, 1.20). A dose-response meta-analysis including seven observations from four studies with at least one exposure group < 1.5 mg/L urinary fluoride showed a non-statistically significant decrease in mean SMD (SMD = −0.13; 95% CI: −0.29, 0.03). Based on these results, effects of fluoride exposure on children's IQ at levels < 1.5 mg/L remain unclear and more studies at lower exposure levels are needed. A dose-response meta-analysis of studies with individual-level data could not be conducted due to the small number of studies (n = 10), the various types of exposure metrics, and the different types of reported effect estimates. More studies with lower levels of fluoride exposure from drinking water are still needed to fully understand potential effects at exposures in ranges typically found in the United States (i.e., <1.5 mg/L). Of note, the negative association between IQ and fluoride exposure via drinking water was statistically significant when extending the dose-response meta-analysis to include IQ measures from groups exposed to <2 mg/L in drinking water (SMD = −0.27; 95% CI: −0.36, −0.17). A statistically significant decrease in mean SMD in children's IQ scores was not seen in urinary fluoride measures of < 2 mg/L (SMD = −0.09; 95% CI: −0.22, 0.03) (**Table A5-3**).

When generalizing findings from the cited studies to exposures in the United States from fluoride in drinking water, it is important to consider that drinking water only comprises a portion of total exposures to fluoride. Although it can be assumed that children in all the studies cited in this document

are also exposed to fluoride from sources other than drinking water, these other exposures are likely to vary considerably depending on individual circumstances. Fluoride concentrations in drinking water alone do not reflect the magnitude of fluoride exposures to children who consume excessive amounts of fluoridated toothpaste or to formula-fed babies who consume powdered formula that is reconstituted with fluoridated water. A few studies also support the possibility of heightened sensitivities to the detrimental cognitive effects of fluoride exposures in individuals with certain polymorphisms in dopamine receptor D2, or catechol-O-methyltransferase (Cui *et al.* 2018, Zhang *et al.* 2015b), impacting dopamine catabolism and receptor sensitivity. Differential exposures to fluoride and genetic susceptibilities of children to fluoride appear to warrant further research.

Table 8. Human Studies with Lower Fluoride Exposure and Effects on IQ		
Study	**Exposure measures [mean ± SD (range)]**	**Notes**
Lower risk-of-bias studies		
Bashash *et al.* (2017)	Maternal urine during pregnancy (mg/L) 0.90 ± 0.35 (0.23–2.36)	Authors concluded that the model suggested a nonlinear relationship with no clear association between IQ scores and maternal urine below 0.8 mg/L.
	Children's urine (mg/L) 0.82 ± 0.38 (0.18–2.8)	
Green *et al.* (2019)	Maternal urine during pregnancy (mg/L) 0.51 ± 0.36 (0.06–2.44) 0.40 ± 0.27 non-fluoridated areas 0.69 ± 0.42 fluoridated areas	Statistical methods indicated that including quadratic or natural-log effects of maternal urine or intake did not significantly improve the model. In addition, the authors tested separate models with two linear splines to see if the effect of maternal urinary fluoride or maternal fluoride intake significantly differed between lower and higher levels based on knots set at 0.5, 0.8, and 1.0 mg/L for urine and 0.4, 0.8, and 1 mg for intake. There were no differences.
	Maternal intake during pregnancy (mg/day) 0.54 ± 0.44 (0.01–2.65) 0.30 ± 0.26 non-fluoridated areas 0.93 ± 0.43 fluoridated areas	
	Drinking water (mg/L)* 0.31 ± 0.23 (0.04–0.87[1]) 0.13 ± 0.06 non-fluoridated areas 0.59 ± 0.08 fluoridated areas	
Cui *et al.* (2018)	Drinking water (mg/L)* 0.20–1.00 non-endemic 1.52–2.49 endemic	Study authors noted that the IQ decreased in a "roughly linear manner as the log-urine fluoride increased." TT genotypes of the dopamine receptor D2 gene had the strongest negative correlation between log-urine fluoride and IQ scores. The study authors determined a safety threshold of urine fluoride levels in subgroup TT as 1.73 mg/L. Drinking water fluoride levels were used to select children from different areas but were not used in the analysis.
	Children's urine Levels not provided; log-transformed with range of approximately −1.2–2.2	
Ding *et al.* (2011)	Drinking water (mg/L) * 1.31 ± 1.05 (0.24–2.84)	Although there was a significant correlation between urinary fluoride and IQ score, the main drop in IQ occurred at urinary fluoride levels of approximately 0.7–1.2 mg/L. At levels below 0.7 mg/L, data suggest a plateau with no apparent change in IQ compared with the mean. Drinking water fluoride levels were not used in the analysis.
	Children's urine (mg/L) 0.10–3.55	

Table 8. Human Studies with Lower Fluoride Exposure and Effects on IQ

Study	Exposure measures [mean ± SD (range)]	Notes
Sudhir *et al.* (2009)	Drinking water (mg/L)* <0.7 (level 1 villages) 0.7–1.2 (level 2 villages) 1.3–4.0 (level 3 villages) >4.0 (level 4 villages)	The number of intellectually impaired children gradually increased with increasing fluoride concentration in drinking water with an increase in IQ grade (which indicates a decrease in IQ) observed in the 0.7–1.2-mg/L villages. Children were placed in exposure groups based on Water Works Department records. Although children brought in water for verification of strata, it was not collected from all children but only from the first child using a different source of water. Therefore, these are considered group-level data. Note that all groups had a large proportion in the "intellectually impaired" category.
Wang *et al.* (2020b)	Drinking water (mg/L)* 1.39 ± 1.01 (0.20–3.90) Children's urine (mg/L) 1.28 ± 1.30 (0.01–5.54)	There was a significantly lower IQ in quartile 3 (1.00–1.90 mg/L) and quartile 4 (>1.90 mg/L), but not quartile 2 (0.70–1.00 mg/L) of drinking water. Urinary fluoride was only associated with a significantly lower IQ in quartile 4 (>2.28 mg/L).
Xiang *et al.* (2003a)	Drinking water (mg/L)* 0.36 ± 0.15 (0.18–0.76) non-endemic village 2.47 ± 0.79 (0.57–4.50) endemic village Endemic subgroups: group A: 0.75 ± 0.14 group B: 1.53 ± 0.27 group C: 2.46 ± 0.30 group D: 3.28 ± 0.25 group E: 4.16 ± 0.22 Children's urine (mg/L) 1.11 ± 0.39 (0.37–2.50) non-endemic village 3.47 ± 1.95 (0.90–12.50) endemic village	IQ in group A in the endemic village was not significantly lower than the non-endemic village, but IQ in all other groups was significantly lower. Although there were only 9 children in group A, the IQ difference was <1 point. Based on simple regression, there was a steady decline in IQ with increasing urinary fluoride.
Yu *et al.* (2018)	Drinking water (mg/L)* 0.50 ± 0.27 normal 2.00 ± 0.75 high Children's urine (mg/L) 0.41 ± 0.49 normal 1.37 ± 1.08 high	Study authors reported that participants' intelligence presented inverse non-linear dose-response relationships with fluoride content, with obvious decreases at relatively high level of fluoride exposure (drinking water fluoride levels at 3.4–3.90 mg/L and urinary fluoride levels at 1.60–2.50 mg/L). Study authors also note a decreased odds for having IQ ≥ 130 with drinking water fluoride at 0.20–1.40 mg/L (40% decrease with each 0.5-mg/L increase in fluoride), but not at higher concentrations.

Table 8. Human Studies with Lower Fluoride Exposure and Effects on IQ		
Study	**Exposure measures [mean ± SD (range)]**	**Notes**
Zhang *et al.* (2015b)	Drinking water (mg/L)* 0.63 (0.58–0.68) control 1.40 (1.23–1.57) endemic fluorosis	There was a steady decline in IQ with increasing serum or urinary fluoride levels. A simple correlation did not find drinking water fluoride significantly correlated with IQ.
	Children's urine (mg/L) 1.1 ± 0.67 control 2.4 ± 1.01 endemic fluorosis	
	Children's serum (mg/L) 0.06 ± 0.03 control 0.18 ± 0.11 endemic fluorosis	
Higher risk-of-bias studies		
Aravind *et al.* (2016)	Drinking water (mg/L)* <1.2 low fluoride area 1.2–2 medium fluoride area >2 high fluoride area	Mean IQ scores (transformed into percentiles) were highest in the medium fluoride area for both boys and girls.
Das and Mondal (2016)	Groundwater (mg/L)* 2.11 ± 1.64 (0.25–9.40)	Based on simple regression, there was a steady decline in IQ with increasing urinary fluoride and increasing exposure dose. Groundwater fluoride levels were not used in the analysis but were used in calculating the children's exposure dose.
	Children's urine (mg/L) 0.45–17.00	
	Children's exposure dose (mg/kg-day) 0.017–0.203	
Li *et al.* (1995)	Children's urine (mg/L) 1.02 non-fluorosis area 1.81 slight fluorosis area 2.01 medium fluorosis area 2.69 severe fluorosis area	A significantly lower IQ score was observed in the medium and severe fluorosis areas compared to the non-fluorosis area. Children's urine was used as an individual measure of exposure to verify that the areas had different fluoride exposure levels; however, analysis was conducted based on residential area.
Qin *et al.* (1990) [translated in Qin *et al.* 2008]	Drinking water (mg/L)* 0.1–0.2 low fluoride area 0.5–1.0 normal fluoride area 2.1–4.0 high fluoride area	Average IQ scores (transformed into percentages) were significantly lower in both the low and high fluoride areas compared with the normal fluoride area.
Sebastian and Sunitha (2015)	Drinking water (mg/L)* 0.40 (low fluoride village) 1.2 (normal fluoride village) 2.0 (high fluoride village)	A significantly lower mean IQ score of children living in the high fluoride area compared with the low and normal fluoride areas was reported. Binary regression models using the low fluoride village as a reference observed an increased odds ratio (1.74) for increased IQ scores in the normal fluoride village and a decreased odds ratio (0.59) in the high fluoride village.
Xu *et al.* (1994)	Drinking water (mg/L)* 0.8 (control area) 0.38 (low fluoride area) 1.8 (high fluoride area)	Both low and high fluoride areas had IQ levels approximately 3 points below the IQ levels in the control area. There was no difference in IQ between the low and high fluoride areas.

*Data are group-level exposure data; exposure data without the asterisks are individual-level exposure data.

[1]Range data were obtained from Till *et al.* (2018).

The conclusion that fluoride is *presumed to be a cognitive neurodevelopmental hazard in children* is based on the consistency of the data; however, most lower risk-of-bias studies observed effects with drinking water concentrations above 1.5 mg/L. As noted above, describing the effects at 1.5 mg/L or below, which is more relevant to the exposures observed in the U.S. population, including from community water fluoridation, is more difficult. In the reviewed studies, when limiting studies to those that evaluated IQ at fluoride levels across a continuum that included the low dose range, results are less consistent.

Limitations of the Evidence Base

Few limitations exist in the lower risk-of-bias epidemiological studies used for the basis of the hazard conclusion. The main limitations in lower risk-of-bias epidemiological studies include:

- Few studies were available that assessed the association between fluoride exposure and the following:
    - Neurodevelopmental or cognitive effects in subjects from communities served by optimally fluoridated versus non-fluoridated water systems.
    - Neurobehavioral (i.e., cognitive) effects (particularly IQ) in adults.
    - Attention-related disorders including ADHD.
- Studies rarely separated the results by gender or provided information to indicate that gender was not a modifying factor, which limits the ability to evaluate how the association between fluoride exposure and cognitive neurodevelopmental effects in children might differ by gender.

Limitations in the epidemiological studies with higher risk of bias include:

- Many of the original publications were in a foreign language and provided limited details on methodology.
- Some studies lacked information regarding exposure and/or had serious limitations in the exposure assessment. Exposure assessment concerns include limited individual exposure information, a lack of information on fluoride sampling methods and timing of the exposure measurements, a lack of quantitation of levels of fluoride in drinking water, and a lack of individual-level information on fluorosis in areas reported to be endemic for fluorosis.
- The comparison groups in studies conducted in areas endemic for fluorosis may have still been exposed to high levels of fluoride or levels similar to those used in water fluoridation in the United States. This factor may have limited the ability to detect true effects.
- Most studies did not provide sufficient direct information (e.g., participation rates) to evaluate selection bias.
- Failure to address potential confounders was a main issue. Many studies conducted simple statistical analyses without accounting for any potential confounders. In cases where adjustments in analyses were made, often these studies did not account for potential confounders considered critical for that study population and outcome.

- Studies conducted in areas with high, naturally-occurring fluoride levels in drinking water often did not account for potential exposures to arsenic or iodine deficiencies in study subjects.
- Many studies did not account for potential exposures to lead as a residual confounder.
- Many studies lacked information on whether the outcome assessors were blind to the exposure group, including studies that examined children in their schools and subjects from high-fluoride communities.

Limitations in the animal studies include:

- The main limitation in the animal studies was the inability to separate possible learning and memory effects from effects on motor activity/coordination or sensory effects.
- Few learning and memory studies in animals evaluated motor activity or sensory effects. Studies that did evaluate motor activity or sensory effects often lacked discussion on general health of the animals when the endpoints measured could be affected by deficits in motor activity or sensory, such as latency to achieve a desired result.

A key data gap in the human and animal bodies of evidence includes the need for mechanistic insight into fluoride-related neurodevelopmental or cognitive changes.

Limitations of the Systematic Review

There are no major limitations of the systematic review. The human body of evidence included a large database of observational studies. Most of the observational studies were cross-sectional; however, nine of these were considered to be functionally prospective in nature. In addition, the systematic review covered a wide range of study designs, populations, and measures of fluoride exposure. The systematic review was designed to cover reports on all potential mechanistic data including effects on the thyroid. After review of the studies evaluating thyroid effects, studies that only evaluated goiters and other effects on thyroid size were not considered in this review. This is not considered a limitation because changes in thyroid size are not functional changes to the thyroid that could specifically indicate a mechanism for thyroid involvement in neurodevelopment. In addition, review of the mechanistic data was limited to in vivo studies with at least one concentration below 20 ppm. This is not considered a limitation for the systematic review since the mechanistic body of evidence was used to evaluate biological plausibility for the effects observed in humans; therefore, data were limited to concentrations that would be more reflective of human exposures. The decision to not more closely evaluate the in vitro data is not considered a limitation because there were sufficient in vivo data, and no key events were identified where in vitro data would provide additional insight.

CONCLUSION

Because the majority of available studies evaluated cognitive neurodevelopmental effects in children, the focus of the hazard conclusions is on cognitive neurodevelopmental effects, primarily IQ. When focusing on findings from studies with exposures in ranges typically found in drinking water in the

United States (0.7 mg/L for optimally fluoridated community water systems)[9] that can be evaluated for dose response, effects on cognitive neurodevelopment are inconsistent and, therefore, unclear. However, when considering all the evidence, including studies with exposures to fluoride levels higher than 1.5 mg/L in water, NTP concludes that fluoride is *presumed to be a cognitive neurodevelopmental hazard to humans*. This conclusion is based on a moderate level of evidence that shows a consistent and robust pattern of findings in human studies across several different populations demonstrating that higher fluoride exposure (e.g., >1.5 mg/L in drinking water) is associated with lower IQ and other cognitive effects in children. Limited and weaker evidence is considered to provide an inadequate level of evidence that fluoride is associated with cognitive effects in adults. The evidence from animal studies is inadequate to inform conclusions on cognitive effects, and the mechanisms underlying fluoride-associated cognitive neurodevelopmental effects are not well characterized.

[9]As of April 2020, 1.08% of persons living in the United States (~ 3.5 million people) were served by CWS supplying ≥ 1.1 mg/L naturally occurring fluoride. CWS supplying water at ≥ 1.5 mg/L naturally occurring fluoride served 0.59% of the U.S. population(~ 1.9 million people), and systems supplying water at ≥ 2 mg/L naturally occurring fluoride served 0.31% of the U.S. population (~1 million people) (https://www.cdc.gov/fluoridation/data-tools/reporting-system.html).

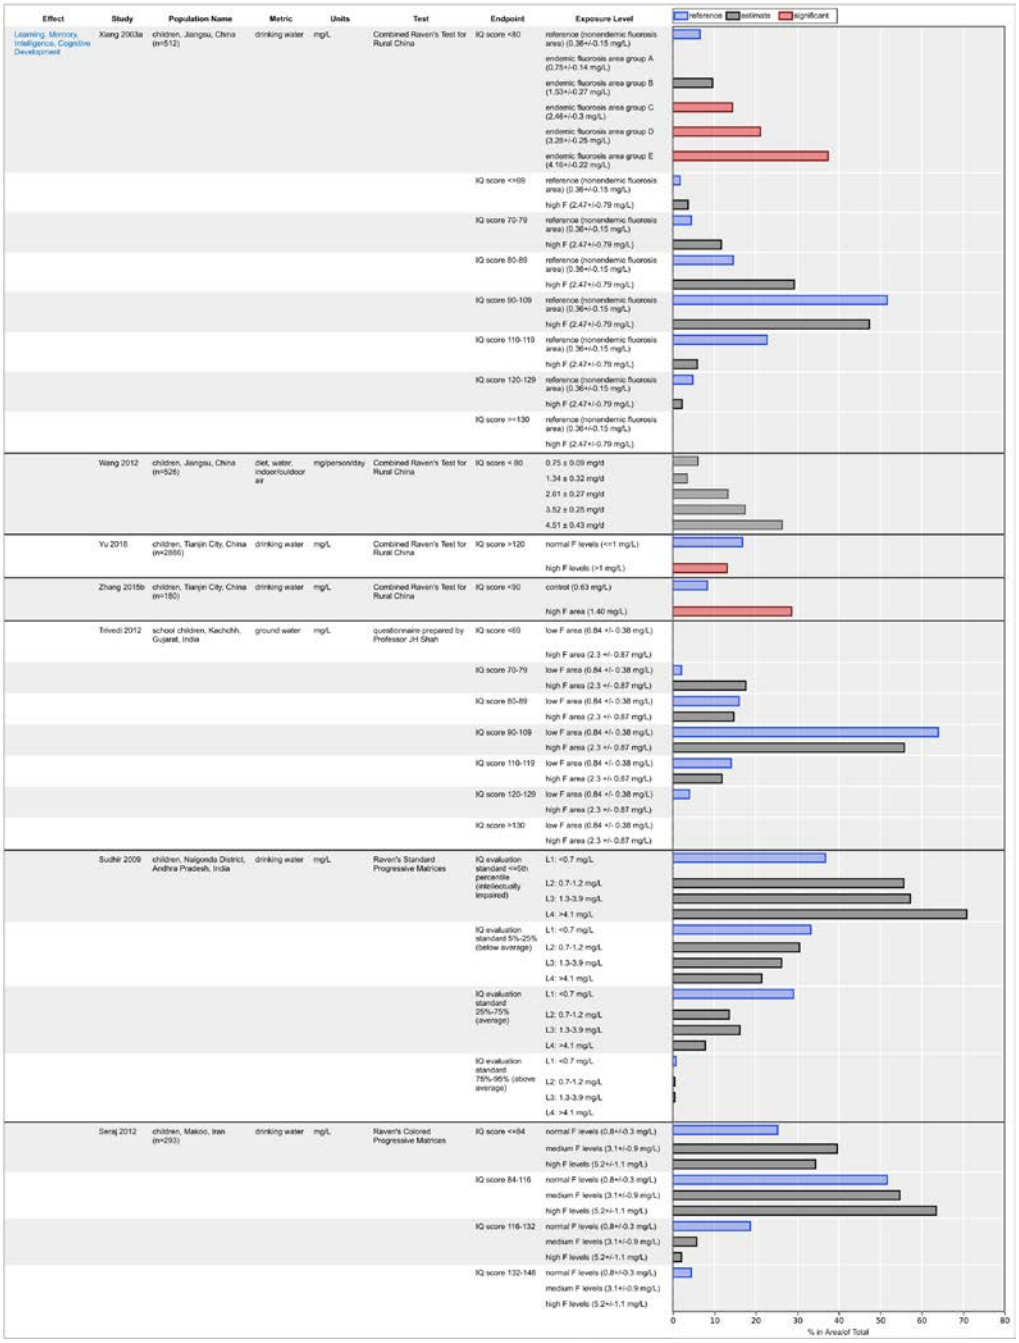
DATA FIGURES

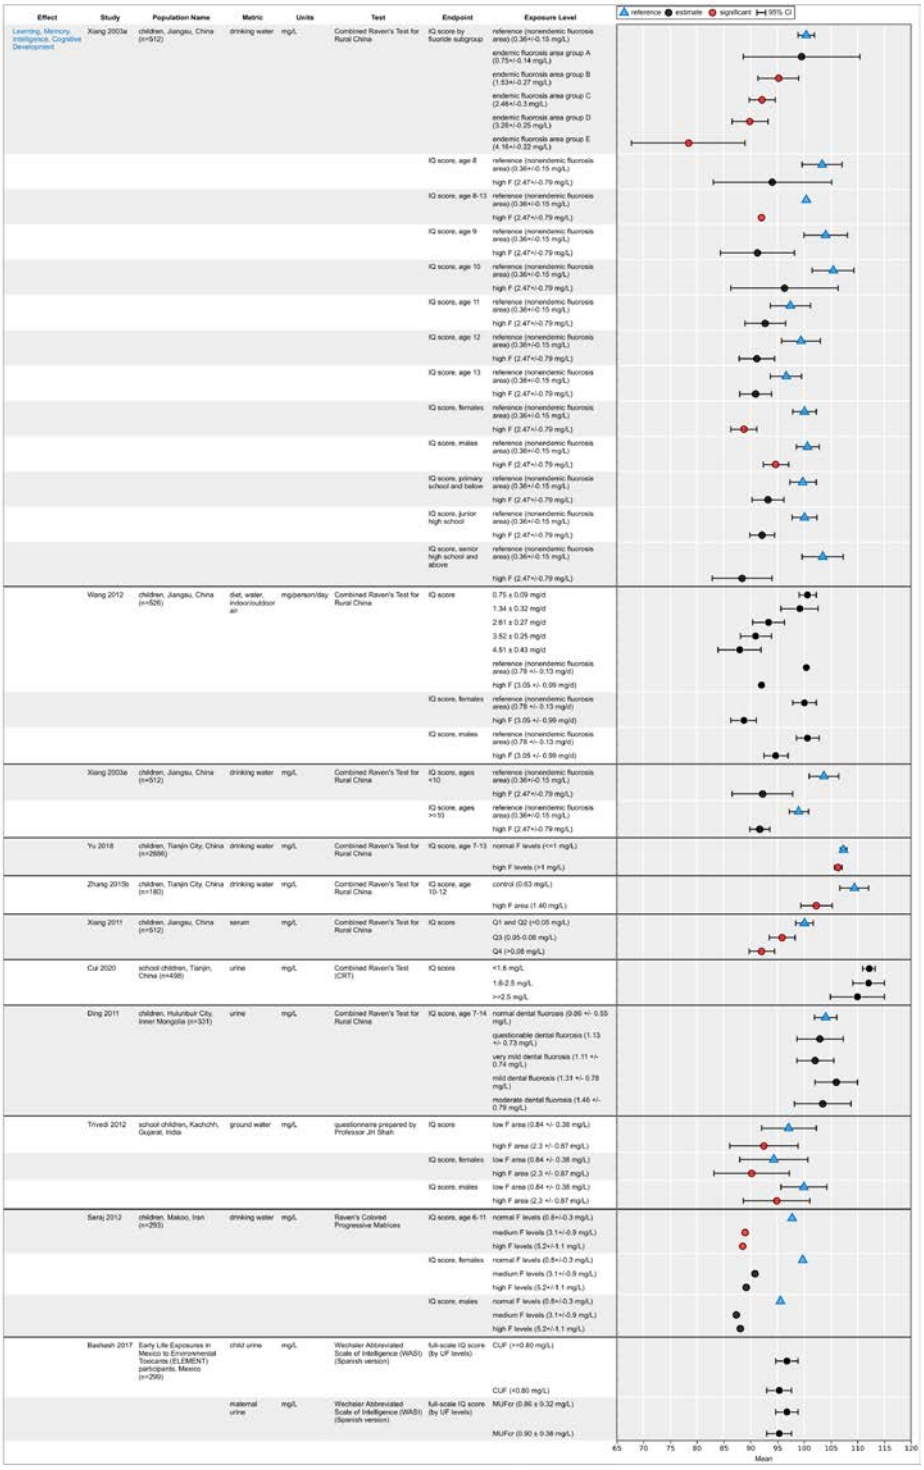
Neurodevelopmental or Cognitive Effects and Outcomes

Figure D1. IQ Distribution in Children by Fluoride Exposure (lower risk-of-bias studies; presented as % in area or % of total group)



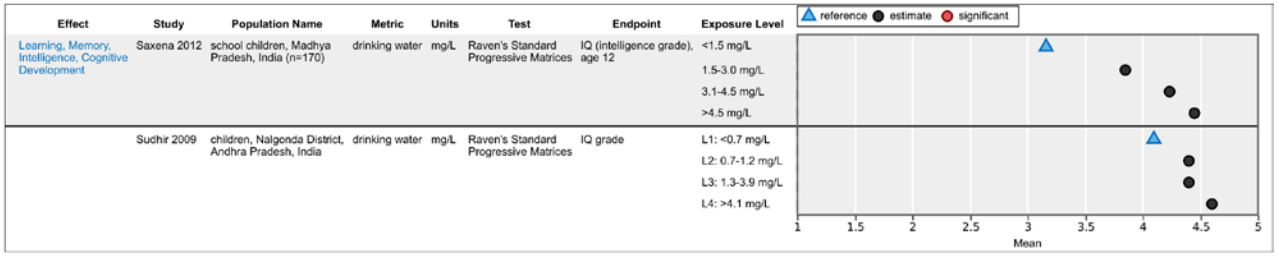
Interactive figure and additional study details in HAWC here. "F" represents fluoride. Differences in intelligence between the reference group and treatment groups were statistically significant although significance was not reported separately for each score level.

Figure D2. Mean IQ in Children by Fluoride Exposure (lower risk-of-bias studies)



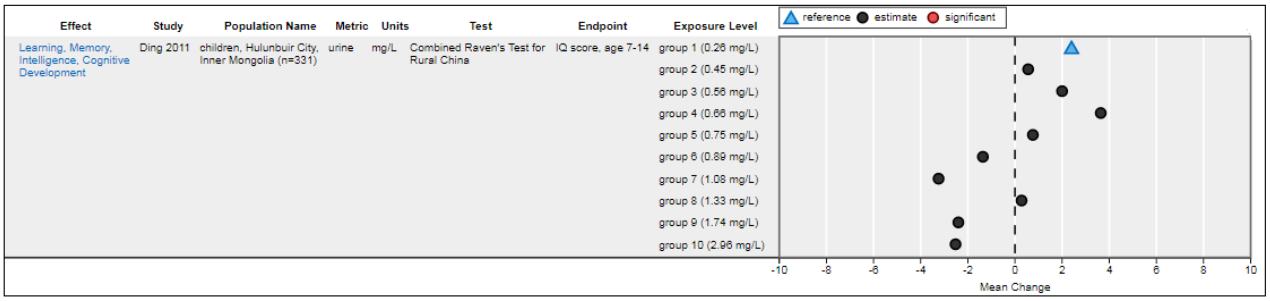
Interactive figure and additional study details in HAWC here. "F" represents fluoride. Three additional publications based on subsample of the larger Yu *et al.* (2018) cohort were identified (Zhao *et al.* 2019, Zhou *et al.* 2019, Zhao *et al.* 2020); however, results from these studies are not presented here. The main study by Yu *et al.* (2018) is considered a better representation of the IQ results. For all studies, SDs are available and can be viewed in HAWC by clicking the data points within the plot area; however, 95% CIs could not be calculated for Seraj *et al.* (2012) because Ns are not available for exposure groups.

Figure D3. Intelligence Grade in Children by Fluoride Exposure (lower risk-of-bias studies; presented as mean)



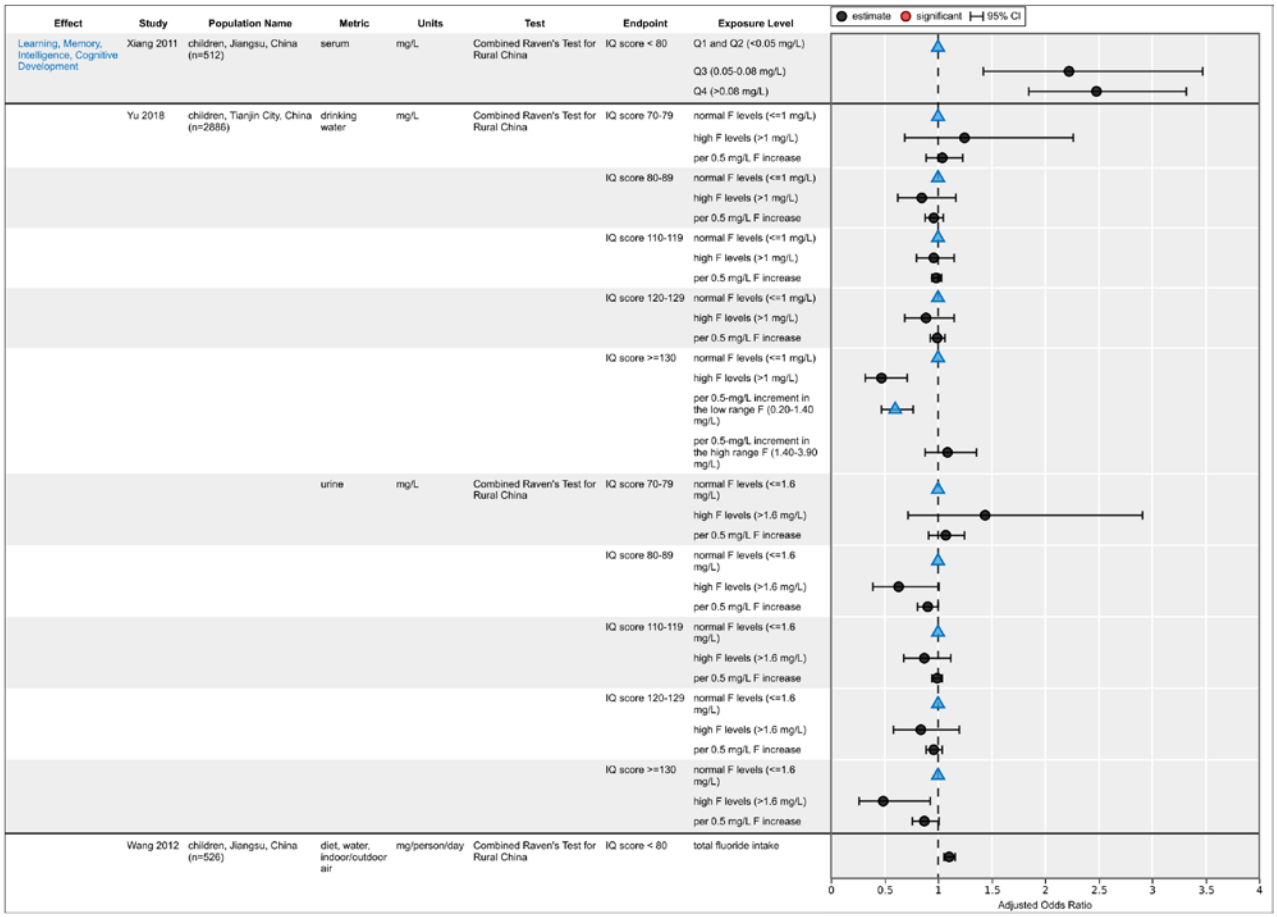
Interactive figure and additional study details in HAWC here. For Saxena *et al.* (2012), children's intelligence was measured using the Raven's Standard Progressive Matrices. Children's scores were converted to percentile and specific grades were allotted based on the percentiles. Grades ranged from intellectually superior (Grade I) to intellectually impaired (Grade V). Results for Soto-Barreras 2019 are not presented here. Outcomes in the study were presented as levels of fluoride exposure associated with each intelligence grade. Results reported were not significant.

Figure D4. Mean Change in IQ in Children by Fluoride Exposure (lower risk-of-bias studies)



Interactive figure and additional study details in HAWC here. For Ding *et al.* (2011), SDs are available and can be viewed in HAWC by clicking the data points within the plot area; however, 95% CIs could not be calculated because Ns for each exposure group are not available.

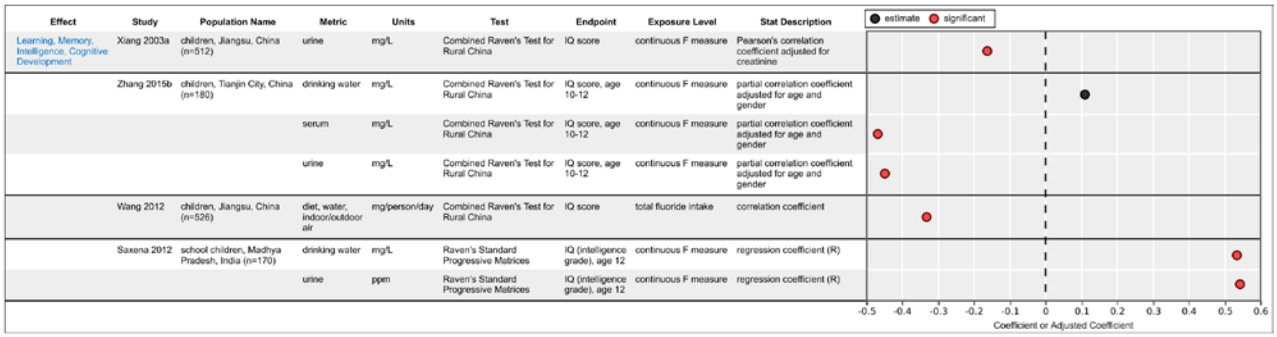
Figure D5. IQ Score in Children by Fluoride Exposure (lower risk-of-bias studies; presented as adjusted OR)



Effect	Study	Population Name	Metric	Units	Test	Endpoint	Exposure Level
Learning, Memory, Intelligence, Cognitive Development	Xiang 2011	children, Jiangsu, China (n=512)	serum	mg/L	Combined Raven's Test for Rural China	IQ score < 80	Q1 and Q2 (<0.05 mg/L)
							Q3 (0.05-0.08 mg/L)
							Q4 (>0.08 mg/L)
	Yu 2018	children, Tianjin City, China (n=2886)	drinking water	mg/L	Combined Raven's Test for Rural China	IQ score 70-79	normal F levels (<=1 mg/L)
							high F levels (>1 mg/L)
							per 0.5 mg/L F increase
						IQ score 80-89	normal F levels (<=1 mg/L)
							high F levels (>1 mg/L)
							per 0.5 mg/L F increase
						IQ score 110-119	normal F levels (<=1 mg/L)
							high F levels (>1 mg/L)
							per 0.5 mg/L F increase
						IQ score 120-129	normal F levels (<=1 mg/L)
							high F levels (>1 mg/L)
							per 0.5 mg/L F increase
						IQ score >=130	normal F levels (<=1 mg/L)
							high F levels (>1 mg/L)
							per 0.5-mg/L increment in the low range F (0.20-1.40 mg/L)
							per 0.5-mg/L increment in the high range F (1.40-3.90 mg/L)
			urine	mg/L	Combined Raven's Test for Rural China	IQ score 70-79	normal F levels (<=1.6 mg/L)
							high F levels (>1.6 mg/L)
							per 0.5 mg/L F increase
						IQ score 80-89	normal F levels (<=1.6 mg/L)
							high F levels (>1.6 mg/L)
							per 0.5 mg/L F increase
						IQ score 110-119	normal F levels (<=1.6 mg/L)
							high F levels (>1.6 mg/L)
							per 0.5 mg/L F increase
						IQ score 120-129	normal F levels (<=1.6 mg/L)
							high F levels (>1.6 mg/L)
							per 0.5 mg/L F increase
						IQ score >=130	normal F levels (<=1.6 mg/L)
							high F levels (>1.6 mg/L)
							per 0.5 mg/L F increase
	Wang 2012	children, Jiangsu, China (n=526)	diet, water, indoor/outdoor air	mg/person/day	Combined Raven's Test for Rural China	IQ score < 80	total fluoride intake

Interactive figure and additional study details in HAWC here. For Xiang *et al.* (2011), there was a significant linear trend across different levels of serum fluoride for IQ score < 80 ($p < 0.001$). For Yu *et al.* (2018), significance levels by IQ score were not reported.

Figure D6. Correlations between IQ Score and Fluoride Exposure in Children (lower risk-of-bias studies; presented as coefficient)

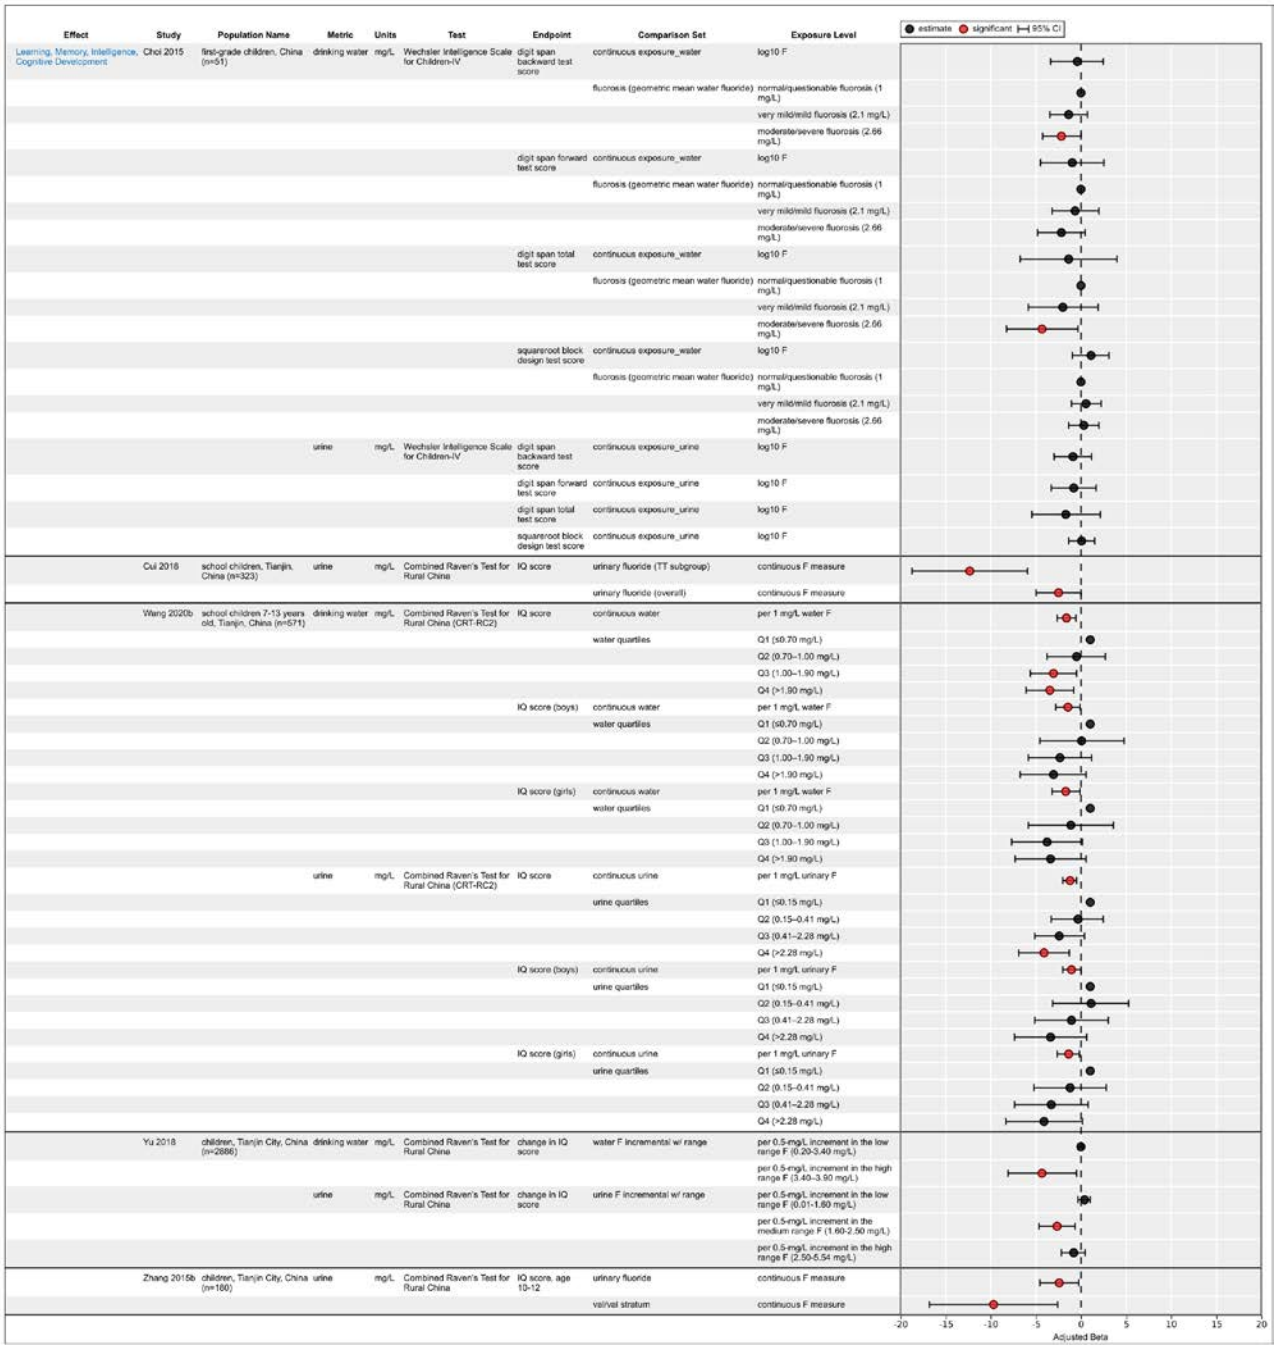


Effect	Study	Population Name	Metric	Units	Test	Endpoint	Exposure Level	Stat Description
Learning, Memory, Intelligence, Cognitive Development	Xiang 2003a	children, Jiangsu, China (n=512)	urine	mg/L	Combined Raven's Test for Rural China	IQ score	continuous F measure	Pearson's correlation coefficient adjusted for creatinine
	Zhang 2015b	children, Tianjin City, China (n=180)	drinking water	mg/L	Combined Raven's Test for Rural China	IQ score, age 10-12	continuous F measure	partial correlation coefficient adjusted for age and gender
			serum	mg/L	Combined Raven's Test for Rural China	IQ score, age 10-12	continuous F measure	partial correlation coefficient adjusted for age and gender
			urine	mg/L	Combined Raven's Test for Rural China	IQ score, age 10-12	continuous F measure	partial correlation coefficient adjusted for age and gender
	Wang 2012	children, Jiangsu, China (n=526)	diet, water, indoor/outdoor air	mg/person/day	Combined Raven's Test for Rural China	IQ score	total fluoride intake	correlation coefficient
	Saxena 2012	school children, Madhya Pradesh, India (n=170)	drinking water	mg/L	Raven's Standard Progressive Matrices	IQ (intelligence grade), age 12	continuous F measure	regression coefficient (R)
			urine	ppm	Raven's Standard Progressive Matrices	IQ (intelligence grade), age 12	continuous F measure	regression coefficient (R)

Interactive figure and additional study details in HAWC here. "F" represents fluoride. For Saxena *et al.* (2012), a significant relationship between water fluoride level and intelligence grade was observed. Increasing intelligence grades reflected increasing levels of impairment (reduced intelligence) in children. Zhao *et al.* (2020) and Zhou *et al.* (2019) also had correlations, but these were based on a subsample of the Yu *et al.* (2018) study (which presented betas and provided a better representation of the IQ data).

Figure D7. Correlations between IQ Score and Fluoride Exposure in Children (lower risk-of-bias studies; presented as adjusted beta)—(a) China; (b) all other areas

(a)



Effect	Study	Population Name	Metric	Units	Test	Endpoint	Comparison Set	Exposure Level
Learning, Memory, Intelligence, Cognitive Development	Choi 2015	first-grade children, China (n=51)	drinking water	mg/L	Wechsler Intelligence Scale for Children-IV	digit span backward test score	continuous exposure_water	log10 F
							fluorosis (geometric mean water fluoride)	normal/questionable fluorosis (1 mg/L)
								very mild/mild fluorosis (2.1 mg/L)
								moderate/severe fluorosis (2.66 mg/L)

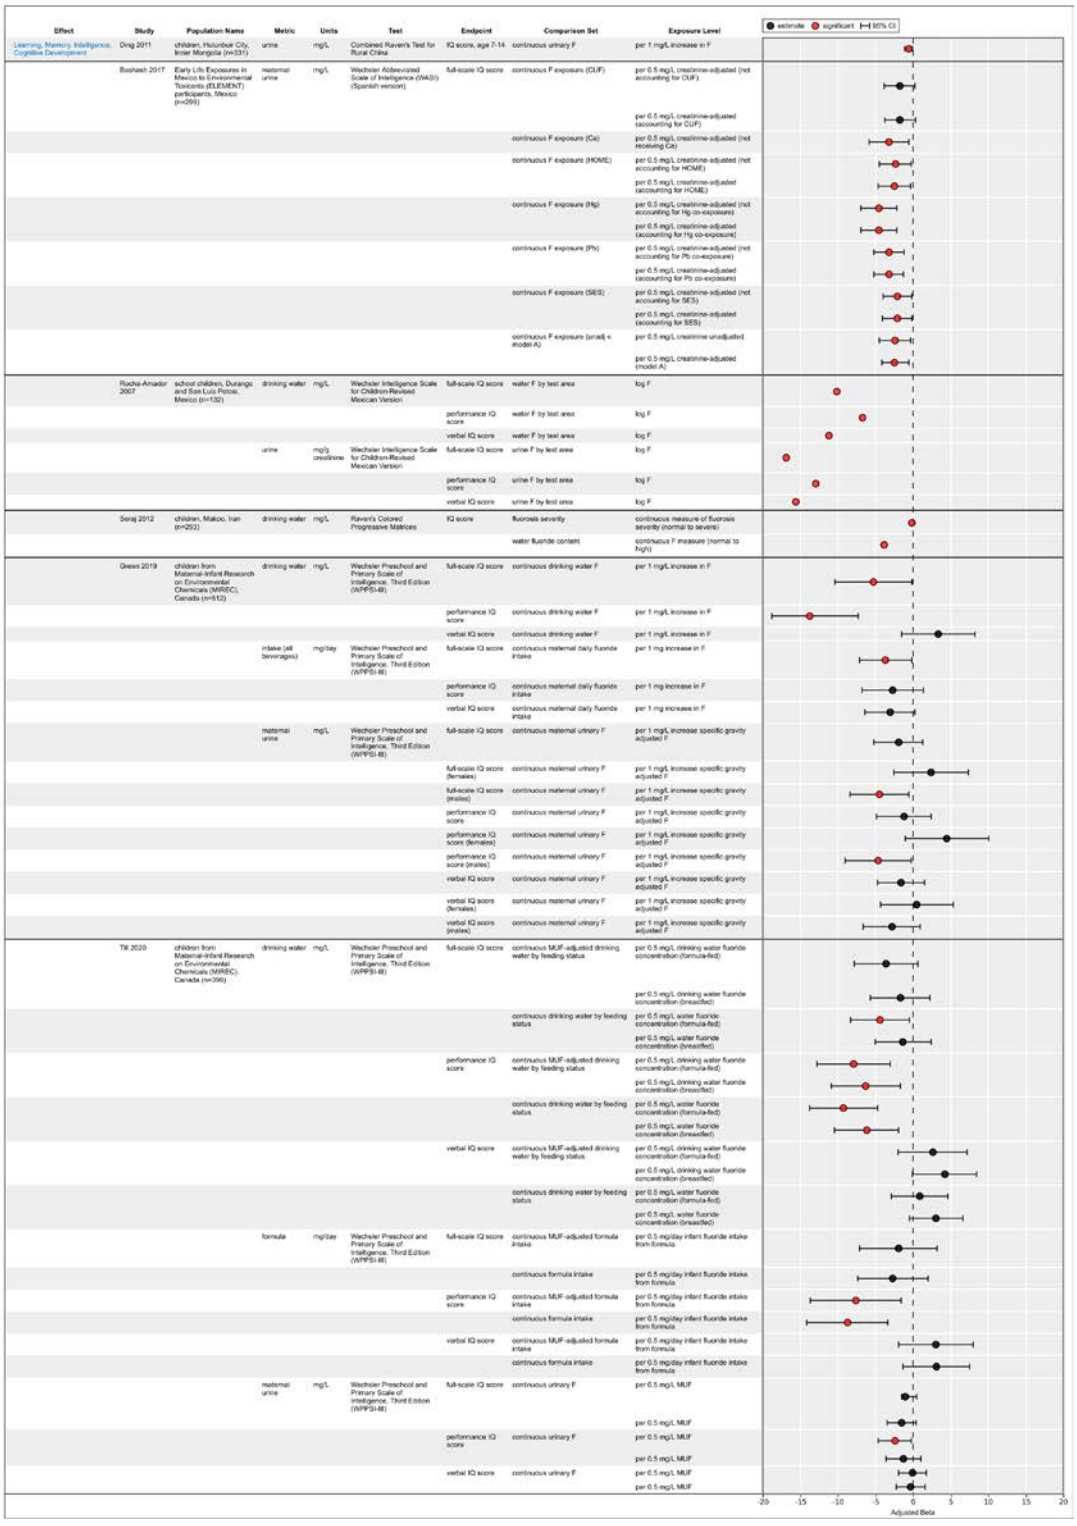
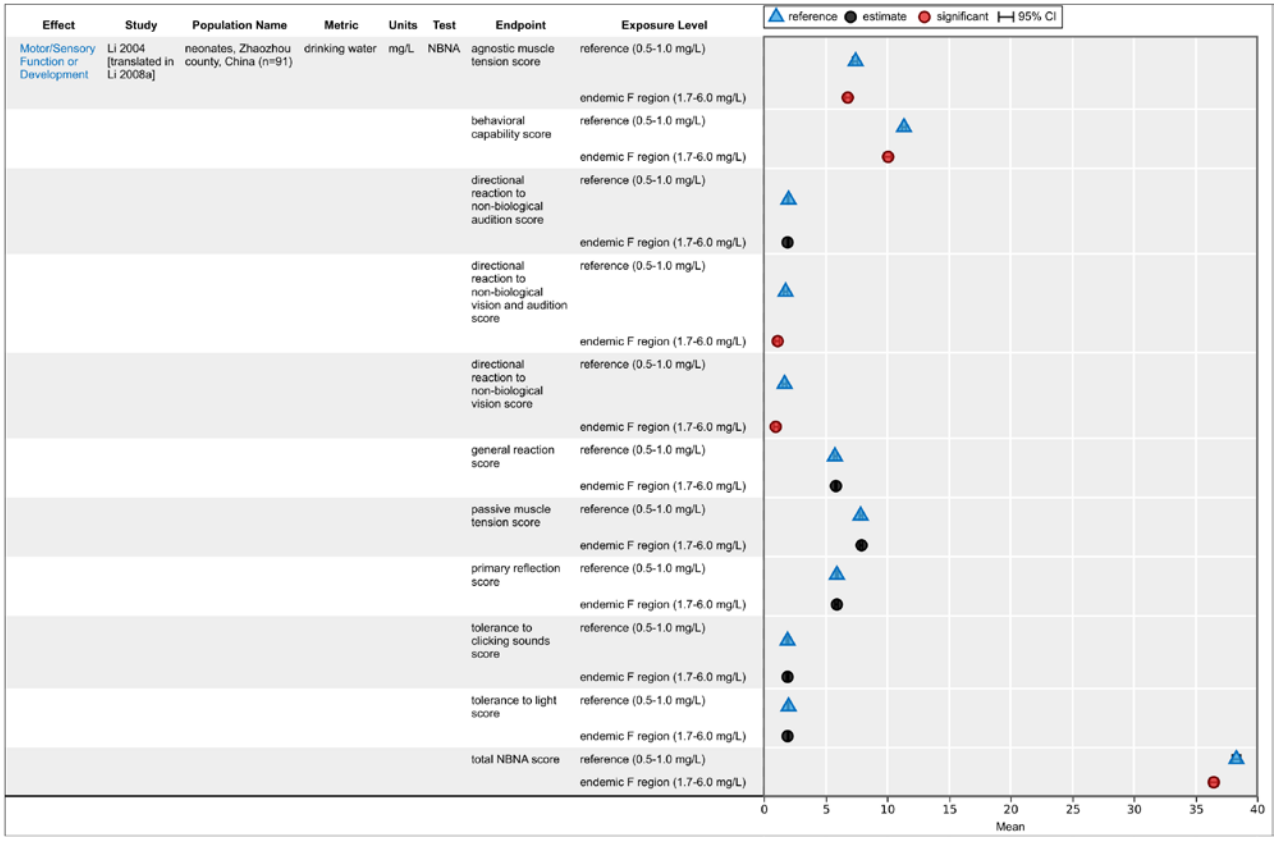
								per 0.5-mg/L increment in the medium range F (1.60-2.50 mg/L)
								per 0.5-mg/L increment in the high range F (2.50-5.54 mg/L)
	Zhang 2015b	children, Tianjin City, China (n=160)	urine	mg/L	Combined Raven's Test for Rural China	IQ score, age 10-12	urinary fluoride	continuous F measure
							val/val stratum	continuous F measure

(b)



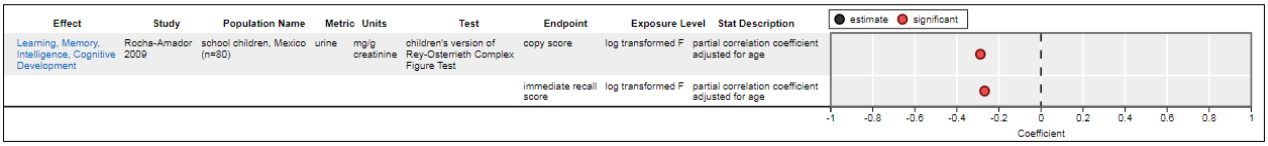
Interactive figure and additional study details in HAWC here for part (a) and here for part (b). "F" represents fluoride. For Yu *et al.* (2018), authors note an obvious decrease in the IQ score at water fluoride exposure levels between 3.40 mg/L and 3.90 mg/L and a similar adverse effect on IQ scores at urinary fluoride exposure levels from 1.60 mg/L to 2.50 mg/L, and so the changes in IQ score are indicated as significant; however, significance levels by change in IQ score were not reported.

Figure D8. Mean Motor/Sensory Scores in Children by Fluoride Exposure (lower risk-of-bias studies)



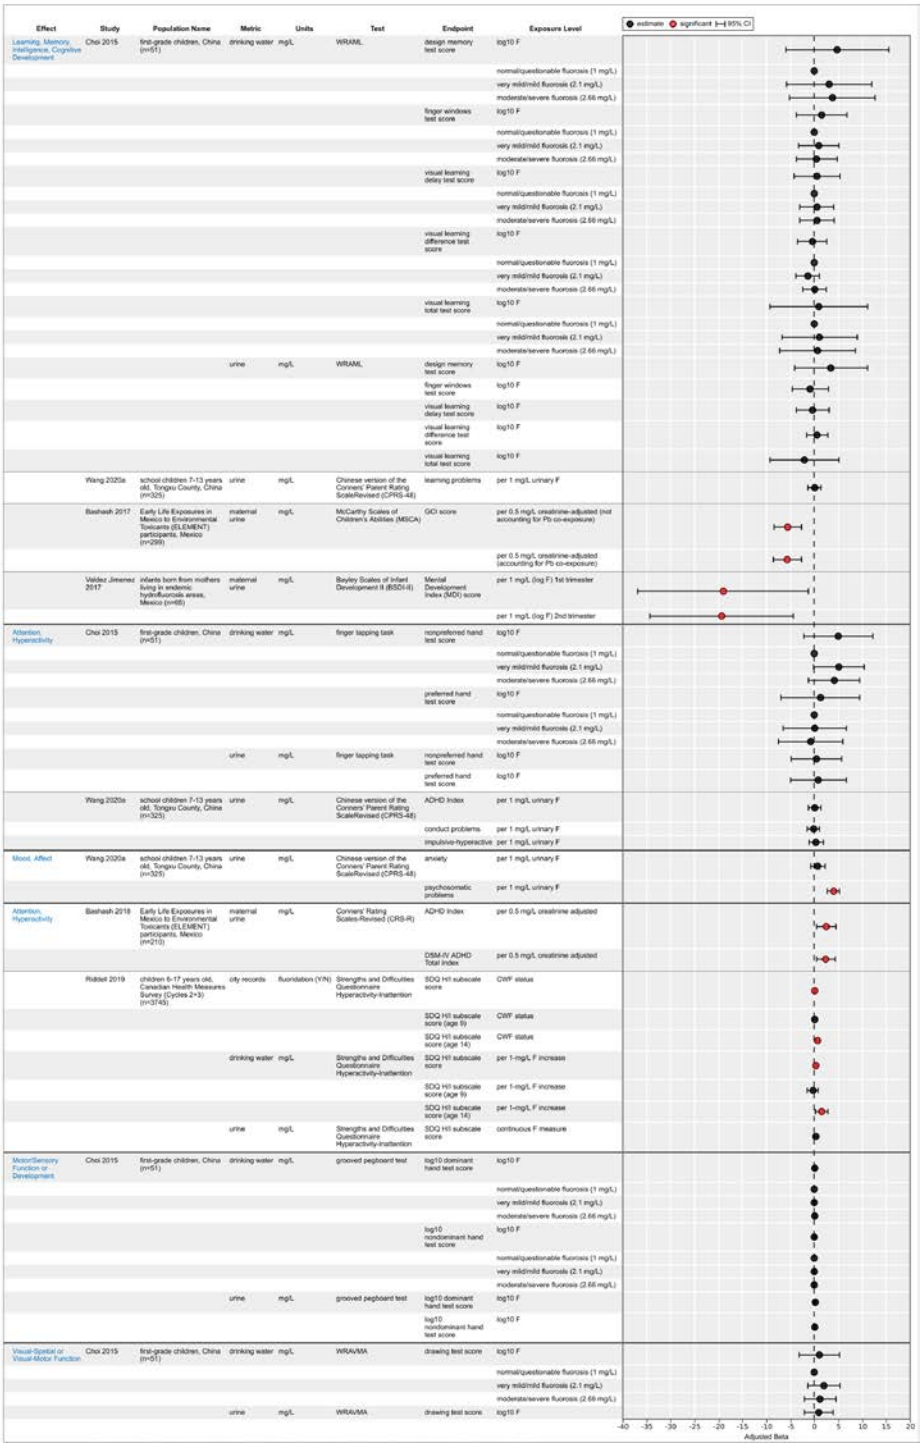
Interactive figure and additional study details in HAWC here. "F" represents fluoride. 95% CIs are small and are within figure symbols and may be difficult to see. Values for SDs and 95% CIs can be viewed in HAWC by clicking the data points within the plot area.

Figure D9. Correlations between Other Neurological Effects and Fluoride Exposure in Children (lower risk-of-bias studies; presented as coefficient)



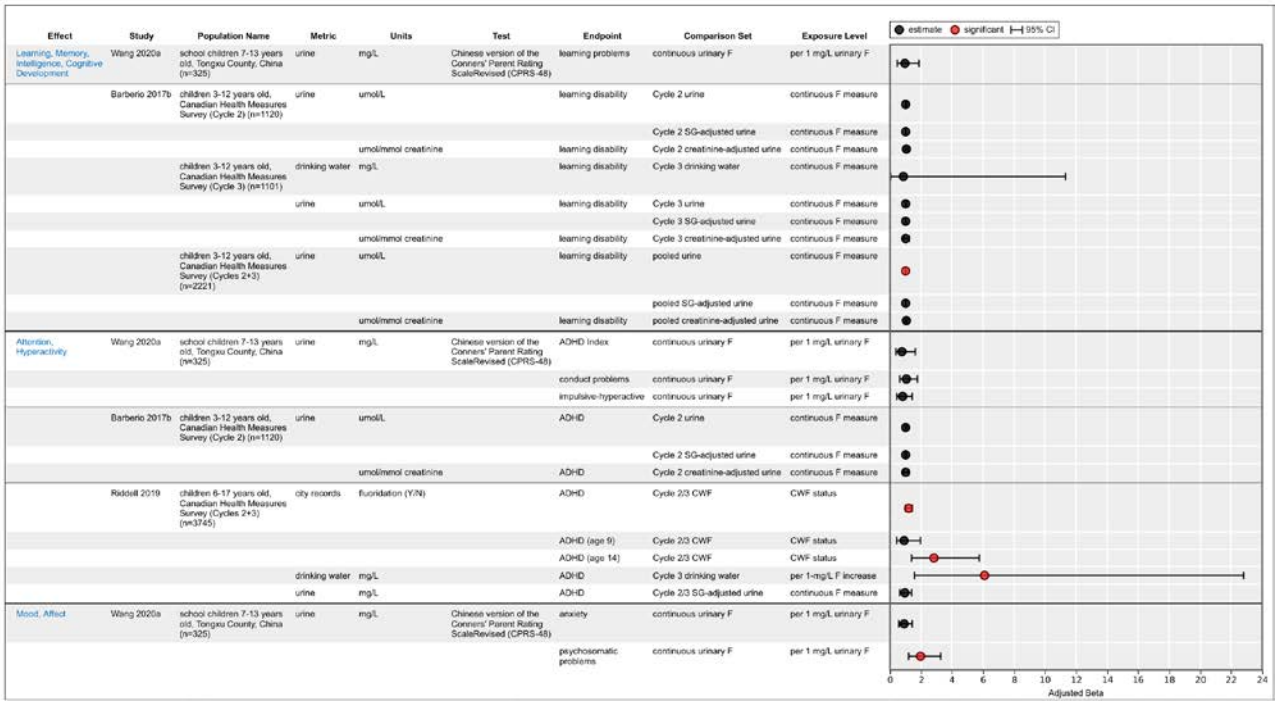
Interactive figure and additional study details in HAWC here. "F" represents fluoride.

Figure D10. Correlations between Other Neurological Effects and Fluoride Exposure in Children (lower risk-of-bias studies; presented as adjusted beta)



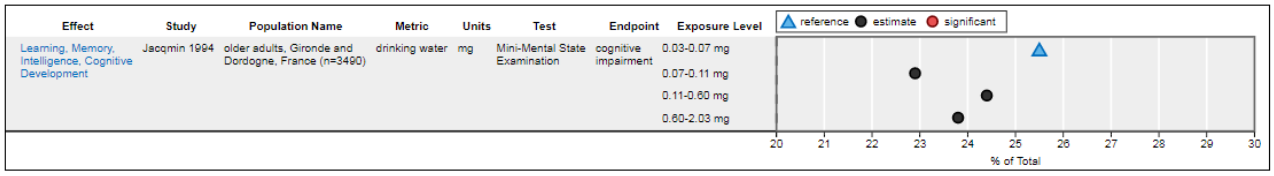
Interactive figure and additional study details in HAWC here. "F" represents fluoride. Bashash *et al.* (2018) observed significant associations between maternal urinary fluoride and ADHD-like symptoms related to inattention (an increase in 0.5 mg/L of maternal urinary fluoride was associated with a 2.84-point increase in the DSM-IV Inattention Index and a 2.54-point increase in Cognitive Problems and Inattention Index). These two scales contributed to the global ADHD Index and the DSM-IV ADHD Total Index shown here.

Figure D11. Correlations between Other Neurological Effects and Fluoride Exposure in Children (lower risk-of-bias studies; presented as adjusted OR)



Interactive figure and additional study details in HAWC here. "F" represents fluoride. Drinking water results for Barberio *et al.* (2017b) have a large confidence interval and are not completely visible in the figure. 95% CIs are 0.068–11.33 and can be viewed in HAWC by clicking the OR within the plot area.

Figure D12. Cognitive Impairment in Adults by Fluoride Exposure (lower risk-of-bias studies; presented as % of total group)



Interactive figure and additional study details in HAWC here. Results from Li *et al.* (2016) suggested that fluoride exposure may be a risk factor for cognitive impairment in elderly subjects; however, results from the study were not conducive to presentation in this visualization.

Note: the roles of individual contractors differed: [a] indicates monograph development; [b] indicates review of data, results, and analyses; [c] indicates database and HAWC support; [d] indicates literature screening, [e] indicates data extraction, [f] indicates risk-of-bias assessment, [g] indicates meta-analysis

Peer Reviewers

The peer reviewers were outside experts selected for their experience with fluoride, developmental neurobehavioral toxicity, and systematic review procedures. Peer reviewers were screened for conflict of interest prior to their service and did not report any conflicts of interest. Service as a peer reviewer does not necessarily indicate that the reviewer endorses the final document.

May 2019	**Revised protocol:** Revised review protocol posted
September 2020	**Revised protocol:** Revised review protocol posted

APPENDICES

Appendix 1. Literature Search Strategy

The strategy for this search is broad for the consideration of neurodevelopmental or cognitive endpoints and comprehensive for fluoride as an exposure or treatment in order to ensure inclusion of relevant papers. The search terms for PubMed are provided below. The specific search strategies for other databases are available in the protocol (https://ntp.niehs.nih.gov/go/785076).

Database	Search Terms

Appendix 2. List of Included Studies

Studies in Humans

As described in **Figure 4**, 159 human studies were included; however, full data extraction was only conducted on studies with neurological outcomes or thyroid hormone data. Data extraction was completed using HAWC. Data were extracted from a subset of included studies in humans (n = 116) and are available in HAWC based on outcome. The following lists of references are organized as studies that are available in HAWC followed by studies that are not available in HAWC. Specifically, data for primary neurodevelopmental or cognitive outcomes (learning, memory, and intelligence) and secondary neurobehavioral outcomes (anxiety, aggression, motor activity, or biochemical changes), as well as thyroid hormone level data, were extracted from included human studies and are available in HAWC. Data for included studies identified through the 2020 literature search update were only extracted for primary neurodevelopmental or cognitive outcomes; a subset of these studies (n = 5) also included secondary neurobehavioral outcomes and/or thyroid hormone level data that were not extracted because those data would not materially advance the human or mechanistic findings. Included human studies that only evaluated other thyroid-related effects such as goiters or thyroid size (n = 43) were not extracted and are not available in HAWC. The list below presents the 159 human studies that were included in the review. An overview of the screening results is outlined in the study selection diagram (**Figure 4**) that reports numbers of included studies as well as numbers of studies excluded for each reason at the full text review stage.

Studies in Non-human Animals

As described in **Figure 4**, 339 non-human mammal studies were included; however, full data extraction was only conducted on studies with primary neurological outcomes and/or secondary functional neurological outcomes (e.g., motor activity). Data extraction was completed using HAWC. Data were extracted from a subset of included studies in animals (n = 123) and are available in HAWC based on outcome. The following lists of references are organized as studies that are available in HAWC followed by studies that are not available in HAWC. Specifically, all primary outcomes and functional neurological secondary outcomes (e.g., motor activity) were extracted from animal studies and are available in HAWC, including studies from the NTP (2016) assessment. Studies are also available in HAWC that evaluated mechanistic effects related to oral fluoride exposure at or below 20 ppm fluoride drinking water equivalents for categories of mechanistic endpoints with the largest amount of available data (i.e., biochemistry of the brain or neurons, neurotransmission, oxidative stress, and histopathology [n = 70]); however, these mechanistic data were generally not extracted. Several animal studies assessed primary neurological outcomes and/or functional neurological secondary outcomes and mechanistic effects in the four mechanistic categories listed above (n = 56). In total, 140 animal studies are available in HAWC (70 with primary neurological outcomes and/or secondary functional neurological outcomes without relevant mechanistic data; 15 with relevant mechanistic data only; and 55 with primary/or secondary functional neurological outcomes with relevant mechanistic data). Studies that evaluated other mechanistic endpoints, as well as studies that only assessed mechanistic effects at fluoride levels above 20 ppm fluoride drinking water equivalents, are not available in HAWC (n = 199). The list below presents the 339 non-human animal studies that were included in the review. An overview of the screening results is outlined in the study selection diagram (**Figure 4**) that reports numbers of included studies as well as numbers of studies excluded for each reason at the full text review stage.

In Vitro Experimental Studies

As described in **Figure 4**, 60 in vitro experimental studies were included; however, data extraction was not conducted on in vitro studies. Therefore, in vitro experimental studies are not available in HAWC with the exception of in vitro studies that also reported in vivo non-human animal data that meet the relevant criteria for being made available in HAWC. The following lists of references are organized as studies that are available in HAWC (n = 6) followed by studies that are not available in HAWC (n = 54).

Studies Available in HAWC

Appendix 4. Details for Lower Risk-of-bias Studies

Barberio *et al.* (2017b)

Study Details:

- ***Study design*:** Cross-sectional
- ***Population*:** Canadian Health Measures Survey (cycles 2 and 3) participants (children aged 3−12 years)
- ***Study area:*** general population of Canada
- ***Sample size:*** 2,221 children (1,120 from Cycle 2, 1,101 from Cycle 3)
- ***Data relevant to the review:*** Associations between learning disability or ADHD (Cycle 2 only) assessed by parent or child self-report and urinary fluoride.
- ***Reported association with fluoride exposure:*** Yes: Significant increase in adjusted OR for learning disability with unadjusted urinary fluoride (1.02; 95% CI: 1.00, 1.03) when Cycle 2 and 3 were combined. No significant associations with urinary fluoride when adjusted for creatinine and/or specific gravity. No significant association between urinary fluoride and ADHD.

Risk of Bias:

- **Author contacts:**
  - Authors were not contacted for additional information because it was not necessary.
- ***Population selection:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* The comparison groups were selected from Cycles 2 and 3 of the Canadian Health Measures Survey. This is a nationally representative sample of residents living in 10 provinces, with clear exclusion criteria provided. Exclusion only represented about 4% of the target population (all Canadian residents 3−79 years old living in 10 provinces). A table of characteristics of the study population is provided.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that the subjects were recruited from the same population using the same methods during the same time frame and exposure groups were similar.
- ***Confounding:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* The study adjusted for sex, age (3–12 years old), household education, and household income adequacy. Variables to discern fluoride source, including drinking water and dental products, were also considered. Cycle 2 data also included adjustments for: 1) children for whom tap water (vs. bottled or other) was the primary source of drinking water at home or away from home and 2) children who had lived in his or her current home for 3 or more years. Confounders such as parental behavioral and mental health disorders, smoking, and nutrition were not discussed. Co-exposure to lead and arsenic are less likely an issue in this population and the lack of information is not considered to appreciably bias the results.
  - *Potentially important study-specific confounders:* All key confounders were considered in this study.
    - *Direction/magnitude of effect*: Not applicable.

- *Basis for rating:* Probably low risk of bias based on direct evidence that key confounders were addressed and indirect evidence that the methods used to collect the information were valid and reliable and that co-exposures were not an issue.

- ***Attrition:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Covariate data were missing for less than 5% of all analyses, apart from household income; household income was reported for only 71–77% of participants and was imputed for the remainder.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that exclusion of subjects from analyses was adequately addressed, and reasons were documented when subjects were removed from the study or excluded from analyses.
- ***Exposure:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Estimates of urinary fluoride (µmol/L) from spot urine were available for a subsample of respondents. Analysis was performed under standardized operating procedures at the Human Toxicology Laboratory of the Institut National de Santé Publique du Québec (accredited under ISO 17025). Fluoride content of urine samples was analyzed using an Orion pH meter with a fluoride ion-selective electrode with limits of detection of 20 µg/L (Cycle 2) and 10 µg/L (Cycle 3). Urinary dilution was addressed by using creatinine-adjusted levels as well as specific gravity-adjusted levels. In Cycle 3 only, estimates of the fluoride concentration of tap water samples collected from randomly selected households were available. The subsample of households selected for tap water sample collection corresponded to the person-level urine fluoride subsample. Analysis of the fluoride concentration of tap water was performed using a basic anion exchange chromatography procedure, with a limit of detection of 0.006 mg/L. QC methods were not addressed.
    - *Direction/magnitude of effect***:** There is not any specific direction or magnitude of bias expected. Urinary fluoride levels are reflective of a recent exposure. Having a single concurrent measurement may not be reflective of the exposure associated with the outcome, but if subjects lived in the same area throughout life the exposure may be an adequate representation. Although there is possible exposure misclassification it would be non-differential.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that exposure was consistently assessed using well-established methods that directly measured exposure.
- ***Outcome:***
  - *Rating:* Probably high risk of bias (-)
  - *Summary:* The primary outcome variable, diagnosis of a learning disability by a health professional, was based on a single item from a household survey asked to all respondents: "Do you have a learning disability?". Answer options were: "yes", "no", "don't know", or the participant refused to answer. For Cycle 2, those who indicated having a learning disability were also asked what kind, with the answer options of: "ADD", "ADHD", "dyslexia", or "other". This question was omitted in Cycle 3 and the reason for omission is not described. Parents or guardians answered all questions for children aged 3–11 years, while children 12 years and older answered questions

themselves. The self-reporting of a learning disability did not appear to have been confirmed by medical records or a health professional. (- for methods based on self-report of diagnosis by a health care professional also in Cycle 3 no specific disabilities were described). Blinding was not a concern as spot urine samples were sent to a separate lab and self-reports would not have knowledge of their urine or tap water exposure level (+ for blinding). Overall rating = -.

- *Basis for rating:* Probably high risk of bias based on indirect evidence that the outcome was measured using an insensitive method in the study population.

- ***Selective Reporting:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* All outcomes outlined in the abstract, introduction, and methods sections were reported in sufficient detail.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that all measured outcomes were reported.
- ***Other potential threats:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:*
    - *Statistical analyses:* Statistical analyses were appropriate for the study.
    - *Other potential concerns:* None identified.
  - *Basis for rating:* Definitely low risk if bias based on direct evidence that the statistical analyses were appropriate and there were no other potential threats to risk of bias identified.
- ***Basis for classification as lower risk-of-bias study overall:*** Probably low risk-of-bias ratings in confounding and exposure. Study strengths include individual exposure measurements and the addressing of potential key confounders but was limited by the cross-sectional study design and insensitive outcome measures.

Bashash *et al.* (2017)

Study Details:

- ***Study design*:** Prospective cohort
- ***Population*:** Early Life Exposures in Mexico to Environmental Toxicants (ELEMENT) participants (pregnant mothers and their children aged 4 or 6–12 years).
- ***Study area:*** Mexico City, Mexico
- ***Sample size:*** 299 mother–child pairs, of whom 287 and 211 had data for the general cognitive index (GCI) and IQ analyses, respectively.
- ***Data relevant to the review:*** Adjusted and unadjusted associations between GCI or IQ scores and maternal or child's urinary fluoride concentrations.
- ***Reported association with fluoride exposure:*** Yes: Significant effect between maternal urinary fluoride and IQ score (adjusted β = −2.50; 95% CI: −4.12, −0.59) and GCI score (adjusted β = −3.15; 95% CI: −5.42, −0.87). No significant effects associated with children's urine.

Risk of Bias:

- **Author contacts:**
  - Authors were not contacted for additional information because it was not necessary.
- ***Population selection:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Study participants were selected from two different cohorts from three hospitals in Mexico City that serve low-to-moderate income populations. One cohort was from an observational study of prenatal lead exposure and neurodevelopment outcomes and the other was from a randomized trial of the effect of calcium on maternal blood lead levels. The authors state that participants had no history of psychiatric disorders, high-risk pregnancies, gestational diabetes, illegal drug use, or continuous prescription drugs, but they do not include any information on smoking habits. Study populations appear to be similar, but there may be some differences because subjects were selected from two different cohorts that were recruited from slightly different time periods.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the exposure groups were similar despite the subjects coming from different original study populations where different methods were used for recruitment.
- ***Confounding:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Data were collected via questionnaire on maternal age, education, marital status at first prenatal visit, birth order, birth weight, gestational age at delivery, maternal smoking, maternal IQ, and HOME scores. All models were adjusted for gestational age at birth, child's sex, birth weight, birth order, child's age at testing, maternal marital status, smoking history, age at delivery, maternal IQ, education, and cohort, with additional testing for children's urinary fluoride, mercury, lead, and calcium. Sensitivity analyses additionally adjusted for HOME score. Confounders not considered included BMI, iodine deficiency, arsenic, and maternal mental health and nutrition. Arsenic is assumed not to be a potential co-exposure in this population as the study authors did not discuss it as an issue but did discuss other co-exposures. Arsenic may have been included in the water quality control program in Mexico City.
  - *Potentially important study-specific confounders:* All key confounders were addressed.
    - *Direction/magnitude of effect***:** Not applicable.
  - *Basis for rating:* Probably low risk of bias based on direct evidence that key confounders including other potential co-exposures were addressed and indirect evidence that the methods used to collect the information were valid and reliable and that arsenic is not likely to be an issue in this study population.
- ***Attrition:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Although there was a large amount of attrition, the study authors clearly describe all reasons for attrition and also provide characteristics to compare those participants included to those excluded. There were some slight differences between those included and those excluded, but there is nothing to indicate that the attrition would potentially bias the results.

  - *Basis for rating:* Probably low risk of bias based on indirect evidence that exclusion of subjects from analyses was adequately addressed, and reasons were documented when subjects were removed from the study or excluded from analyses.
- ***Exposure:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Urinary fluoride concentrations were determined in spot urine samples (2nd morning void) collected from mothers (during at least one trimester) and children ages 6–12 years. Fluoride content was measured using ion-selective electrode-based assays. QC methods were described including between laboratory correlations. All samples were measured in duplicate. Extreme outliers were excluded. Urinary dilution was addressed by using creatinine-adjusted levels.
    - *Direction/magnitude of effect***:** Not applicable.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that exposure was consistently assessed using well-established methods that directly measured exposure.
- ***Outcome:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Outcome was assessed using the McCarthy Scales of Children's Abilities (MSCA) in 4-year-old children (translated into Spanish) and the Wechsler Abbreviated Scale of Intelligence (WASI) in 6–12-year-olds. The WASI is a well-established test and the validity of both tests is well documented by the authors. Inter-examiner reliability was evaluated and reported with a correlation of 0.99 (++ for methods). The study report stated that psychologists were blind to the children's fluoride exposure (++ for blinding). Overall rating for methods and blinding = ++.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that the outcome was blindly assessed using instruments that were valid and reliable in the study population.
- ***Selective Reporting:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* All outcomes outlined in the abstract, introduction, and methods are reported in sufficient detail.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that all measured outcomes were reported.
- ***Other potential threats:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:*
    - *Statistical analyses:* Statistical analyses used were appropriate for the study.
    - *Other potential concerns:* None identified.
  - *Basis for rating:* Definitely low risk if bias based on direct evidence that the statistical analyses were appropriate and there were no other potential threats to risk of bias identified.
- ***Basis for classification as lower risk-of-bias study overall:*** Definitely or probably low risk-of-bias ratings in confounding, exposure, and outcome. Study strengths include individual exposure measurements, outcome blindly assessed, and the prospective cohort study design.

Bashash *et al.* (2018)

Study Details:

- ***Study design*:** Prospective cohort
- ***Population*:** ELEMENT participants (pregnant mothers and their children aged 6–12 years)
- ***Study area:*** Mexico City, Mexico
- ***Sample size:*** 210 mother–child pairs
- ***Data relevant to the review:*** Associations between ADHD and other attention/impulsivity scores and maternal urinary fluoride concentrations.
- ***Reported association with fluoride exposure:*** Yes: Significant associations between maternal urinary fluoride and Conners' Rating Scales-Revised (CRS-R) scores, including Cognitive Problems + Inattention Index (adjusted β = 2.54; 95% CI: 0.44, 4.63), DSM-IV Inattention Index (adjusted β = 2.84; 95% CI: 0.84, 4.84), DSM-IV ADHD Total Index (adjusted β = 2.38; 95% CI: 0.42, 4.34), and ADHD Index (adjusted β = 2.47; 95% CI: 0.43, 4.50).

Risk of Bias:

- **Author contacts:**
  - Authors were not contacted for additional information because it was not necessary.
- ***Population selection:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Participants were a subset of mother-child dyads enrolled in various longitudinal birth cohort studies of the Early Life Exposure in Mexico to Environmental Toxicants (ELEMENT) project. Subjects were included from two of the four cohorts for which maternal urinary samples were available. Participants in cohort 2A were recruited between 1997 and 1999, and participants in cohort 3 were recruited from 2001 to 2003. Inclusion and exclusion criteria were applied consistently across the two cohorts. A table of subject characteristics was provided in the study and any differences were considered in the analysis. Study populations appear to be similar, but there may be some differences because subjects were selected from two different cohorts: one from an observational study on prenatal lead exposure and the other from a randomized trial on the effects of calcium on blood lead levels. In addition, they were recruited from slightly different time periods.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the exposed groups were similar, and any differences were taken into account in the analysis.
- ***Confounding:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Questionnaires were used to collect information on maternal age, maternal education, history of smoking, and marital status during the first pregnancy visit. Child information at birth included birth weight, sex, birth order, and gestational age as calculated by the nurse. Mothers also responded to an SES questionnaire during the visit when the psychometric tests were administered. The Home Observation for Measurement of the Environment (HOME) score was evaluated in a subset of participants. Covariates were selected a priori. Models adjusted for maternal age at

delivery, years of education, marital status, smoking history, gestational age at birth, age at outcome assessment, child's sex, birth order, SES, cohort, and calcium intervention.

- *Potentially important study-specific confounders:* None identified, although this study did not specifically address arsenic or other co-exposures. Bashash *et al.* (2017) addressed potential co-exposure to lead and mercury but did not address arsenic. Arsenic was potentially addressed as part of the water quality program in Mexico City.
  - *Direction/magnitude of effect*: Not applicable.
- *Basis for rating:* Probably low risk of bias based on direct evidence that key confounders were addressed and indirect evidence that the methods used to collect the information were valid and reliable and that arsenic and other potential co-exposures are not likely to be an issue in this study population.

- ***Attrition:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Although there was a large amount of attrition from the original cohorts, it was unlikely related to outcome or exposure and there were very little missing data from those included in the study. Of the 231 mothers with a minimum of one maternal urine fluoride measurement and matching outcome identified for the project, only 17 were excluded based on incomplete demographic and outcome information.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that exclusion of subjects from analyses was adequately addressed, and reasons were documented when subjects were removed from the study or excluded from analyses.
- ***Exposure:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Mothers provided at least one spot urine sample during pregnancy. As described in Bashash *et al.* (2017), urinary concentrations were determined on second morning void. Fluoride content was measured using ion-selective electrode-based assay. Bashash *et al.* (2017) describes QC methods. All samples were measured in duplicate and extreme outliers were excluded. Urinary dilution was addressed by using creatinine-adjusted levels.
    - *Direction/magnitude of effect*: N/A
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that exposure was consistently assessed using well-established methods that directly measured exposure.
- ***Outcome:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Behaviors associated with ADHD were assessed using the Spanish version of the Conners' Rating Scales-Revised, which has been validated for the evaluation of ADHD. Mothers completed the CRS-R at the same follow-up visit that the child completed the CPT-II tests. All tests were applied under the supervision of an experienced psychologist (++ for methods); however, a limitation of the study noted by the authors was only using parent reports and not teacher reports as they can vary from one another. Blinding was not reported, but it is unlikely that the mothers were aware of their urinary fluoride levels. Although mothers may have had knowledge that they were receiving fluoride through fluoridated salt or naturally occurring fluoride in their water, they would not have knowledge that this was relevant to the study purpose as

the ADHD tests were conducted for the original cohort (as was acknowledged by the study authors in the discussion). (++ for blinding). Overall rating = ++.
    - *Basis for rating:* Definitely low risk of bias based on direct evidence that the outcome was blindly assessed using instruments that were valid and reliable in the study population.
- ***Selective Reporting:***
    - *Rating:* Definitely low risk of bias (++)
    - *Summary:* All outcomes outlined in the abstract, introduction, and methods were reported in sufficient detail.
    - *Basis for rating:* Definitely low risk of bias based on direct evidence that all measured outcomes were reported.
- ***Other potential threats:***
    - *Rating:* Definitely low risk of bias (++)
    - *Summary:*
        - *Statistical analyses:* Statistical analyses used were appropriate for the study.
        - *Other potential concerns:* None identified.
    - *Basis for rating:* Definitely low risk if bias based on direct evidence that the statistical analyses were appropriate and there were no other potential threats to risk of bias identified.
- ***Basis for classification as lower risk-of-bias study overall:*** Definitely or probably low risk-of-bias ratings in confounding, exposure, and outcome. Study strengths include individual exposure measurements, outcome blindly assessed, and the prospective cohort study design.

Choi *et al.* (2015)

Study Details:

- ***Study design*:** Cross-sectional
- ***Population*:** First grade children (ages 6–8 years)
- ***Study area:*** Mianning County in southern Sichuan, China
- ***Sample size:*** 51 first grade children
- ***Data relevant to the review:*** Associations between learning, memory, IQ (digit span for auditory span and working memory and block design for visual organization and reasoning components of WISC-IV only), visual motor ability, motor ability, and manual dexterity with continuous urine or drinking water fluoride levels. Study also had information based on dental fluorosis score.
- ***Reported association with fluoride exposure:*** Yes: Compared to the normal/questionable dental fluorosis, the moderate/severe dental fluorosis group was associated with significantly lower total (adjusted β = −4.28; 95% CI: −8.22, −0.33) and backward digit span scores (adjusted β = −2.13; 95% CI: −4.24, −0.02). Linear correlation between fluoride in urine (adjusted β = −1.67; 95% CI: −5.46, 2.12) and in drinking water (adjusted β = −1.39; 95% CI: −6.76, 3.98) with total digit span was observed but not significant. Other outcomes not significantly associated with fluoride exposure.

Risk of Bias:

- **Author contacts:**
  - Authors were not contacted for additional information because it was not necessary.
- ***Population selection:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Subjects were selected during the same time frame using the same methods. Fifty-one first-grade children residing in Mianning County in southern Sichuan, China were included in this pilot study. It is not specified if the 51 children represented all the first-grade children from this area or if some refused to participate. Children who did not speak Chinese, were not students at the Primary School of Sunshui Village in Mianning County, or those with chronic or acute disease that might affect neurobehavioral function tests were excluded. Demographic characteristics are presented in Table 1 of the study, which indicates that subjects were similar. Potential confounders are adjusted for in the statistical analyses.
  - *Basis for Rating:* Definitely low risk of bias based on direct evidence that the exposure groups were similar and were recruited within the same time frame using the same methods with no evidence of differences in participation/response rates.
- ***Confounding:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* The parents or guardians completed a questionnaire on demographic and personal characteristics of the children (sex, age at testing, parity, illnesses before age 3, and past medical history) and caretakers (age, parity, education and occupational histories, residential history, and household income). A 20-µL capillary blood sample was collected at the school by a Mianning County Center for Disease Control (CDC) health practitioner and tested for possible iron deficiency which could be used as a covariate of neurodevelopmental performance. Confounders that were not assessed include: maternal BMI, parental mental health, maternal smoking status, maternal reproductive factors, parental IQ, and HOME score. However, the study authors noted that confounding bias appeared to be limited due to the minimal diversity in the social characteristics of the subjects. The study authors indicated that CDC records documented that levels of other contaminants including arsenic and lead were very low in the area. Iodine differences were not specifically addressed, but there is no indication from the information provided that this might be a concern.
  - *Potentially important study-specific confounders:* All key confounders were considered in this study.
    - *Direction/magnitude of effect***:** Not applicable.
  - *Basis for rating:* Probably low risk of bias because there is direct evidence that the key confounders are taken into account and indirect evidence that co-exposure to arsenic is likely not an issue in this area and that methods used for collecting the information were valid and reliable.
- ***Attrition:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* The majority of results were reported for the 51 children stated to be included in the pilot study. In Table 5 of the study, the N for each dental fluorosis

category only totals 43, but the text indicates 8 children did not have a Dean Index because teeth had not erupted.

- o *Basis for rating:* Probably low risk of bias based on indirect evidence that exclusion of subjects from analyses was adequately addressed, and reasons were documented when subjects were removed from the study or excluded from analyses.

- ***Exposure:***
  - o *Rating:* Probably low risk of bias (+)
  - o *Summary:* The study used three different measurements of fluoride exposure: well water fluoride concentrations from the residence during pregnancy and onwards, fluoride concentrations from children's first morning urine samples, and degree of children's dental fluorosis. Fluoride concentrations in community well water were measured and recorded by Mianning County CDC; specific methods were not reported, but they likely used standard methods as they were conducted by the CDC and were likely the same as those used to measure the fluoride in urine. Migration of subjects was noted to be limited. Well water fluoride concentrations of the mother's residence during pregnancy and onward were used to characterize a child's lifetime exposure. To provide a measure of the accumulated body burden, each child was given a 330-mL (11.2-oz) bottle of Robust© distilled water (free from fluoride and other contaminants) to drink the night before the clinical examinations, after emptying the bladder and before bedtime. The first urine sample the following morning was collected at home, and the fluoride concentration was determined on a 5-mL sample using an ion-specific electrode at the Mianning CDC. There is no indication that urinary fluoride levels accounted for dilution nor was it clear that the method of administering water to the children and collection methods sufficiently controlled for differences in dilution. One of the investigators, a dentist, performed a blinded dental examination on each child's permanent teeth to rate the degree of dental fluorosis using the Dean Index. The Dean Index is a commonly used index in epidemiological studies and remains the gold standard in the dentistry armamentarium. The Index has the following classifications: normal, questionable, very mild, mild, moderate, and severe. Quality control (QC) procedures are not reported but were likely appropriate.
    - ▪ *Direction/magnitude of effect***:** Current levels were used to assess lifetime exposure. This is likely to be a non-differential exposure misclassification and direction of bias is unknown. Because subject migration appears to be limited, it is likely that the current fluoride levels are adequate reflections of past exposure. Dental fluorosis would be an indicator that exposure occurred in the past and there was a fair correlation between degree of dental fluorosis and current urine and water fluoride levels, with both increasing with increasing levels of dental fluorosis.
  - o *Basis for rating:* Probably low risk of bias based on indirect evidence that exposure was consistently assessed using well-established methods that directly measure exposure.
- ***Outcome:***
  - o *Rating:* Probably low risk of bias (+)
  - o *Summary:* The study authors adopted culture-independent tests considered feasible for children aged 6 to 8 years. The Wide Range Assessment of Memory and Learning

(WRAML) was used for the assessment of memory and learning. Three subtests were also used. The Finger Windows subtest assesses sequential visual memory. The Design Memory subtest assesses the ability to reproduce designs from memory following a brief exposure. The Visual Learning subtest assesses the ability to learn the locations of pictured objects over repeated exposures. The Wechsler Intelligence Scale for Children-Revised (WISC-IV) included digit span for auditory span and working memory and block design for visual organization and reasoning. The grooved pegboard test assesses manual dexterity. The tests used have been validated on a western population. Although there is no information provided to indicate that they were validated on the study population, the study authors indicated that the tests were culture-independent (+ for methods). Blinding of the outcome assessors or steps to minimize potential bias was not reported. However, it is unlikely that the assessors had knowledge of the individual exposure as children all came from the same area, and water and urine levels were tested at the CDC. (+ for blinding). Overall = +.

    - *Basis for rating:* Probably low risk of bias based on indirect evidence that all outcomes were assessed blindly using instruments that were valid and reliable in the study population.
- ***Selective Reporting:***
    - *Rating:* Definitely low risk of bias (++)
    - *Summary:* All outcomes outlined in the abstract, introduction, and methods are reported in sufficient details.
    - *Basis for rating:* Definitely low risk of bias based on direct evidence that all measured outcomes were reported.
- ***Other potential threats:***
    - *Rating:* Definitely low risk of bias (++)
    - *Summary:*
        - *Statistical analyses:* Statistical analyses were appropriate. Data were log-transformed when necessary.
        - *Other potential concerns:* It should be noted that this study was a pilot study and, therefore, had a relatively small sample size (i.e., 51 children).
    - *Basis for rating:* Definitely low risk if bias based on direct evidence that the statistical analyses were appropriate and there were no other potential threats to risk of bias identified.
- ***Basis for classification as lower risk-of-bias study overall:*** Probably low risk-of-bias ratings in the confounding, exposure, and outcome risk-of-bias domains. Study strengths include individual fluoride measurements with blinding at outcome assessment likely. All key confounders and many other confounders were taken into account in the study design or analysis.

Cui *et al.* (2018)

Study Details:

- ***Study design*:** Cross-sectional

- ***Population*:** School children aged 7–12 years from four schools in two districts in China with different fluoride levels
- ***Study area:*** Jinghai and Dagang in Tianjin City, China
- ***Sample size:*** 323 school children
- ***Data relevant to the review:*** IQ scores by urine fluoride levels.
- ***Reported association with fluoride exposure:*** Yes: Significant correlation between IQ score and urinary fluoride (adjusted β = −2.47).

Risk of Bias:

- **Author contacts:**
  - Authors were contacted in June 2019 to obtain additional information for risk-of-bias evaluation.
- ***Population selection:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Four schools were selected from the same district in China. The schools were selected based on levels of fluoride in the local drinking water and the degree of school cooperation. No details were provided on the number of schools in given areas or the difficulty in getting school cooperation. It was noted that the residents in the four areas had similar living habits, economic situations, and educational standards. Although authors do not provide the specific data to support this, fluoride levels and IQ scores were provided by different subject characteristics. The areas were classified as historically endemic fluorosis and non-fluorosis. Cluster sampling was used to select the grades in each school according to previously set child ages, and classroom was randomly selected with all students within a selected classroom included. Reasons for exclusion do not appear to be related to exposure or outcome.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the exposure groups were similar and recruited within the same time frame using the same methods, with no evidence of differences in participation/response rates.
- ***Confounding:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* The measurements of all covariates were obtained by structured questionnaires that were completed by children with the help of their parents. Confounders that were assessed include: child's gender, child's ethnicity, child's age, child's BMI, birth (normal vs abnormal), mother's age at delivery, mother's education, income per family member, mother's smoking/alcohol during pregnancy, family member smoking, environmental noise, iodine region (non-endemic vs iodine-excess-endemic area), factory within 30 m of residence, iodine salt, diet supplements, seafood/pickled food/tea consumption, surface water consumption, physical activity, stress, anger, anxiety/depression, trauma, having a cold 5 times a year, thyroid disease in relatives, mental retardation in relatives, and cancer in relatives. Covariates not considered include parity, maternal and paternal IQ, and quantity and quality of caregiving environment (e.g., HOME score). The authors report that there are no other environmentally toxic substances that may affect intelligence, such as high arsenic or iodine deficiency according to the Tianjin Centers for Disease Prevention and Control.

- *Potentially important study-specific confounders:* All key confounders were considered in this study.
  - *Direction/magnitude of effect*: Not applicable.
- *Basis for rating:* Probably low risk of bias because there is indirect evidence that the key confounders are considered, methods for collecting the information are valid and reliable, and co-exposure to arsenic is likely not an issue in this area.

- ***Attrition:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Of the 400 children enrolled, 35 were excluded because they did not have informed consent signed by a guardian or they moved out of the area. Forty-two children were excluded because they did not have a DRD2 genotyping measurement. It is unclear if these children were from the same schools or if they were evenly distributed throughout the study area. It was also unclear if the excluded subjects were similar to those included in the study. In the study, some analyses had fewer than the 323 subjects, but this seems reasonable given the subgroups that were being evaluated.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that exclusion of subjects from analyses was adequately addressed, and reasons were documented when subjects were removed from the study or excluded from analyses.
- ***Exposure:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Although children were selected based on area fluoride levels, fluoride in the urine was used in the analysis. Urine was collected from each child the morning of enrollment and analyzed within a week. Fluoride levels were measured using an ion-selective electrode according to the China standard. A brief description of the method was provided, but no QC methods were reported. The study authors did not account for urinary dilution in the spot samples.
    - *Direction/magnitude of effect*: Not accounting for dilution could cause there to be some exposure misclassification. The direction and magnitude would depend on where the differences occurred.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that exposure was consistently assessed using acceptable methods that provide individual levels of exposure.
- ***Outcome:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* IQ was measured by professionals using the Combined Raven's Test-The Rural in China method, which is the appropriate test for the study population (++ for methods). Blinding or other methods to reduce bias were not reported. Although it is unlikely that the outcome assessor would have knowledge of the child's urine fluoride levels, there is potential that they would know if the child was from an endemic or non-endemic area if the IQ tests were conducted at the child's school, and there was no information provided on how the IQ tests were administered. Correspondence with the study author noted the cross-sectional nature of the study with outcome and exposure assessed at the same time making the outcome assessors blind to the exposure. However, there is still potential for knowledge of the area (+ for blinding).

    - *Basis for rating:* Probably low risk of bias based on indirect evidence that the outcome was blindly assessed using instruments that were valid and reliable in the study population.
- ***Selective Reporting:***
    - *Rating:* Definitely low risk of bias (++)
    - *Summary:* All outcomes in the abstract, introduction, and methods are reported in sufficient details.
    - *Basis for rating:* Definitely low risk of bias based on direct evidence that all measured outcomes were reported.
- ***Other potential threats:***
    - *Rating:* Definitely low risk of bias (++)
    - *Summary:*
        - *Statistical analyses:* Statistical analyses were appropriate. Data were log-transformed when necessary.
        - *Other potential concerns:* None identified.
    - *Basis for rating:* Definitely low risk if bias based on direct evidence that the statistical analyses were appropriate and there were no other potential threats to risk of bias identified.
- ***Basis for classification as lower risk-of-bias study overall:*** Probably low risk-of-bias ratings in confounding, exposure, and outcome. Study strengths include individual exposure measurements but is limited by the cross-sectional study design and lack of accounting for urine dilution. All key confounders were accounted for in the study design or analysis.

Cui *et al.* (2020)

Study Details:

- ***Study design*:** Cross-sectional
- ***Population*:** School children aged 7–12 years
- ***Study area:*** Tianjin City, China (one randomly selected school from each district based on iodine levels in the water), presumably was an expansion of the Cui *et al.* (2018)
- ***Sample size:*** 498 school children
- ***Data relevant to the review:*** IQ scores by urine fluoride levels.
- ***Reported association with fluoride exposure:*** No: No significant difference in IQ score based on a one-way ANOVA in the three different urinary fluoride categories.

Risk of Bias:

- **Author contacts:**
    - Authors were not contacted for the 2020 publication. Authors were contacted in June 2019 for additional information on the Cui *et al.* (2018) publication. Information obtained from that correspondence may have been used for additional information in the 2020 publication.
- ***Population selection:***
    - *Rating:* Probably low risk of bias (+)

- *Summary:* Subjects were recruited from 2014 to 2018. One school was selected from each district where water concentrations of water iodine were <10, 10–100, 100–150, 150–300 and >300 µg/L. In each school, classes were randomly sampled for the appropriate age group of 7–12 years old. A table of subject characteristics was provided by IQ. A total of 620 children were recruited, and 122 children who did not have complete information or enough blood sample were excluded. Reasons for exclusion do not appear to be related to exposure or outcome. The characteristics of the 498 included children are presented.
- *Basis for rating:* Probably low risk of bias based on indirect evidence that the exposure groups were similar and were recruited within the same time frame using the same methods, with no evidence of differences in participation/response rates.

- ***Confounding:***
  - *Rating:* Probably high risk of bias (-)
  - *Summary:* It was noted by the study authors that there were no other environmental poisons except water fluoride. Other studies also conducted in this area of China noted specifically that arsenic was not a concern. Iodine was addressed as that was one of the main points of the study. Twenty-one factors (provided in Table 1 of the study) were selected as confounders, and a homemade questionnaire of unspecified validity was used for obtaining the information. It was noted that child age, stress, and anger were significantly associated with IQ although it is unclear if these varied by fluoride level. However, Cui *et al.* (2018) indicates that stress and anger were not significantly associated with fluoride, and it is assumed that results would be similar for this study even though more children were included in the current study.
  - *Potentially important study-specific confounders:* Age (children 7–12 years old)
    - *Direction/magnitude of effect*: Age is a potential confounder for IQ, even in the narrow age range evaluated in this study. The direction of effects may depend on the number of children in each age group within the different urinary fluoride categories; however, these data were not provided. In general, there were fewer subjects ≤ 9 years of age (i.e., 111) compared to > 9 years of age (i.e., 387) with a significantly higher IQ in the ≤9-year-old age group. Therefore, if exposure were higher in the older subjects, this could bias away from the null.
  - *Basis for rating:* Probably high risk of bias because there is indirect evidence that age was not addressed as a confounder and it may be related to both IQ and exposure.
- ***Attrition:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Of the 620 (20%) children recruited, 122 were excluded due to incomplete information or inadequate blood sample. No information was provided to indicate if there were similarities or differences in the children included versus the children excluded, but exclusion is unlikely to be related to either outcome or exposure.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that exclusion of subjects from analyses was adequately addressed, and reasons were documented when subjects were removed from the study or excluded from analyses.
- ***Exposure:***
  - *Rating:* Probably low risk of bias (+)

- *Summary:* Children's morning urine was collected with a clean polyethylene tube and fluoride was measured using a fluoride ion-selective electrode following Chinese standard WS/T 89-2015. A brief description was provided, but no QC methods were reported. The study authors do not account for urinary dilution in the spot samples.
  - *Direction/magnitude of effect*: Not accounting for dilution could cause there to be some exposure misclassification. The direction and magnitude would depend on where the differences occurred.
- *Basis for rating:* Probably low risk of bias based on indirect evidence that exposure was consistently assessed using acceptable methods that provide individual levels of exposure.

- ***Outcome:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* IQ was measured using the Combined Raven's Test, which is an appropriate test for the study population (++ for methods). Blinding was not mentioned; however, the outcome assessors would not likely have knowledge of the child's urinary fluoride. Subjects appear to have been recruited based on iodine levels and it is, therefore, unlikely that there would be any knowledge of potential fluoride exposure. Correspondence with the study authors for the Cui *et al.* (2018) study also indicated that the outcome assessors would have been blind.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the outcome was blindly assessed using instruments that were valid and reliable in the study population.
- ***Selective Reporting:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* All outcomes in the abstract, introduction, and methods are reported in sufficient details.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that all measured outcomes were reported.
- ***Other potential threats:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:*
    - *Statistical analyses:* The IQ scores are stated to be normally distributed, but there is no evidence that this was in fact tested. A t-test or one-way ANOVA was used to make comparisons between IQ and fluoride. The primary focus of the study was to evaluate associations between thyroid hormones or dopamine levels on IQ (not between fluoride and IQ). It should also be noted that regardless of the analysis conducted, there is no adjustment for school and no accounting for the clustering of children from the same school.
    - *Other potential concerns:* None identified.
  - *Basis for rating:* Probably low risk if bias based on indirect evidence that the statistical analyses were appropriate and there were no other potential threats to risk of bias identified.
- ***Basis for classification as lower risk-of-bias study overall:*** Probably low risk-of-bias ratings in exposure and outcome. Study strengths include individual exposure measurements, but the

study is limited by the cross-sectional study design, lack of accounting for urine dilution, and by not addressing age as a potential confounder.

Ding *et al.* (2011)

Study Details:

- ***Study design*:** Cross-sectional
- ***Population*:** Elementary school children aged 7–14 years old
- ***Study area:*** Hulunbuir City, Inner Mongolia, China
- ***Sample size:*** 331 school children
- ***Data relevant to the review:*** IQ mean difference based on 10 categories of urine fluoride.
- ***Reported association with fluoride exposure:*** Yes: Significant association between urinary fluoride and IQ score (each increase in urinary fluoride of 1 mg/L was associated with an IQ score 0.59 points lower; 95% CI: −1.09, −0.08).

Risk of Bias:

- **Author contacts:**
  - Authors were not contacted for additional information because it was not necessary.
- ***Population selection:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* The study randomly selected 340 7–14-year-olds from four nearby elementary schools in Hulunbuir. Authors stated that the four elementary schools appeared to be very similar in teaching quality. The study authors noted that they followed the principles of matching social and natural factors like economic situation, educational standards, and geological environments as much as possible; however, how this was done is unclear and no table of study subject characteristics by group was provided.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the exposure groups were similar and were recruited within the same time frame using the same methods, with no evidence of differences in participation/response rates.
- ***Confounding:***
  - *Rating:* Probably high risk of bias (-)
  - *Summary:* It was noted that none of the four sites had other potential neurotoxins including arsenic in their drinking water. While they did not provide the specifics, they did provide a reference. In addition, iodine deficiency was noted as not being issue in any of the four areas. Age was the only confounder adjusted in the model. While dental fluorosis severity by % female was reported, not enough data were provided to determine if it was a confounder that should have been considered in the regression. The study authors note that future studies will include covariates such as parents' educational attainment, mother's age at delivery, and household income.
  - *Potentially important study-specific confounders:* Gender
    - *Direction/magnitude of effect*: There is not enough information to determine if there is an effect from gender. There were some differences in dental fluorosis

level by gender, but it is unclear how this might impact the results or if the distribution of gender differed by age.

- *Basis for rating:* Probably high risk of bias based on indirect evidence that there were differences in gender that were not considered in the study design or analyses.

- ***Attrition:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Data were relatively complete (i.e., <5% loss). Of the 340 subjects selected for inclusion, 5 were excluded because they lived in the area for less than a year with an additional 4 not consenting to participate.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that exclusion of subjects from analysis was adequately addressed, and reasons were documented when subjects were removed from the study or excluded from analyses.
- ***Exposure:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Spot urine samples were collected and measured using China CDC standards. All samples were analyzed twice using a fluoride ion-selective electrode. Recovery rates were specified as 95–105% with an LOD of 0.05 mg/L. Water samples were collected from small-scale central water supply systems and tube wells with handy pumps and were processed using standard methods similar to the urine samples. Quality assurance validation was reported. A blind professional examiner evaluated the children for dental fluorosis using the Dean's Index. All urine and water samples were above the LOD. Urine levels were the primary exposure measure used in the analysis. The study authors did not account for urinary dilution in the spot samples. The mean urine fluoride concentration was correlated with the dental fluorosis levels.
    - *Direction/magnitude of effect***:** Spot urine samples that did not account for dilution could have exposure misclassification. The misclassification is likely non-differential and potential direction of bias is unknown.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that exposure was consistently assessed using well-established methods that directly measure exposure.
- ***Outcome:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* IQ was determined using the Combined Raven's Test-The Rural in China (CRT-RC3) (++ for methods). Although blinding was not reported, it is unlikely that the IQ assessors had knowledge of the children's urine levels or even of the water levels from the four sites as these were sent to a separate lab for testing (+ for blinding). Overall rating for methods and blinding = +.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the outcome was blindly assessed using instruments that were valid and reliable in the study population.
- ***Selective Reporting:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* All outcomes outlined in the abstract, introduction, and methods are reported in sufficient details.

  - *Basis for rating:* Definitely low risk of bias based on direct evidence that all measured outcomes were reported.
- ***Other potential threats:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:*
    - *Statistical analyses:* Statistical analyses were reasonable (ANOVA and multiple linear regression), but consideration of homogeneity of variance was not reported. The NASEM (2020) review pointed out a potential concern for the lack of accounting for clustering at the school-level since children were selected from four elementary schools. However, as pointed out in the ***Selection*** domain, the authors stated that they followed the principles of matching social and natural factors like economic situation, educational standards, and geological environments as much as possible and that the four elementary schools appeared to be very similar in teaching quality.
    - *Other potential concerns:* None identified.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the statistical analyses were appropriate and that there were no other potential threats to risk of bias.
- ***Basis for classification as lower risk-of-bias study overall:*** Probably low risk-of-bias ratings in exposure and outcome. Study strengths include individual exposure measurements, but the study is limited by the cross-sectional study design, lack of accounting for urine dilution, and by not addressing gender as a potential confounder.

Green *et al.* (2019)

Study Details:

- ***Study design*:** Prospective cohort
- ***Population*:** Maternal-Infant Research on Environmental Chemicals (MIREC) participants (pregnant mothers and their children aged 3–4 years)
- ***Study area:*** 10 cities, Canada
- ***Sample size:*** 512 mother−child pairs (238 from non-fluoridated areas, 162 from fluoridated areas; 264 females, 248 males)
- ***Data relevant to the review:*** Adjusted linear regression models evaluating associations between IQ in both genders together and separate with maternal urinary fluoride across all three trimesters or estimated maternal fluoride intake.
- ***Reported association with fluoride exposure:*** Yes: Significantly lower full-scale IQ with 1-mg/L increases in maternal urinary fluoride in boys (adjusted β = −4.49), but not girls (adjusted β = 2.40) and not in sexes combine (adjusted β = −1.95); significantly lower full-scale IQ with 1-mg increases in maternal intake in sexes combined (adjusted β = −3.66 [no sex interaction]); significantly lower full-scale IQ with 1-mg/L increases in drinking water fluoride in sexes combined (adjusted β = −5.29 [no sex interaction]).

Risk of Bias:

- **Author contacts:**

- Authors were contacted in June 2019 for additional information for the risk if bias evaluation.

- ***Population selection:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Pregnant women were recruited from the same population, during the same timeframe, and using the same methods as the MIREC program. Methods were reported in detail.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that the exposed groups were similar and were recruited with the same methods during the same time frame.
- ***Confounding:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* The study considered several possible covariates including maternal age, pre-pregnancy BMI, marriage status, birth country, race, maternal education, employment, income, HOME score, smoking during pregnancy, secondhand smoke in the home, alcohol consumption during pregnancy, parity, child's gender, child's age at testing, gestational age, birth weight, time of void, and time since last void. The study also conducted secondary analyses to test for lead, mercury, arsenic, and PFOA. There is no indication of any other potential co-exposures in this study population. Iodine deficiency or excess could not be assessed but is not expected to differentially occur. The study was not able to assess parental IQ or mental health disorders. Methods used to obtain the information included questionnaires and laboratory tests.
  - *Potentially important study-specific confounders:* All key confounders were addressed.
    - *Direction/magnitude of effect:* Not applicable.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the methods used to collect the information were valid and reliable and direct evidence that key confounders including potential co-exposures were addressed.
- ***Attrition:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Of the 610 recruited children, 601 (98.5%) completed testing. Of the 601 mother-child pairs, 512 (85.2%) had all three maternal urine samples and complete covariate data, and 400 (66.6%) had data available to estimate fluoride intake.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that exclusion of subjects from analyses was adequately addressed, and reasons were documented when subjects were removed from the study or excluded from analyses.
- ***Exposure:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Spot urine samples from all three trimesters of pregnancy were evaluated using appropriate methods, and results were adjusted for creatinine and specific gravity. Fluoride intake was estimated based on fluoride water levels and information on consumption of tap water and other water-based beverages (e.g., tea, coffee) was obtained via questionnaire.
    - *Direction/magnitude of effect***:** There is not any specific direction or magnitude of bias expected. Urinary fluoride levels are reflective of a recent exposure.

Having measurements from all three trimesters of pregnancy provides a better representation of actual exposure than a single measurement although the potential for missed high exposure is possible. However, the possibility of the occurrence of missed high exposure would be similar in all females and would be non-differential. For the fluoride intake, exposure was based on the fluoride levels in the water at the residence. If women worked outside the home and the majority of intake occurred from areas outside the home (and were different from levels in the home), there is potential to bias toward the null.

- *Basis for rating:* Probably low risk of bias based on indirect evidence that exposure was consistently assessed using well-established methods that directly measured exposure.

- ***Outcome:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* The Wechsler Preschool and Primary Scale of Intelligence was normalized for ages 2.5–<4.0 and child sex using the U.S population-based norms. Blinding was not reported, but it is unlikely that the outcome assessors had knowledge of the maternal fluoride level or were aware if the city had fluoridated water.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the outcome was blindly assessed using instruments that were valid and reliable in the study population.
- ***Selective Reporting:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* All outcomes were reported.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that all measured outcomes were reported.
- ***Other potential threats:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:*
    - *Statistical analyses:* Linear regression was performed. Regression diagnostics were used to test assumptions for linearity, normality, and homogeneity. There were two potential influential observations (based on Cook's distance), and sensitivity analyses re-estimated the models without these two variables. Further sensitivity analyses were also conducted. Although city was accounted for as a covariate in the regression models, the city effect should have been a random effect rather than a fixed effect to account for potential clustering of results within each city. Although the analysis used individual-level exposure rather than city-level exposure, if the exposure levels within a city are highly correlated (which might be expected given that some cities were fully on fluoridated water and others were not), the fixed-effect model could still produce biased estimates. However, correspondence with the study authors indicated that a supplemental analysis using a random effects multi-level model showed similar results to the main model.
    - *Other potential concerns:* None identified.

  - *Basis for rating:* Definitely low risk if bias based on direct evidence that the statistical analyses were appropriate and there were no other potential threats to risk of bias identified.
- ***Basis for classification as lower risk-of-bias study overall:*** Probably low risk-of-bias ratings in confounding, exposure, and outcome. Study strengths include individual exposure measurements, prospective cohort design, and addressing potential key confounders.

Li *et al.* (2004) [translated in Li *et al.* 2008a]

Study Details:

- ***Study design*:** Cross-sectional
- ***Population*:** Full term, normal neonates 24–72 hours old from healthy mothers
- ***Study area:*** Zhaozhou County, Heilongiang Province, China
- ***Sample size:*** 91 neonates (46 males and 45 females)
- ***Data relevant to the review:*** Comparison of neurobehavioral capacity between children in the high-fluoride area compared to the control area.
- ***Reported association with fluoride exposure:*** Yes: Significant differences in neurobehavioral assessment total scores between high-fluoride (36.48 ± 1.09) and control groups (38.28 ± 1.10); significant differences in total neurobehavioral capacity scores as measured by non-biological visual orientation reaction and biological visual and auditory orientation reaction between the two groups (11.34 ± 0.56 in controls compared to 10.05 ± 0.94 in high-fluoride group).

Risk of Bias:

- **Author contacts:**
  - Authors were not contacted for additional information because it was not necessary.
- ***Population selection:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* There is indirect evidence that the exposure groups were similar. They were recruited during the same time frame using the same methods. From 2002 to 2003, 273 neonates were born in a hospital in Zhaozhou County, China. Ninety-one of 273 full-term neonates (46 males, 45 females) were randomly selected. Mothers ranged in age from 20 to 31 years, met multiple health criteria, and had not changed residence during pregnancy. Authors report that the two study groups are located in the same area with similar climate, living habits, economic and nutritional conditions, and cultural backgrounds, but do not provide these data in the manuscript. There is no statistically significant difference in the mode of delivery, birth weight, infant length, or sex. Subjects were separated into exposure groups after random selection.
  - *Basis for Rating:* Probably low risk of bias based on indirect evidence that the exposure groups were similar and were recruited within the same time frame using the same methods with no evidence of differences in participation/response rates.
- ***Confounding:***
  - *Rating:* Probably low risk of bias (+)

- *Summary:* No confounders were specifically controlled in the analysis. The study authors note similarities in characteristics in the two populations (i.e., living habits, economic and nutritional conditions, and cultural backgrounds), but do not provide these data nor do they indicate what specific characteristics were considered. There were no significant differences in infant gender, birth method, gestational age, or infant weight and length. All tests were conducted when children were 1–3 days old. No potential co-exposures were discussed. Although arsenic is considered a potential issue in China, water quality maps indicate that there is a 25–50% probability that the drinking water in that area exceeds the WHO guideline for arsenic of 10 µg/L.
- *Potentially important study-specific confounders:* Key confounders, including child's age, child's gender, and measures of socioeconomic status (SES), were similar between exposure groups; however, arsenic was not taken into account. Arsenic often occurs in the drinking water along with fluoride in some Chinese populations; however, based on water quality maps, arsenic does not appear to be an issue in Zhaozhou County of the Heilongjiang Province. Iodine deficiencies are not mentioned.
  - *Direction/magnitude of effect*: The presence of arsenic would potentially bias away from the null if it were present with fluoride. Deficiencies in iodine would potentially bias away from the null if it were present in areas of higher fluoride, but toward the null if it were present in areas of lower fluoride.
- *Basis for rating:* Probably low risk of bias based on indirect evidence that the key confounders are taken into account, co-exposure to arsenic is likely not an issue in this area, and methods used for collecting the information are valid and reliable.

- ***Attrition:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Although authors did not discuss why they only randomly selected 91 of the 273 neonates available, results were available for all 91 subjects.
  - *Basis for rating:* Definitely low risk of bias based on results being available for all subjects.
- ***Exposure:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Subjects were split into control and high-fluoride groups based on fluoride levels in their places of residence. Although the levels were provided (1.7–6.0 mg/L for the high-fluoride group compared to 0.5–1.0 mg/L for the control group), it was not reported how or when these levels were measured. Urine was collected when women were hospitalized, but before labor began. Urine samples were sent to a specific lab for measurement using fluoride ion-selective electrode. It was noted that this procedure strictly followed the internal controls of the laboratory indicating quality control. Level of detection (LOD) was not provided. Urinary fluoride levels were significantly higher in the high-fluoride mothers (3.58 ±1.47 mg/L) compared to the control-group mothers (1.74±0.96 mg/L). There was indirect evidence that exposure was consistently assessed using well-established methods that directly measure exposure. Although results were mainly based on exposure area, they were supported by urine data making exposure misclassification less of a concern.

        - *Direction/magnitude of effect*: There is high variability in both water fluoride and urine fluoride in the subjects from the high-exposure area. Although there is no overlap in the water fluoride levels in the exposure areas, there is some overlap in the urine concentrations in the mothers from the two areas. This may reflect the single measurement and pose no specific bias, or it could indicate that some mothers in the high-fluoride area have lower fluoride exposure, which could bias the results toward the null.
    - *Basis for rating:* Probably low risk of bias based on indirect evidence that exposure was consistently assessed using well-established methods that directly measure exposure.
- ***Outcome:***
    - *Rating:* Probably low risk of bias (+)
    - *Summary:* A standard neonatal behavioral neurological assessment method was carried out by professionals in the pediatric department working in neonatal section trained specifically for these programs and passing the training exams. (+ for methods). The examinations were carried out 1 to 3 days after delivery. Because urine samples were collected on the day of delivery and sent to a separate laboratory, it is likely that the outcome assessors were blind. Although the subjects were separated by fluoride exposure area, it is not likely that the professionals were aware of the exposure as the tests were conducted in the hospital (+ for blinding).
    - *Basis for rating:* Probably low risk of bias based on indirect evidence that the outcome was assessed blindly using instruments that were valid and reliable in the study population.
- ***Selective Reporting:***
    - *Rating:* Probably low risk of bias (+)
    - *Summary:* The study authors reported numerous endpoints in sufficient detail; however, because they did not provide a list of endpoints tested there is no direct evidence that all were reported.
    - *Basis for rating:* Probably low risk of bias based on indirect evidence that all the study's measured outcomes were reported.
- ***Other potential threats:***
    - *Rating:* Probably low risk of bias (+)
    - *Summary:*
        - *Statistical analyses:* Statistical analyses were reasonable (t-test), but consideration of homogeneity of variance was not reported. This was a translated study.
        - *Other potential concerns:* It should be noted that, although the study states that subjects were randomly selected, it is unclear why only 91 subjects were included and if they were randomly selected to obtain equal groups in the high-fluoride and control groups.
    - *Basis for rating:* Probably low risk of bias based on indirect evidence that statistical analyses were appropriate and that there were no other potential threats to risk of bias.
- ***Basis for classification as lower risk-of-bias study overall:*** Probably low risk-of-bias ratings in the confounding, exposure, and outcome risk-of-bias domains. Study strengths include individual fluoride measurements to support the differences in the two areas. Tests were noted

to be conducted at the hospital providing indirect evidence that blinding was not a concern during the outcome evaluation. Although there was some potential for bias due to the lack of accounting for arsenic or iodine deficiencies, co-exposure to arsenic is likely not a major concern according to groundwater quality maps.

Riddell *et al.* (2019)

Study Details:

- ***Study design*:** Cross-sectional
- ***Population*:** Canadian Health Measures Survey (cycles 2 and 3) participants (children aged 6−17 years)
- ***Study area:*** general population, Canada
- ***Sample size:*** 3,745 children
- ***Data relevant to the review:*** Adjusted odds ratios for ADHD and attention symptoms per 1 unit increase in urinary fluoride, by water fluoride in the tap water, or community fluoridation status.
- ***Reported association with fluoride exposure:*** Yes: Significantly increased odds of ADHD diagnosis (adjusted OR = 6.10; 95% CI: 1.60, 22.8) or hyperactivity/inattentive symptoms (adjusted beta = 0.31; 95% CI: 0.04, 0.58) per 1-mg/L increase in tap water fluoride. Also, a significant association between ADHD diagnosis (adjusted OR = 1.21; 95% CI: 1.03, 1.42) or hyperactivity/inattentive symptoms (adjusted beta = 0.11; 95% CI: 0.02, 0.58) and community water fluoridation status. No significant associations with urinary fluoride levels.

Risk of Bias:

- **Author contacts:**
  - Authors were not contacted for additional information because it was not necessary.
- ***Population selection:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Subjects were part of Cycles 2 and 3 of the Canadian Health Measures Survey. This is a nationally representative sample of residents living in 10 provinces. Specific inclusion criteria were provided. This study was restricted to children 6–17 years of age with different fluoride measurements that consisted of three participant samples. One of the samples was only available in Cycle 3.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that the exposed groups were similar and were recruited with the same methods during the same time frame.
- ***Confounding:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Covariates included in all models included child's age at test, child's sex, ethnicity, BMI, parents' education, total household income, exposure to cigarette smoke inside the home, and log-transformed concurrent blood lead levels. Confounders such as parental behavioral and mental health disorders, quantity and quality of caregiving environment, and co-exposure to arsenic were not discussed. Rationale for selection of covariates was based on relationship to ADHD diagnosis and to fluoride metabolism based on literature review and consultation with an ADHD expert. There is no

information of the source if data for covariates, but this is likely the questionnaires from the Canadian Health Measures Survey, which are considered standardized and validated.

- o *Potentially important study-specific confounders:* All key confounders were considered in this study.
  - *Direction/magnitude of effect***:** Not applicable.
- o *Basis for rating:* Probably low risk of bias because there is indirect evidence that the key confounders are taken into account, co-exposure to arsenic is likely not an issue in this area, and methods used for collecting the information were valid and reliable.

- ***Attrition:***
  - o *Rating:* Probably low risk of bias (+)
  - o *Summary:* There is no information indicating that there were any data excluded due to missing covariates. All exclusions of children were described and reasonable (i.e., drinking bottled water when considered city fluoridation as a measure of fluoride exposure). Outliers were stated to be excluded, but methods for determining this were provided and it was noted that the outliers were 0.27% of the values.
  - o *Basis for rating:* Probably low risk of bias based on indirect evidence that exclusion of subjects from analyses was adequately addressed, and reasons were documented when subjects were removed from the study or excluded from analyses.
- ***Exposure:***
  - o *Rating:* Probably low risk of bias (+)
  - o *Summary:* **Urinary Fluoride:** Spot urine samples were collected under normal non-fasting conditions and analyzed using an Orion pH meter with a fluoride ion-selective electrode after being diluted with an ionic adjustment buffer. Analysis was performed at the Human Toxicology Laboratory of the Institut National de Sante Publique du Quebec. The precision and accuracy of the fluoride analyses, including quality control and quality assurance, were described by Health Canada (2015). The limits of detection were 20 µg/L for Cycle 2 and 10 µg/L for Cycle 3 with no values below detection. Fluoride levels were adjusted for specific gravity.

    Water Fluoride in Tap water: Tap water was collected at the subjects' homes in Cycle 3 only. Samples were analyzed for fluoride concentrations using anion exchange chromatography procedure with a LOD of 0.006 mg/L. Values below the LOD were imputed with LOD/square root 2. Of the 980 samples, 150 (16%) were below detection.
    Chlorinate Water Fluoride status: This was determined by viewing reports on each city's website or contacting the water treatment plant (provided in supplemental material). Children were excluded if they drank bottled water, had a well, had a home filtration system, lived in the current residence for 2 years or less, or lived in an area with mixed city fluoridation.
    - *Direction/magnitude of effect***:** There is not any specific direction or magnitude of bias expected. Urinary fluoride levels are reflective of a recent exposure, but the study authors adjusted to account for dilution. The possibility of exposure misclassification would be similar in all subjects and would be non-differential. There is less potential for exposure misclassification in regard to tap water or chlorinated water fluoride status as children who drank bottled water were

excluded and children who had a home filtration system were excluded from the chlorinated water status.

- *Basis for rating:* Probably low risk of bias based on indirect evidence that exposure was consistently assessed using well-established methods that directly measured exposure.

- ***Outcome:***
  - *Rating:* Probably high risk of bias (-)
  - *Summary:*
    Strengths and Difficulties Questionnaire (SDQ): The questionnaire was administered to youths under 18 years. Children aged 6–11 years had SDQ ratings provided by parents and guardians, but youths aged 12−17 years completed the questionnaire themselves. Tests consist of 25 items with a 3-point scale. Items were divided into five subscales: emotional problems, conduct problems, hyperactivity-inattention, peer problems, and prosocial behavior. The current study only used the hyperactivity-inattention subscale. Validation of this method was not reported (- for methods).
    ADHD: Ninety percent of youths with ADHD are diagnosed after age 6 years. For children aged 6–11 years, ADHD diagnosis was provided by parents, but youths age 12−17 years completed the questionnaire themselves. Cycle 2 asked "Do you have a learning disability?" and if yes asked to specify the type (4 options available and described). In Cycle 3, parents were asked directly whether they had ADHD, and children 12 years and older were asked if they had a physician diagnosis of ADHD and, if so, what subtype. (- for methods because different methods were used and only the children 12 years and older in cycle 3 were asked specifically about doctor diagnosis). Both were measured in both cycles. Blinding is not likely an issue as subjects would not have knowledge of the urine or tap water fluoride levels. However, they would likely have knowledge of the city.
  - *Basis for rating:* Probably high risk of bias based on indirect evidence that the outcome was assessed using insensitive methods that varied based subject age.
- ***Selective Reporting:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* All outcomes outlined in the abstract, introduction, and methods sections were reported in sufficient details.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that all measured outcomes were reported.
- ***Other potential threats:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:*
    - *Statistical analyses:* Logistic regression was used for ADHD results. Box-Tidewell tests were used to check the linearity of the relationship with the continuous predictors. Linear regression was used for the SDQ scores using Huber-White standard errors. All regressions were tested for interactions between age and fluoride and sex and fluoride. Sensitivity analyses were conducted to test the different cycles.
    - *Other potential concerns:* None identified.

- *Basis for rating:* Definitely low risk if bias based on direct evidence that the statistical analyses were appropriate and there were no other potential threats to risk of bias identified.

- ***Basis for classification as lower risk-of-bias study overall:*** Probably low risk-of-bias ratings in confounding and exposure. Study strengths include individual exposure measurements and the addressing of potential key confounders but was limited by the cross-sectional study design and insensitive outcome measures.

Rocha-Amador *et al.* (2007)

Study Details:

- ***Study design*:** Cross-sectional
- ***Population*:** Children aged 6–10 years
- ***Study area:*** Moctezuma (low fluoride, low arsenic) and Salitral (high fluoride, high arsenic) of San Luis Potosí State and 5 de Febrero (high fluoride, high arsenic) of Durango State, Mexico
- ***Sample size:*** 132 children
- ***Data relevant to the review:*** Associations between full-scale IQ, performance IQ, verbal IQ and child's urine or water fluoride levels.
- ***Reported association with fluoride exposure:*** Yes: Significant associations between fluoride and IQ scores (full-scale IQ adjusted βs of –10.2 with water and −16.9 with urine; CIs not reported); arsenic also present, but the effect was smaller (full-scale IQ adjusted βs of –6.15 with water and –5.72 with urine; CIs not reported).

Risk of Bias:

- **Author contacts:**
  - Authors were not contacted for additional information because it was not necessary.
- ***Population selection:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* All children in 1st through 3rd grades in three rural areas in Mexico (n = 480) were screened for study eligibility including age, time at residence, and address. Authors report that the three selected communities were similar in population and general demographic characteristics. Children who had lived in the area since birth and were 6–10 years old were eligible to participate (n = 308). Of the 308 children, 155 were randomly selected and the response rate was 85%, but participation was not reported by area. It was noted, however, that no significant differences in age, gender, or time of residence were observed between participants and non-participants. Timeframe for selection was not mentioned but appears to be similar. Sociodemographic characteristics of subjects was provided in Table 1 of the study. There was a significant difference in SES and transferrin saturation, but these were taken into account in the analysis.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the populations were similar and differences were noted and addressed in the analysis.
- ***Confounding:***

- *Rating:* Probably low risk of bias (+)
- *Summary:* The study design or analysis accounted for child's age, sex, SES, transferrin saturation, weight, height, blood lead levels, and mother's education. Arsenic levels were highly correlated with fluoride levels and it was stated that each was tested alone, and arsenic was found to have less of an effect. The authors noted in the methods that they tested for an interaction between arsenic and fluoride. Smoking was not addressed and methods for measuring many of the confounders were not reported.
- *Potentially important study-specific confounders:* Arsenic
  - *Direction/magnitude of effect*: Presence of arsenic, which also demonstrated an association, would bias away from the null.
- *Basis for rating:* Probably low risk of bias based on indirect evidence that the methods used to collect the information were valid and reliable and direct evidence that key confounders were addressed.

- ***Attrition:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Of 155 children randomly selected for study participation, 85% responded to enroll. According to the authors, there were no significant differences in age, gender, or time of residence between responders and non-responders. However, no data are provided to support this, and no breakdown of responders/non-responders by region is provided. Data were provided for the 132 children agreeing to participate.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that exclusion of subjects from analyses was adequately addressed, and reasons were documented when subjects were removed from the study or excluded from analyses.
- ***Exposure:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Urine samples were collected on the same day as psychological evaluations and were analyzed for fluoride according to NIOSH Method 8308 (Fluoride in Urine). For QC, a reference standard was also used (NIST SRM 2671a). Urine samples were also analyzed for arsenic by using the Atomic Absorption Spectrophotometer with hydride system (Perkin-Elmer, model AAnalyst 100, Wellesley, United States) and used a reference standard for QC. Levels were adjusted for urinary creatinine levels to account for dilution in the spot samples. Tap water samples were collected from each child's home on the day of biological monitoring. Fluoride was measured with a sensitive, specific ion electrode. Detailed methods are provided including internal quality controls. It was noted that in the high fluoride group it was common to drink bottled water low in fluoride and to only use the tap water for cooking; therefore, urine was considered the most appropriate measure of exposure. Only children who had lived at the same residence since birth were included.
    - *Direction/magnitude of effect*: Not applicable.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that exposure was consistently assessed using well-established methods that directly measured exposure.
- ***Outcome:***
  - *Rating:* Probably low risk of bias (+)

  - *Summary:* Neuropsychological profiles were assessed through the WISC-RM (revised for Mexico). This is a well-established test appropriately adjusted for the study population. However, no additional validation is provided (+ for methods). The study report stated that the test assessors were masked to both arsenic and fluoride water levels (++ for blinding). Overall rating for methods and blinding = +.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the outcome was blindly assessed using instruments that were valid and reliable in the study population.
- ***Selective Reporting:***
  - *Rating:* Probably high risk of bias (-)
  - *Summary:* It was reported that an interaction between fluoride and arsenic was measured, but it was only noted in the discussion that the study design precluded testing statistical interaction between fluoride and arsenic. This provides indirect evidence of selective reporting.
  - *Basis for rating:* Probably high risk of bias based on indirect evidence that there was selective reporting.
- ***Other potential threats:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:*
  - *Statistical analyses:*
    - *Statistical analyses:* Statistical analyses used were appropriate for the study.
    - *Other potential concerns:* None identified.
  - *Basis for rating:* Definitely low risk if bias based on direct evidence that the statistical analyses were appropriate and there were no other potential threats to risk of bias identified.
- ***Basis for classification as lower risk-of-bias study overall:*** Definitely or probably low risk-of-bias ratings in confounding, exposure, and outcome. Study strengths include individual exposure measurements and outcomes blindly assessed, but it is limited by the cross-sectional study design and not being able to completely rule out the influence of arsenic in the results.

Rocha-Amador *et al.* (2009)

Study Details:

- ***Study design*:** Cross-sectional
- ***Population*:** Children aged 6–11 years
- ***Study area:*** Durango, Mexico
- ***Sample size:*** 80 children
- ***Data relevant to the review:*** Associations between visuospatial organization and visual memory (using the Rey-Osterrieth Complex Figure Test, children's version) and urinary fluoride levels in the children.
- ***Reported association with fluoride exposure:*** Yes: Significant correlation between urinary fluoride and visuospatial organization (r = −0.29) and visual memory (r = −0.27) scores. No significant correlations with arsenic.

Risk of Bias:

- **Author contacts:**
  - Authors were not contacted for additional information because it was not necessary.
- ***Population selection:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Subjects were from the same population and were recruited during the same time frame using the same methods. Although this study compared three sites with antecedents of environmental pollution to mixtures of either F–As, Pb–As, or DDT–PCBs, authors evaluated each contaminant separately. The only area of interest is the area with F and As contamination. The area in Durango state (5 de Febrero) where drinking water is polluted naturally with F and As at levels exceeding 6 and 19 times, respectively, the World Health Organization (WHO) limits (WHO 2008). Children attending public schools were screened through personal interviews for study eligibility. Inclusion criteria were children between 6 and 11 years old, living in the study area since birth, and whose parents signed the agreement to participate. Children with a neurological disease diagnosed by a physician and reported by the mother were excluded from the study. The final sample for the F–As was 80. Participation rates were not reported. Selected demographic characteristics are presented in Table 1 of the study.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the populations were similar and recruited during the same time frame using the same methods.
- ***Confounding:***
  - *Rating:* Probably high risk of bias (-)
  - *Summary:* Confounding factors in children tested in the analysis included blood lead (PbB), age, gender, and height-for-age z-scores; only age had significant associations and was included in the final analysis. Arsenic was also assessed and analyzed separately from fluoride. Arsenic in urine was analyzed by atomic absorption spectrophotometer coupled to a hydride system (Perkin-Elmer model AAnalyst 100). Although the model did not adjust for arsenic, arsenic in the F–As group was not associated with either endpoint. PbB was analyzed with a Perkin-Elmer 3110 atomic absorption spectrophotometer using a graphite furnace. Authors note that the mean blood lead level in the F–As study area was 5.2 µg/dL and 8% of the children had values above the reference value of 10 µg/dL. PbB was stated not to affect results and was not included in the final analysis. Other confounding data were obtained during the study interview. Father's education was provided and, in the F–As group, was stated to range from 0–16 years, but this was not considered. Maternal education, smoking, and SES were also not considered. The authors provide an SES score of 5.9 ± 1.4 for the 5 de Febrero region (the fluoride region). It is not clear if this would vary by fluoride or arsenic levels.
  - *Potentially important study-specific confounders:* SES.
    - *Direction/magnitude of effect***:** There are insufficient data to determine the magnitude or direction of effect. If there is an association between fluoride exposure and SES, the direction of effect would depend on the association.

- *Basis for rating:* Probably high risk of bias based on indirect evidence that the SES was not accounted for in the study design or analysis and may have varied by fluoride levels.

- ***Attrition:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Data are complete. All 80 participants stated to be the final sample for the site of interest (F–As) were included in all analyses.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that there was no attrition.
- ***Exposure:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Fluoride in urine (FU) was analyzed according to method 8308 (''fluoride in urine'') from the National Institute of Occupational Safety and Health (NIOSH 1984) with a sensitive specific ion electrode. As a quality control check, reference standard ''fluoride in freeze dried urine'' (NIST SRM 2671a) was analyzed. The accuracy was 97.0 +/- 6.0%. Levels of FU and AsU were adjusted for urinary creatinine, which was analyzed by a colorimetric method (Bayer Diagnostic Kit, Sera-Pak1 Plus). However, details on the collection methods were not reported.
    - *Direction/magnitude of effect***:** Spot urine samples in a small sample size (i.e., 80 children) may have some exposure misclassification. Adjusting for dilution reduces the potential for misclassification based on differences in dilution. Exposure misclassification would be non-differential.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that exposure was consistently assessed using well-established methods that directly measured exposure.
- ***Outcome:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* IQ is assessed through the Rey-Osterrieth Complex Figure Test (ROCF). This is a less well-established method, although the authors provide citations suggesting it has been validated and standardized for the Mexican population (+ for methods). According to the study report, the neuropsychologist who administered the test was blinded to all exposure types and levels. (++ for blinding). Overall rating for methods and blinding = +.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the outcome was blindly assessed using instruments that were valid and reliable in the study population.
- ***Selective Reporting:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* All outcomes outlined in the abstract, introduction, and methods were reported in sufficient details.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that all measured outcomes were reported.
- ***Other potential threats:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:*
    - *Statistical analyses:* Statistical analyses used were appropriate for the study.
    - *Other potential concerns:* None identified.

  - *Basis for rating:* Definitely low risk if bias based on direct evidence that the statistical analyses were appropriate and there were no other potential threats to risk of bias identified.
- ***Basis for classification as lower risk-of-bias study overall:*** Probably low risk-of-bias ratings in exposure and outcome. Study strengths include individual exposure measurements and outcomes blindly assessed, but it is limited by the cross-sectional study design, lack of addressing SES in the study population, co-exposure with arsenic, and use of spot samples in a small population.

Saxena *et al.* (2012)

Study Details:

- ***Study design*:** Cross-sectional
- ***Population*:** Children aged 12 years
- ***Study area:*** Madhya Pradesh, India
- ***Sample size:*** 170 children
- ***Data relevant to the review:*** Mean IQ grade (not standard scores) by water fluoride quartiles or continuous or by continuous urinary fluoride.
- ***Reported association with fluoride exposure:*** Yes: Significant correlation between water (r = 0.534; p = 0.000) and urinary (r = 0.542; p = 0.000) fluoride levels and IQ score.

Risk of Bias:

- **Author contacts:**
  - Authors were contacted in August of 2017 to obtain additional information for risk-of-bias evaluation.
- ***Population selection:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* There was indirect evidence that subjects were similar and were recruited using the same methods during the same time frame. The study participants were selected from a stratified cluster of geographic areas based on fluoride concentration in groundwater. According to the authors, the selected villages were similar in population and demographic characteristics. Data are provided to show the breakdown in SES, parental education, height/age, and weight/height and no significant differences were noted. Participation was stated to be voluntary, but participation rates were not provided. It is unclear if the 170 subjects were selected with 100% participation or if the 170 subjects were all that were asked to participate, but it appears that all subjects participated. Timing of the recruitment was not provided but is assumed to occur during the same time frame.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that subjects were similar and recruited using the same methods during the same time frame.
- ***Confounding:***
  - *Rating:* Probably low risk of bias (+)

- *Summary:* There was indirect evidence that key confounders including potential co-exposures were addressed using reasonable methods. A questionnaire, completed with the assistance of parents, was used to collect information on child characteristics (age, sex, height, weight), residential history, medical history (including illness affecting nervous system and head trauma), educational level of the head of the family (in years), and SES of the family. The SES was recorded according to the Pareek and Trivedi classification. The nutritional status of the children was calculated using the Waterlow's classification, which defines two groups for malnutrition using height for age ratio (chronic condition) and weight for height ratio (acute condition). Within both groups, it categorizes the malnutrition as normal, mildly impaired, moderately impaired, or severely impaired. Urinary lead and arsenic were analyzed using the atomic absorption spectrophotometer (Perkin-Elmer, Wellesley, United States). Urinary iodine was measured using the Dunn method. Authors do not report which covariates were included in the multivariate regression models; however, there was no difference in reported demographic characteristics. All subjects were the same age, and there was no difference in iodine, lead, or arsenic between the groups. Mean urinary arsenic levels did increase with increasing fluoride even though there was no significant difference by group.
- *Potentially important study-specific confounders:* All key confounders were considered in this study.
  - *Direction/magnitude of effect*: Not applicable.
- *Basis for rating:* Probably low risk of bias based on indirect evidence that the methods used to collect the information were valid and reliable and that key confounders including potential co-exposures were addressed.

- ***Attrition:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Results were provided for all 170 children stated to be included in the study.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence of no attrition.
- ***Exposure:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* A sample of 200 mL of drinking water was collected at each child's home. The fluoride levels were analyzed by a fluoride ion-selective electrode, Orion 9609BN (Thermo Fisher Scientific Inc., West Palm Beach, United States). Each subject was also asked to collect a sample of their first morning urine. The fluoride content in the urine was determined using a fluoride ion-selective electrode, Orion 9609BN (Thermo Fisher Scientific Inc., West Palm Beach, United States). QA/QC and LOD were not reported and urinary dilution was not assessed. Although only current levels were measured, children who had changed water source since birth were excluded.
    - *Direction/magnitude of effect*: Spot urine samples that did not account for dilution could have exposure misclassification. The misclassification is likely non-differential and not likely to bias in any specific direction. Children who had changed water since birth were excluded, but it was not specifically noted that the fluoride in the water source was stable over the years.

    - *Basis for rating:* Probably low risk of bias based on indirect evidence that exposure was consistently assessed using well-established methods that directly measured exposure.
- ***Outcome:***
    - *Rating:* Probably low risk of bias (+)
    - *Summary:* Intelligence is assessed using the Raven's Standard Progressive Matrices and categorized into five grade levels. Although it was not noted that the test was validated to the study population, the test is visual and would be applicable to most populations (+ for methods). There is no mention of blinding by test administrators or evaluators and the exposure groups come from different geographic areas. It was also not reported who measured the levels of fluoride from the home or urine samples. Correspondence with the study authors indicated that the outcome assessors were blind to the children's fluoride status (++ for blinding). Overall rating for methods and blinding = +.
    - *Basis for rating:* Probably low risk of bias based on indirect evidence that the outcome was blindly assessed using instruments that were valid and reliable in the study population.
- ***Selective Reporting:***
    - *Rating:* Definitely low risk of bias (++)
    - *Summary:* All outcomes outlined in the abstract, introduction, and methods are reported in sufficient detail.
    - *Basis for rating:* Definitely low risk of bias based on direct evidence that all measured outcomes were reported.
- ***Other potential threats:***
    - *Rating:* Probably low risk of bias (+)
    - *Summary:*
        - *Statistical analyses:* Statistical analyses were reasonable (ANOVA), but consideration of homogeneity of variance was not reported.
        - *Other potential concerns:* None identified.
    - *Basis for rating:* Probably low risk of bias based on indirect evidence that the statistical analyses were appropriate, and there were no other potential threats to risk of bias identified.
- ***Basis for classification as lower risk-of-bias study overall:*** Probably low risk-of-bias ratings in confounding, exposure, and outcome. Study strengths include individual exposure measurements and the addressing of potential key confounders, but it was limited by the cross-sectional study design and lack of addressing dilution in the urine samples.

Seraj *et al.* (2012)

Study Details:

- ***Study design*:** Cross-sectional
- ***Population*:** Children aged 6–11 years
- ***Study area:*** five villages, Makoo, Iran
- ***Sample size:*** 293 children

- ***Data relevant to the review:*** IQ (mean and distribution) assessed by Raven's Colored Progressive Matrices and presented by fluoride area, beta was also provided for water fluoride.
- ***Reported association with fluoride exposure:*** Yes: Significant correlation between water fluoride and IQ score (adjusted β = −3.865; CIs not reported); significantly higher IQ score in normal area (97.77 ± 18.91) compared with medium (89.03 ± 12.99) and high (88.58 ± 16.01) areas.

Risk of Bias:

- **Author contacts:**
  - Authors were not contacted for additional information because it was not necessary.
- ***Population selection:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Subjects were selected from five villages in Makoo. The villages were stated to all be rural with similar general demographic and geographic characteristics and were comparable in terms of SES and parental occupations. Children were 6–11 years old. Age, gender, and education were taken into account in the analysis. No other characteristics were provided or discussed. Participation rates were not reported. There is indirect evidence that the populations were similar, and some possible differences were addressed.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that subjects were similar and recruited using the same methods during the same time frame.
- ***Confounding:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Age, gender, dental fluorosis intensity, and educational levels (child's and parents') were evaluated as potential confounders. Other potential confounders such as smoking were not discussed. Information was obtained from a detailed questionnaire. Lead was measured, but only found in low levels in the drinking water throughout the study regions. Iodine in the water was also stated to be measured and residents were receiving iodine-enriched salt. Arsenic was not addressed, but there is no evidence that arsenic levels would vary across villages in this area.
  - *Potentially important study-specific confounders:* All key confounders were considered in this study.
    - *Direction/magnitude of effect***:** Not applicable.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the methods used to collect the information were valid and that key confounders including potential co-exposures were addressed or were not likely to be an issue in the study area.
- ***Attrition:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Attrition was low if it occurred. It was noted that 293 out of 314 children living in the villages were recruited. It is not clear if 21 children were excluded based on exclusion criteria or if they refused to participate; however, this accounts for less than 10% of the population and results were available for all 293 subjects.

- *Basis for rating:* Definitely low risk of bias based on direct evidence that exclusion of subjects from analyses was adequately addressed, and reasons were documented when subjects were removed from the study or excluded from analyses.

- ***Exposure:***
  - *Rating:* Probably high risk of bias (-)
  - *Summary:* Exposure was primarily based on area of residence. Fluoride in the groundwater was analyzed by the SPADNS (Sulfophenylazo dihydroxynaphthalene-disulfonate) method, utilizing 4000 UV-Vis spectrophotometer (Hach Company, Germany) in the environmental health engineering laboratory of the Public Health School of Tehran University of Medical Sciences. Specific details were not provided on methods of collection, samples locations, or if these locations represented the primary sources of drinking water for the subjects. Villages were categorized into normal (0.5–1 ppm), moderate (3.1±0.9 ppm), and high (5.2±1.1 ppm) fluoride based on the mean fluoride content of all seasons presumably for the stated 12-year time period. Subjects were stated to be long-life residents of the village. Dental fluorosis was also measured and increased in severity with fluoride levels; however, all areas had some degree of dental fluorosis. Although authors used an average fluoride level in varying seasons over presumably 12 years, they used a less-established method without reporting reliability or validity, nor did they provide data to indicate that the mean was truly representative of the fluoride levels over time and throughout the village. Although dental fluorosis severity increased with increasing fluoride levels, the data could also indicate potential exposure misclassification.
    - *Direction/magnitude of effect***:** The presence of dental fluorosis in all groups indicates that there may have been different exposure in some children at a younger age. Although there were only about 20 children in the "normal" fluoride group with very mild to mild dental fluorosis, this could bias the results toward the null because those children may have experienced a higher level of fluoride at some point. The other two fluoride groups were exposed to fluoride levels that likely exceeded those in the "normal" fluoride group.
  - *Basis for rating:* Probably high risk of bias based on indirect evidence that exposure was assessed using insensitive methods.

- ***Outcome:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Intelligence was evaluated using the Raven's Color Progressive Matrices. This is a well-established method. Although the study authors did not provide data to indicate that the methods were valid in this study population, the test is designed to be culturally diverse. (+ for methods). The study report stated that test administrators were blinded. (++ for blinding). Overall rating for methods and blinding = +.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that outcomes were blindly assessed using instruments that were valid and reliable in the study population.

- ***Selective Reporting:***
  - *Rating:* Probably low risk of bias (+)

  - *Summary:* All outcomes outlined in the abstract, introduction, and methods were reported. However, because they did not report the method for obtaining the betas in Table 4 of the study, it is not clear if these were adjusted or unadjusted betas.
  - *Basis for rating:* Probably low risk of bias based on direct evidence that all the study's measured outcomes were reported, but the results were not sufficiently reported.
- ***Other potential threats:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:*
    - *Statistical analyses:* Statistical comparisons between groups were reasonable (ANOVA), but consideration of homogeneity of variance was not reported. In addition, the methods for obtaining the betas were not reported.
    - *Other potential concerns:* None identified.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the statistical analyses were appropriate and there were no other potential threats to risk of bias identified.
- ***Basis for classification as lower risk-of-bias study overall:*** Probably low risk-of-bias ratings in confounding and outcome. Study strengths include addressing potential key confounders, but it was limited by the cross-sectional study design and the group-level exposure data.

Soto-Barreras *et al.* (2019)

Study Details:

- ***Study design*:** Cross-sectional
- ***Population*:** Children aged 9–10 years
- ***Study area:*** Chihuahua, Mexico
- ***Sample size:*** 161 children
- ***Data relevant to the review:*** Water fluoride, urinary fluoride, exposure dose, and dental fluorosis index by IQ grade.
- ***Reported association with fluoride exposure:*** No: No significant associations between fluoride exposure and IQ grades.

Risk of Bias:

- **Author contacts:**
  - Authors were not contacted for additional information because it was not necessary.
- ***Population selection:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Subjects were selected using a multistage cluster sampling. During the first stage, 13 public elementary schools were randomly selected from a pool of 73 using a cluster sample design. Secondly, only fourth grade students were included. Authors stated that they wanted to keep the same grade level, but they were not specific as to why fourth graders were selected as opposed to any other grade. Lastly, only children whose parents or guardians attended and responded to the survey were included. There is no information provided on how the 13 schools selected may be similar or different from the 60 schools not selected. There is no information provided on the number of

children in the fourth grade to know participant rates. It was only noted that 245 children were examined, but 161 were included after the exclusion rules were applied. Inclusion and exclusion criteria are presented. Reasons for exclusion do not appear to be related to exposure or outcome. Characteristics of participants and non-participants are not compared; however, characteristics of the 161 included children were provided and any differences were taken into account in the analysis.

- *Basis for rating:* Probably low risk of bias based on indirect evidence that the exposed groups were similar and were recruited using similar methods during the same time frame.

- ***Confounding:***
  - *Rating:* Probably high risk of bias (-)
  - *Summary:* No confounders was considered when evaluating fluoride associations with intelligence; they were only applied when evaluating fluoride levels and dental caries. Based on Table 4 of the study, there was no significant association between IQ grade and child's age, sex, parental education, or SES status. No other information was reported or considered. There is no information on potential co-exposures. Based on water quality maps, the arsenic prediction indicates a greater than 50% probability of exceeding the WHO guidelines for arsenic of 10 µg/L in areas of Chihuahua, Mexico.
  - *Potentially important study-specific confounders:* Arsenic.
    - *Direction/magnitude of effect***:** The direction and magnitude of effects is unknown. There is potential for arsenic to occur in the study area, but it is not known how it relates to fluoride exposure. If they occur together in the water, it will bias away from the null; however, if they occurred in different areas, there is potential to bias toward the null.
  - *Basis for rating:* Probably high risk of bias based on indirect evidence that there is potential for exposure to arsenic that was not sufficiently addressed.
- ***Attrition:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* A total of 161 of 245 children were included in the study. Exclusion criteria are presented and are unrelated to outcome or exposure. For the 161 children, there are no missing outcome data.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that exclusion of subjects from analyses was adequately addressed, and reasons were documented when subjects were removed from the study or excluded from analyses.
- ***Exposure:***
  - *Rating:* Probably low risk of bias (+);Probably high risk of bias (-)
  - *Summary:* **Urinary Fluoride (probably low risk of bias):** First morning void urine samples were collected based on NIOSH methods. Water samples were also stated to be collected, but it does not appear that methods followed any particular standard, and there is no indication that subjects were provided with collection containers. Analysis was based on a calibration curve using fluoride ion selective electrode. QC methods were mentioned. Based on results, there were values below detection limits, but LODs or % below LOD were not reported.

Daily fluoride exposure (probably high risk of bias): Daily fluoride exposure was based on the water fluoride level, drinking water consumption (based on parental report of how many glasses of water consumed), and body weight.

- *Direction/magnitude of effect***:** Spot urine samples that did not account for dilution could have exposure misclassification. The misclassification is likely non-differential and is not likely to bias in any specific direction. Daily exposure was based partially on parental report of water consumption. The direction and magnitude of effect is unknown.

- *Basis for rating:* Probably low risk of bias based on indirect evidence that exposure was consistently assessed using well-established methods that directly measured exposure. The daily fluoride exposure is probably high risk of bias because there is indirect evidence that the exposure was assessed using methods of unknown validity.

- ***Outcome:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Intellectual ability was evaluated using Raven's Colored Progressive Matrices by an independent examiner. Some details were provided, but it was not stated that the tests were assessed blind; however, there is no indication that subjects were from high fluoride areas and the assessor would not have knowledge of the urine or water fluoride levels. Results for children were converted into a percentile according to age (details not provided) and overall scores were assigned an intellectual grade of I to V as described in the report.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the outcome was blindly assessed using instruments that were valid and reliable in the study population.
- ***Selective Reporting:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* All outcomes outlined in the abstract, introduction, and methods were reported in sufficient detail.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that all measured outcomes were reported.
- ***Other potential threats:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:*
    - *Statistical analyses:* The main analysis was for dental caries. Although they make conclusions on fluoride and IQ, they do not use the same analytical methods for both outcomes. Table 4 of the study provides a p-value although it is not clear what the p-value represents; it is presumed to be the Kruskal Wallis p-value. It appears that a Kolmogorov-Smirnov test was used to determine variable distribution and a Kruskal Wallis test was used to compare among the groups with a Dunn's test if significant.
    - *Other potential concerns:* None identified.
  - *Basis for rating:* Probably low risk if bias based on indirect evidence that the statistical analyses were appropriate and there were no other potential threats to risk of bias identified.

- ***Basis for classification as lower risk-of-bias study overall:*** Probably low risk-of-bias ratings in exposure and outcome. Study strengths include individual exposure measurements and outcomes blindly assessed, but is limited by the cross-sectional study design, lack of accounting for urine dilution, and by not addressing potential exposures to arsenic in the study area.

Sudhir *et al.* (2009)

Study Details:

- ***Study design*:** Cross-sectional
- ***Population*:** Children aged 13–15 years
- ***Study area:*** Nalgonda district (Andhra Pradesh), India
- ***Sample size:*** 1,000 children
- ***Data relevant to the review:*** Mean IQ grade (not standard scores) or IQ distribution by water fluoride strata (<0.7, 0.7-1.2, 1.3-4.0, and >4.0 ppm).
- ***Reported association with fluoride exposure:*** Yes: Significantly increased number of intellectually impaired children with increasing drinking water fluoride levels.

Risk of Bias:

- **Author contacts:**
  - Authors were contacted in September of 2017 for additional information related to risk-of-bias evaluation, but no response was received.
- ***Population selection:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Children were selected from the same general population during the same time frame and were then broken down into nearly equal exposure groups. A cross-sectional study was conducted among 13–15-year-old school children of Nalgonda district, Andhra Pradesh between August and October 2006. Data were collected from the school children who were life-long residents of Nalgonda district, Andhra Pradesh and who consumed drinking water from the same source during the first 10 years of life. A stratified random sampling technique was used. The entire geographical area of Nalgonda district was divided into four strata based on different levels of naturally occurring fluoride in the drinking water supply. Children were randomly selected from schools in the different strata. It was noted that the 1,000 selected children were equally divided among all four strata, however, each group did not have 250 children (but instead 243−267 in each group). Participation rates are not reported. Exclusion criteria included: children who had a history of brain disease and head injuries, children whose intelligence had been affected by congenital or acquired disease, children who had migrated or were not permanent residents, children with orthodontic brackets, and children with severe extrinsic stains on their teeth. Age and gender data are presented in Table 1 of the study, but this information is not presented by the different fluoride groups.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that subjects were similar and were recruited using the same methods during the same time frame.

- ***Confounding:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Data were collected using a self-administered questionnaire and clinical examination. The self-administered questionnaire requested information on demographic data (appears to cover age and sex), permanent residential address, staple food consumed, liquids routinely consumed, and aids used for oral hygiene maintenance (fluoridated or nonfluoridated). SES was measured using the Kakkar socio-economic status scale (KSESS) with eight closed-ended questions related to parental education, family income, father's occupation, and other factors. All children were asked to fill out the form, and the answers obtained were scored using Kakkar socio-economic status scoring keys. Based on this scoring, children were divided into three groups—lower class, middle class, or upper class. Age, sex, and SES were not found to be significantly associated with IQ. Other confounders including smoking were not addressed. Co-exposures such as arsenic and lead were not addressed; however, there is no indication that lead is a co-exposure in this population and arsenic is not likely a major concern in this area based on water quality maps.
  - *Potentially important study-specific confounders:* Key confounders age, gender, and measures of SES were similar between exposure groups; however, arsenic was not taken into account. Arsenic often occurs in the drinking water along with fluoride in some Indian populations; however, based on water quality maps, this does not appear to be an issue in the Nalgonda district of Andhra Pradesh. Iodine deficiencies are not mentioned.
    - *Direction/magnitude of effect***:** The presence of arsenic would potentially bias away from the null if present with fluoride. Deficiencies in iodine would bias away from the null if present in areas of high fluoride, but toward the null if present in areas of non-high fluoride.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the key confounders are considered, co-exposure to arsenic is likely not an issue in this area, and methods used for collecting the information were valid and reliable.
- ***Attrition:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Results were available for the 1,000 children selected to participate.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence of no attrition.
- ***Exposure:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Children were placed into one of four strata based on the level of fluoride in drinking water. Collection of water samples was done in the districts. The placement into strata was based on fluoride levels obtained from documented records of District Rural Water Works Department. Once the children were assigned to strata, it was confirmed that the fluoride level of their drinking water was within the strata assigned. This was done using the methodology followed in National Oral Health Survey and Fluoride Mapping 2002–2003. During the initial visits to the schools, the children were interviewed regarding their history of residence and source of drinking water from birth to 10 years. The first child meeting criteria was given a bottle for water collection and

the next child was only given a bottle for collection if the water source was different than that of a previous child. Children were asked to collect the sample of water from the source that was used in the initial 10 years of their life and was collected the next day. It was not reported if all bottles were returned. The water samples collected were subjected to water fluoride analysis using an ion-specific electrode, Orion 720A fluoride meter at District Water Works, Nalgonda to confirm the fluoride levels in the water before commencement of clinical examination. LOD and QA/QC details were not reported.

        - *Direction/magnitude of effect*: There is some potential for exposure misclassification based on recall of the children on the source of water used in their first 10 years of life. The misclassification is likely non-differential and not likely to bias in any specific direction. Children who had changed water since birth were excluded, but it was not specifically noted that the fluoride in the water source was stable over the years.
    - *Basis for rating:* Probably low risk of bias based on indirect evidence that exposure was consistently assessed using well-established methods that directly measured exposure.
- ***Outcome:***
    - *Rating:* Probably high risk of bias (NR)
    - *Summary:* The Raven's standard progressive matrices (1992 edition) was used to assess IQ. Exams were carried out by a single examiner. Calibration of the examiner was done before the study and in the middle of the study, but it was not clear if this applied to the IQ evaluation or only to the clinical examination. This Raven's test is a standard test and although there is no information provided to indicate that the methods were reliable and valid in the study population, this test was created to be culturally fair (+ for methods). Blinding or other methods to reduce potential bias were not reported (NR for blinding). No response was received to an e-mail request for clarification in September 2017. Overall rating for methods and blinding = NR.
    - *Basis for rating:* Probably high risk of bias based on indirect evidence that the outcome was not assessed blind and could bias the results.
- ***Selective Reporting:***
    - *Rating:* Definitely low risk of bias (++)
    - *Summary:* All outcomes outlined in the abstract, introduction, and methods are reported in sufficient detail.
    - *Basis for rating:* Definitely low risk of bias based on direct evidence that all measured outcomes were reported.
- ***Other potential threats:***
    - *Rating:* Definitely low risk of bias (++)
    - *Summary:*
        - *Statistical analyses:* Statistical analyses were appropriate and no other threats to internal validity were identified.
        - *Other potential concerns:* None identified.
    - *Basis for rating:* Definitely low risk of bias based on direct evidence that the statistical analyses were appropriate and there were no other potential threats to risk of bias identified.

- ***Basis for classification as lower risk-of-bias study overall:*** Probably low risk-of-bias ratings in confounding and exposure. Study strengths include verification of exposure measurements and the addressing of potential key confounders, but it was limited by the cross-sectional study design and lack of information on blinding during outcome assessment.

Till *et al.* (2020)

Study Details:

- ***Study design*:** Prospective cohort
- ***Population*:** MIREC participants (pregnant mothers and their children aged 3–4 years)
- ***Study area:*** 10 cities, Canada
- ***Sample size:*** 398 mother−child pairs (247 from non-fluoridated areas, 151 from fluoridated areas; 200 breastfed as infants, 198 formula-fed as infants)
- ***Data relevant to the review:*** Adjusted linear regression models evaluating associations between IQ with water fluoride concentration (with or without adjusting for maternal urine) in formula-fed or breast-fed infants or by fluoride intake from formula.
- ***Reported association with fluoride exposure:*** Yes: Significantly lower performance IQ with water fluoride (adjusted βs = −9.26 formula-fed, −6.19 breastfed) and fluoride intake from formula (adjusted β = −8.76); significantly lower full-scale IQ with water fluoride in formula-fed (adjusted β = −4.40); no significant changes in full-scale IQ for water fluoride in breastfed children or fluoride intake from formula-fed children; no significant changes in verbal IQ scores with fluoride exposure.

Risk of Bias:

- **Author contacts:**
  - Authors were not contacted for additional information because it was not necessary.
- ***Population selection:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Pregnant women were recruited between 2008 and 2011 by the MIREC program from 10 cities across Canada. Inclusion and exclusion criteria were provided. Additional details were stated to be available in Arbuckle *et al.* (2013). A total of 610 children were recruited to participate in the developmental follow-up with 601 children completing all testing. The demographic characteristics of women included in the current analyses (n = 398) were not substantially different from the original MIREC cohort (N = 1945) or the subset without complete water fluoride and covariate data (n = 203). A table of characteristics of the study population is provided. Approximately half of the children lived in nonfluoridated cities and half lived in fluoridated cities.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that the exposed groups were similar and were recruited with the same methods during the same time frame.
- ***Confounding:***
  - *Rating:* Probably low risk of bias (+)

- *Summary:* Covariates were selected a priori that have been associated with fluoride, breast feeding, and children's intellectual ability. Final covariates included child's sex and age at testing, maternal education, maternal race, second-hand smoke in the home, and HOME score. City was considered but was excluded from the models. Confounders that were not assessed include: parental mental health, iodine deficiency/excess, parental IQ, and co-exposure to arsenic and lead. Co-exposure to arsenic is less likely an issue in this Canadian population and the lack of information is not considered to appreciably bias the results.
- *Potentially important study-specific confounders:* All key confounders were considered in this study.
    - *Direction/magnitude of effect***:** Not applicable.
- *Basis for rating:* Probably low risk of bias based on direct evidence that key confounders were addressed and indirect evidence that the methods used to collect the information were valid and reliable and co-exposures were not an issue.

- ***Attrition:***
    - *Rating:* Probably low risk of bias (+)
    - *Summary:* Of 610 children, 601 (98.5%) in the MIREC developmental study who were ages 3–4 years completed the neurodevelopment testing. Of the 601 children who completed the neurodevelopmental testing, 591 (99%) completed the infant feeding questionnaire and 398 (67.3%) reported drinking tap water. It was noted that the demographic characteristics were not substantially different from the original MIREC cohort or the 203 subjects without complete water fluoride or covariate data.
    - *Basis for rating:* Probably low risk of bias based on indirect evidence that exclusion of subjects from analyses was adequately addressed, and reasons were documented when subjects were removed from the study or excluded from analyses.
- ***Exposure:***
    - *Rating:* Probably low risk of bias (+)
    - *Summary:* Information on breastfeeding was obtained via questionnaire at 30–48 months. Fluoride concentration in the drinking water was assessed by daily or monthly reports provided by water treatment plants. Water reports were first linked with mothers' postal codes and the daily or weekly amounts were averaged over the first 6 months of each child's life. Additional details can be found in Till *et al.* (2018). Maternal urinary exposure was used to assess fetal fluoride exposure. Procedures can be found in Green *et al.* (2019).
        - *Direction/magnitude of effect***:** There is not any specific direction or magnitude of bias expected. Urinary fluoride levels are reflective of recent exposure. The possibility of the exposure misclassification would be similar in all subjects and would be non-differential. For the fluoride intake from formula, exposure was based on the fluoride levels in the water at the residence and the proportion of time that the infant was not exclusively breastfed. This exposure misclassification would also be non-differential.
    - *Basis for rating:* Probably low risk of bias based on indirect evidence that exposure was consistently assessed using well-established methods that directly measured exposure.
- ***Outcome:***

- *Rating:* Probably low risk of bias (+)
- *Summary:* Intelligence was tested using the Wechsler Preschool and Primary Scale of Intelligence III. This is appropriate for both the study population and age group. This is considered a gold standard test. It was not reported whether the evaluators were blind to the child's fluoride exposure status during the assessment. Although it is unlikely that the assessors had knowledge of the specific drinking water levels or maternal urine levels, there is potential that the outcome assessors had knowledge of the city the child lived in and if the city was fluoridated or non-fluoridated. Correspondence with the study authors on the outcome assessment for Green *et al.* (2019) indicated that it was unlikely that the testers had knowledge of the city's fluoridation. The same is assumed here. Specific measurements included were identified.
- *Basis for rating:* Probably low risk of bias based on indirect evidence that the outcome was blindly assessed using instruments that were valid and reliable in the study population.

- ***Selective Reporting:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* All outcomes outlined in the abstract, introduction, and methods were reported in sufficient details.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that all measured outcomes were reported.
- ***Other potential threats:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:*
    - *Statistical analyses:* Regression diagnostics were used to test assumptions for linearity, normality, and homogeneity. There were two potential influential observations (based on Cook's distance), and sensitivity analyses re-estimated the models without these two variables. Effect modification by breastfeeding status was evaluated. Interestingly, all regression coefficients were divided by 2 to represent change in IQ per 0.5-mg/L change in fluoride. One concern is posed by the lack of accounting for city in the regression models, ideally as a random effect. The authors explored including city as a covariate in the models; however, city was not included either because it was strongly multi-collinear with water fluoride concentration (VIF > 20) (model 1, with water fluoride concentration) or because fluoride intake from formula is a function of water fluoride concentration (assessed at the city level) and was therefore deemed redundant (model 2). However, the models use city-level water fluoride concentrations (and in sensitivity analyses, adjust for maternal urinary fluoride) which warrant exploration of city as a random effect rather than a fixed effect (as would be by just having it included as a covariate). Even including individual-level maternal urinary fluoride might not fully account for lack of city, given that the subjects were from six different cities, with half of them fully on fluoridated water. Hence, even individual-level exposures are likely to be correlated at the city level. Based on a previous analysis (Green *et al.* 2019), it is unlikely that

exclusion of city from models (as a fixed or random effect) would impact the effect estimates.
        - *Other potential concerns:* None identified.
    - *Basis for rating:* Probably low risk if bias based on indirect evidence that the statistical analyses were appropriate and there were no other potential threats to risk of bias identified.
- ***Basis for classification as lower risk-of-bias study overall:*** Probably low risk-of-bias ratings in confounding, exposure, and outcome. Study strengths include individual exposure measurements, prospective cohort design, and the addressing of potential key confounders.

Trivedi *et al.* (2012)

Study Details:

- ***Study design*:** Cross-sectional
- ***Population*:** Children aged 12−13 years
- ***Study area:*** Kachchh, Gujarat, India
- ***Sample size:*** 84 children
- ***Data relevant to the review:*** Mean IQ scores and distribution by low and high fluoride villages.
- ***Reported association with fluoride exposure:*** Yes: Significantly lower IQ score in the high fluoride (92.53 ± 3.13) compared to the low fluoride (97.17 ± 2.54) areas in boys and girls combined (as well as separately). Villages with higher fluoride levels had a larger percentage of subjects with IQ scores of 70–79, while the lower fluoride villages had a greater percentage of IQ scores > 109.

Risk of Bias:

- **Author contacts:**
    - Authors were contacted in September of 2017 to obtain additional information for risk-of-bias evaluation.
- ***Population selection:***
    - *Rating:* Probably low risk of bias (+)
    - *Summary:* There is insufficient information provided on the sampling methods to determine if the populations were similar. Although it was noted that samples were obtained for groundwater quality from March to May of 2011, there is no indication that the children were selected at the same time or during a similar time frame. Correspondence with the author indicates that children were selected within a week of the water collection based on random selection of a school in the village. Study participants were selected from six different villages of the Mundra region of Gujarat, India. Subjects were grouped into high and low villages based on the level of fluoride in the drinking water of those villages. The number of subjects per village were not reported, but it was noted that there were 50 children in the low fluoride group and 34 children in the high fluoride group. It is not clear if the differences in numbers were based on different participation rates or if there were fewer children in the high fluoride villages. Recruitment methods including any exclusion criteria and participation rates

were not provided. SES was stated to be low and equal based on questionnaire information, but the results were not provided. It should also be noted that only regular students (having attendance more than 80%) of standard 6th and 7th grades were selected, but it was not noted if attendance varied by village. Correspondence with the study author indicated that there was an average of 20 students per class with an average of 40 students per village. It appears that keeping the requirement for 80% attendance was a limiting factor that caused different numbers of children by area; however, this was applied similarly to both groups.

- *Basis for rating:* Probably low risk of bias based on indirect evidence that subjects were similar and recruited using the same methods during the same time frame.

- ***Confounding:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Children were stated to be students of the 6th and 7th standard grades. Age was not addressed, but the children would all be of similar age based on the grades included. Results were reported for males and females separately as well as combined. SES and iodine consumption were stated to be analyzed via a questionnaire and were standardized on the basis of the 2011 census of India. Although it was noted in the abstract that the SES was equal (no data provided), the study report did not mention the iodine results. Although the study authors did not address arsenic or lead, they did provide physicochemical analyses for the water samples from the six different villages. Information on arsenic in the water is not provided, but based on water quality maps, arsenic is not expected to be a major concern in this study area.
  - *Potentially important study-specific confounders:* Key confounders age, gender, and measures of SES were similar between exposure groups; however, arsenic was not taken into account. Arsenic often occurs in the drinking water along with fluoride in some Indian populations; however, based on water quality maps, arsenic does not appear to be an issue in the study area.
    - *Direction/magnitude of effect***:** Presence of arsenic would potentially bias away from the null if present with fluoride or toward the null if present in the reference group.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the methods used to collect the information were valid and reliable, that potential co-exposures were not an issue, and that key confounders were addressed.

- ***Attrition:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Results were provided for 84 children, but the methods do not indicate how many children were initially selected to participate nor were any exclusion criteria provided. It was noted in the results that 84 children had their groundwater and urine tested, but it was not noted if analyses were restricted to these children or if exposures were assessed in all the children who had IQ measurements. Correspondence with the study author indicated that the main reason for exclusion was a <80% attendance rate, with fluoride and IQ measured on all 84 children who met the criteria.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence of no attrition.

- ***Exposure:***

- *Rating:* Probably low risk of bias (+)
- *Summary:* Children in villages were grouped based on fluoride levels that were assessed in groundwater (low F villages versus high F villages). The average concentration of these levels was considered to be the levels in the drinking water with confirmation using urinary fluoride levels. The groundwater samples were selected to cover major parts of the taluka and represent overall groundwater quality. Ten samples were obtained from each village. Fluoride was measured in the groundwater using ion exchange chromatography. Although urine levels were also significantly higher in the high fluoride village, no information was provided on how or when the urinary samples were obtained or how they were measured. However, correspondence with the study author indicated that the groundwater and urine fluoride levels were available for all 84 children indicating that the urine measures were available for the children that had IQ measures. The urine samples were stated to be collected at the same time that the second water sample was collected.
  - *Direction/magnitude of effect*: Fluoride levels were measured in both the drinking water and urine. Although there is some variability in the measurements, there is no overlap between the two groups and the urine and drinking water levels in the children support each other. Any potential exposure misclassification would be non-differential and direction and magnitude are unknown.
- *Basis for rating:* Probably low risk of bias based on indirect evidence that exposure was consistently assessed using well-established methods that directly measured exposure.

- ***Outcome:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Outcome methods were only noted to be reported in Trivedi *et al.* (2007), which was scored as follows: IQ was measured in the children of both areas using a questionnaire prepared by Professor JH Shah, copyrighted by Akash Manomapan Kendra, Ahmedabad, India, and standardized on the Gujarati population with 97% reliability rate in relation to the Stanford-Binet Intelligence Scale (+ for methods). Blinding or other methods to reduce bias are not reported, but correspondence with the study author indicated that the teachers were blind to the status of fluoride. The teachers administered the tests in the presence of a research fellow. It is not completely clear who scored the tests, but it is assumed the teachers. (+ for blinding). Overall rating for methods and blinding = +.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the outcomes were blindly assessed using instruments that were valid and reliable in the study population.
- ***Selective Reporting:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* All outcomes outlined in the abstract, introduction, and methods are reported in sufficient detail.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that all measured outcomes were reported.
- ***Other potential threats:***

- *Rating:* Probably low risk of bias (+)
- *Summary:*
  - *Statistical analyses:* Statistical analyses were reasonable (paired sample T-test), but consideration of homogeneity of variance was not reported.
  - *Other potential concerns:* No other threats to internal validity were identified.
- *Basis for rating:* Probably low risk of bias based on indirect evidence that the statistical analyses were appropriate and there were no other potential threats to risk of bias identified.

- ***Basis for classification as lower risk-of-bias study overall:*** Probably low risk-of-bias ratings in confounding, exposure, and outcome. Study strengths include individual exposure measurements and the addressing of potential key confounders but was limited by the cross-sectional study design.

Valdez Jimenez *et al.* (2017)

Study Details:

- ***Study design*:** Prospective cohort
- ***Population*:** Infants aged 3–15 months
- ***Study area:*** Durango City and Lagos de Moreno, Jalisco, Mexico
- ***Sample size:*** 65 infants
- ***Data relevant to the review:*** The Bayley Scales of Infant Development II was used to assess Mental Development Index Scale and the Psychomotor Development Index scale in children 3 to 15 month and evaluated for associations with first and second trimester maternal urine fluoride.
- ***Reported association with fluoride exposure:*** Yes: Significant correlation between maternal urinary fluoride and MDI score during first trimester (adjusted β = −19.05; SE = 8.9) and second trimester (adjusted β = −19.34; SE = 7.46).

Risk of Bias:

- **Author contacts:**
  - Authors were not contacted for additional information because it was not necessary.
- ***Population selection:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Subjects were recruited from two endemic areas in Mexico. The study authors do not provide information on the similarities or differences between the two areas nor do they indicate if there were different participation rates. However, recruitment methods were the same. Women receiving prenatal care in health centers located in Durango City and Lagos de Moreno, Jalisco, Mexico were recruited in 2013–2014. Participation rates are not likely to be an issue as characteristics were similar between those who participated and those who did not. Although they did not provide characteristics by area, the characteristics provided do not indicate any differences that may be biased by the selection. Considering the age range for the non-participants, the mean age for non-participants appears to be incorrect (or the age range is incorrect);

however, there does not appear to be a difference that would potentially indicate selection bias.
    - *Basis for rating:* Probably low risk of bias based on indirect evidence that the exposure groups were similar and were recruited with the same methods in the same time frame, with no evidence of differences or issues with participation/response rates.
- ***Confounding:***
    - *Rating:* Probably high risk of bias (-)
    - *Summary:* Questionnaires were used to obtain information about sociodemographic factors, prenatal history, mother's health status before pregnancy (e.g., use of drugs, vaccines, diseases) and the type of water for drinking and cooking. The marginalization index (MI) was obtained from the National Population Council (CONAPO). Two additional surveys were conducted during the 2nd and 3rd trimester of pregnancy to get information about the mother's health, pregnancy evolution, and sources of water consumption. A survey was also conducted to get information about childbirth (type of birth, week of birth, weight and length of the baby at birth, Apgar and health conditions of the baby during the first month of life). This information was corroborated with the birth certificate. Linear regression models included gestational age, children's age, marginality index, and type of drinking water. Bivariate analysis was conducted on the other factors including child's gender prior to conducting multivariable regression models. Some important confounders were not considered, including parental mental health, IQ, smoking, and potential co-exposures.
    - *Potentially important study-specific confounders:* Arsenic is a potential co-exposure in this area of Mexico.
        - *Direction/magnitude of effect***:** If arsenic were present as a co-exposure it would bias the results away from the null.
    - *Basis for rating:* Probably high risk of bias based on indirect evidence that there is a potential for co-exposure with arsenic that was not addressed.
- ***Attrition:***
    - *Rating:* Definitely low risk of bias (++)
    - *Summary:* Out of the 90 women selected for inclusion in the study, 65 approved the participation of their infants. The authors provide a table of characteristics between women who consented to their children's cognitive evaluation and those that only participated in biological monitoring. There were no significant differences between the groups. There were fewer women who provided urine during the second and third trimesters. All specified children are included in the relevant analyses.
    - *Basis for rating:* Definitely low risk of bias based on direct evidence that exclusion of subjects from analyses was adequately addressed, and reasons were documented when subjects were removed from the study or excluded from analyses.
- ***Exposure:***
    - *Rating:* Definitely low risk of bias (++)
    - *Summary:* Fluoride exposure is assessed through morning urine samples and water fluoride levels collected from the children's homes. Sampling methodology is appropriately documented, and water levels were quantified through specific

ion-sensitive electrode assays. QC was described and accuracy was >90%. Urinary fluoride was corrected by specific gravity.

- *Direction/magnitude of effect*: Not applicable.

- *Basis for rating:* Definitely low risk of bias based on direct evidence that exposure was consistently assessed using well-established methods that directly measured exposure.

- ***Outcome:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Neurodevelopment was assessed with the Bayley Scales of Infant Development II (BSDI-II) that was noted to be reliable and valid for evaluating children from 3 months to 5 years of age. The average age of children assessed was 8 months, with a range of 3–15 months) (++ for methods). The study report stated that a trained psychologist who was blinded about the mother's fluoride exposure evaluated the infants at home (++ for blinding). Overall rating for methods and blinding = ++.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that the outcome was blindly assessed using instruments that were valid and reliable in the study population.
- ***Selective Reporting:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* All outcomes outlined in the abstract, introduction, and methods were reported. Table 4 of the study only displays data for trimesters 1 and 2. Although 3rd trimester data were collected, they were not reported, likely because data were only available for 29 subjects. No discussion of this was provided.
  - *Basis for rating:* Probably low risk of bias because, although it appears some data were not reported, it is likely because there were insufficient data and not because the authors were selectively reporting the results.
- ***Other potential threats:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:*
    - *Statistical analyses:* Statistical analyses used were appropriate for the study.
    - *Other potential concerns:* No other potential concerns were identified. In the peer-review report, NASEM (2020) cited the following as potential concerns: "the large difference in numbers of males and females in the offspring (20 males, 45 females), and apparently incorrect probabilities were reported for age differences between participants and nonparticipants, high rates of cesarean deliveries and premature births among participants (degree of overlap not reported), and incorrect comparisons of observed prematurity rates with national expected rates." However, these concerns were taken in consideration in other domains (***Selection, Confounding)***.
  - *Basis for rating:* Definitely low risk if bias based on direct evidence that the statistical analyses were appropriate and there were no other potential threats to risk of bias identified.
- ***Basis for classification as lower risk-of-bias study overall:*** Definitely low risk-of-bias ratings in exposure and outcome. Study strengths include individual exposure measurements and

outcome blindly assessed, but it is limited by the cross-sectional study design and lack of accounting for potential co-exposures to arsenic.

Wang *et al.* (2012)

Study Details:

- ***Study design*:** Cross-sectional
- ***Population*:** Children aged 8–13 years (possibly the same population as Xiang *et al.* (2003a))
- ***Study area:*** Wamiao and Xinhuai villages located in Sihong County, Jiangsu Providence, China
- ***Sample size:*** 526 school children
- ***Data relevant to the review:*** Mean IQ and % low IQ (< 80) by total fluoride intake.
- ***Reported association with fluoride exposure:*** Yes: Significantly lower mean IQ in the high fluoride village (92.02 ± 13.00) compared to the control village (100.41 ± 13.21); when high exposure group was broken into 4 exposure groups, a dose-dependent decrease in IQ and increase in % with low IQ observed; significant correlation between total fluoride intake and IQ (r = −0.332); OR for IQ<80 per increase in total fluoride intake=1.106; 95% CI 1.052–1.163).

Risk of Bias:

- **Author contacts:**
  - Authors were not contacted for additional information because it was not necessary.
- ***Population selection:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* The study appears to be the same population as Xiang *et al.* (2003a) and Xiang *et al.* (2011); however, the study does not cite these studies as providing additional information and numbers of children differ; therefore, it may be a separate analysis on the same villages. The years of testing were not provided so it cannot be determined if study subjects are the same. Two villages, Wamiao and Xinhuai, located 64 km apart in Sihong County, Jiangsu Province were selected for the study. Wamiao is a village in a region with severe endemic fluorosis and Xinhuai is a village in a non-endemic fluorosis region. Neither village has fluoride pollution from coal or industrial sources. Villages were stated to be similar in terms of annual per capita income, transportation, education, medical conditions, the natural environment, and lifestyle. All primary students ages 8–13 years currently in school in either village were surveyed with exclusions noted. Of 243 children from Wamiao, 236 (97.12%) were included, and of 305 children from Xinhuai, 290 (95.08%) were included. No table of subject characteristics was provided.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the exposure groups were similar and were recruited using the same methods within the same time frame, with direct evidence that there was no difference in participation/response rates.
- ***Confounding:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Logistic regression of low IQ rate and total fluoride intake adjusted for age and sex. Both villages had hand-pumped well water for drinking water, but the authors

do not mention if arsenic was also present in the drinking water. However, a publication by Xiang *et al.* (2013) on this study area indicates that Xinhuai (the low fluoride area) had significantly higher arsenic levels compared to Wamiao (the endemic fluorosis area), which would bias toward the null. Areas were stated to be similar in annual per capita income, transportation, education, medical conditions, the natural environment, and lifestyle; however, no details were provided. This study did not address other co-exposures, but other studies on populations in these villages (Xiang *et al.* 2011, Xiang *et al.* 2003a) indicate that iodine and lead are not concerns.

- *Potentially important study-specific confounders:* Arsenic often occurs in the drinking water along with fluoride in some Chinese populations; however, based on information provided in Xiang *et al.* (2013), arsenic concentrations were higher in the low fluoride area compared to the high fluoride area.
  - *Direction/magnitude of effect*: Presence of arsenic in this study population would potentially bias toward the null.
- *Basis for rating:* Probably low of risk bias because there is indirect evidence that the key confounders are take into account, methods used for collecting the information were valid and reliable, and co-exposures to arsenic and lead and iodine deficiency are not attributing to the effect observed in this area.

- ***Attrition:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Data are reported for all 526 children noted to be included in the study. There is a slight discrepancy in the reported total number of children from the high-fluoride village and the number of participants from the high-fluoride village between this paper (236 participated of 243 total children) and the 2003 and 2011 publications on the same study population (222 of 238). This discrepancy is not explained but is not expected to appreciably bias the results.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that exclusion of subjects from analyses was adequately addressed, and reasons were documented when subjects were removed from the study or excluded from analyses.
- ***Exposure:***
  - *Rating:* Probably low risk of bias (+); Probably high risk of bias (-)
  - *Summary:* **Water fluoride (+ probably low risk of bias):** Exposure was based on drinking water levels and fluoride intake. Residents in the Wamiao village were divided into five groups based on fluoride levels in the drinking water. Clean, dry polyethylene bottles were used to collect 50 mL of drinking water from each student's household and fluoride content was measured.

    Total fluoride intake (- probably high risk of bias): Six families from each of the five Wamiao groups were randomly selected as dietary survey households. Intakes of various foods by each person at each meal and intakes of unboiled water, boiled water, and tea were surveyed for four consecutive days. Methods for food collection were described. Five representative households from each village were selected based on geographic location, population distribution, housing structure, and other conditions. Indoor air samples were collected once daily for five consecutive days; outdoor air was sampled at two points once daily for five days. Methods for determining fluoride

content in samples were noted to follow specific guidelines. Calculation of total fluoride intake was stated to follow Appendix A of the People's Republic of China Health Industry Standard with some details provided. Although it is assumed the method is valid, it was not detailed how each fluoride determination was made for each subject, and it appears that total fluoride intake was determined based on data from select subjects and not all subjects.

- *Direction/magnitude of effect*: There is potential for exposure misclassification based on calculating fluoride intake based on measurements from a few select subjects rather than all subjects. The direction and magnitude of effect cannot be assessed based on the information provided.

- *Basis for rating:* Probably low risk of bias based on indirect evidence that exposure was consistently assessed using well-established methods that directly measured exposure. The intake is probably high risk of bias because there is indirect evidence that the exposure was assessed using methods of unknown validity.

- ***Outcome:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* IQ of each child was measured with the Combined Raven's Test for Rural China (CRT-RC) (++ for methods). The test was stated to be administered to the children independently in a school classroom under the supervision of three exam proctors. Testing methods, testing language, and testing conditions were all in strict accordance with the CRT-RC guidebook. Major testing personnel received necessary training by the Psychology Department of East China Normal University. The children undergoing IQ testing and the test scorers were kept double-blinded throughout the testing process. (++ for blinding). Overall rating= ++.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that the outcome was blindly assessed using instruments that were valid and reliable in the study population.
- ***Selective Reporting:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* All outcomes outlined in the abstract, introduction, and methods are reported in sufficient detail.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that all measured outcomes were reported.
- ***Other potential threats:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:*
    - *Statistical analyses:* Although it was noted that a logistic regression was used to determine the odds of having low IQ with increasing fluoride intake, no details were provided on any of the other tests conducted. Because this is the same population evaluated in Xiang *et al.* (2003a) and Xiang *et al.* (2011), it is assumed that the same methods were used even if this study population consisted of different children.
    - *Other potential concerns:* None identified.

  - *Basis for rating:* Probably low risk if bias based on indirect evidence that the statistical analyses were appropriate and there were no other potential threats to risk of bias identified.
- ***Basis for classification as lower risk-of-bias study overall:*** Definitely or probably low risk-of-bias ratings in confounding, exposure, and outcome. Study strengths include individual exposure measurements with blinding at outcome assessment but is limited by the cross-sectional study design and not using individual measurements to calculate fluoride intake. All key confounders were accounted for in the study design or analysis, but there is potential for the presence of arsenic to bias toward the null.

Wang *et al.* (2020a)

Study Details:

- ***Study design*:** Cross-sectional
- ***Population*:** School children aged 7–13 years
- ***Study area:*** Tongxu County, China
- ***Sample size:*** 325 school children
- ***Data relevant to the review:*** Associations between ADHD and other measures of learning disability with urine fluoride concentrations.
- ***Reported association with fluoride exposure:*** Yes: Significant correlation between psychosomatic problems and urinary fluoride (adjusted β = 4.01 [95% CI: 2.74, 5.28]) and increased risk of a T-score > 70 with increasing urinary fluoride (adjusted OR = 1.97 [95% CI: 1.19, 3.27]). No significant associations with ADHD or other measures of learning disability.

Risk of Bias:

- **Author contacts:**
  - Authors were contacted in July of 2020 to obtain additional information for risk-of-bias evaluation. No response was received.
- ***Population selection:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Subjects were recruited in 2017 from Tongxu County, China. Children were selected from four randomly selected primary schools in the area. Selection was based on specified inclusion rules. It was noted that the living habits and diets of the participants from the four schools were well matched, but details were not provided. The area did not have industrial pollution within 1 km of the living environment of the children, and it was noted that the children were not exposed to other neurodevelopmental toxicants (lead, cadmium, arsenic, or mercury). A table of subject characteristics was provided in the study, but not by school or exposure. This is a pilot study, and it is not explicitly stated if all eligible subjects participated in the study. There is no information on participation rates or if they varied by school.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the exposed groups were recruited using similar methods during the same time frame and that any differences between the exposed groups were considered in the statistical analyses.

- ***Confounding:***
    - *Rating:* Probably low risk of bias (+)
    - *Summary:* It was noted that subjects were well matched in terms of living habits and diets, but there were no specifics provided. It was noted that there was no industrial exposure or exposure to other neurotoxins such as lead, cadmium, arsenic, or mercury. Covariates were collected using a standardized and structured questionnaire completed by the children and their guardians under the direction of investigators, but reliability or validity of the questionnaire was not reported. Information collected included age, gender, weight, height, parental education level, and parental migration (or work as migrant workers). IQ scores evaluated by the Combined Raven's Test-the Rural in China were used to represent basic cognitive function. Models were adjusted for age, BMI, gender, mother and father migration, and urinary creatinine. Adjustments were not made for parental education, race/ethnicity, maternal demographics (e.g., maternal age, BMI), parental behavioral and mental health disorders (e.g., ADHD, depression), smoking (e.g., maternal smoking status, secondhand tobacco smoke exposure), reproductive factors (e.g., parity), iodine deficiency/excess, maternal (and paternal) IQ, quantity and quality of caregiving environment (e.g., HOME score), or SES other than parental migration. There is no evidence to suggest that SES would differ substantially among the four rural schools in the same area of China that were randomly selected.
    - *Potentially important study-specific confounders:* SES.
        - *Direction/magnitude of effect***:** Direction and magnitude is unknown. It was noted that the subjects were matched in terms of living habits and diet and this could be an indication that SES was not different among the groups, but details were not provided.
    - *Basis for rating:* Probably low risk of bias because there is indirect evidence that the key confounders are considered, that the methods for collecting the information were valid and reliable, and that co-exposure to arsenic is not an issue in this area.
- ***Attrition:***
    - *Rating:* Definitely low risk of bias (++)
    - *Summary:* Data are complete. It was noted that there were 325 subjects included and results were available on all subjects.
    - *Basis for rating:* Definitely low risk of bias based on direct evidence that there was no attrition.
- ***Exposure:***
    - *Rating:* Probably low risk of bias (+)
    - *Summary:* Spot urine samples were collected from each child in the early morning into cleaned polyethylene tubes. Fluoride concentrations were measured using fluoride ion-selective electrode (with reference to Ma *et al.* (2017); however, that reference cites Zhou *et al.* (2012). Therefore, no QC methods or LODs were available. Fluoride concentrations were creatinine-adjusted.
        - *Direction/magnitude of effect***:** Spot urine samples only account for recent exposure. Although this could cause there to be some exposure misclassification, the number of subjects should help dilute any issues with the non-differential misclassification.

    - *Basis for rating:* Probably low risk of bias based on indirect evidence that exposure was consistently assessed using acceptable methods that provide individual levels of exposure.
- ***Outcome:***
    - *Rating:* Probably high risk of bias (NR)
    - *Summary:* Children's behavior was assessed by the Chinese version of the Conners' Parent Rating Scale-Revised (CPRS-48). The homogeneity reliability of Cronbach α in the Chinese version of CPRS-48 was 0.932; the correlation of Spearman-brown split-half was 0.900; and the retest reliability of total score was 0.594. Raw scores for each subscale are converted into sex- and age-adjusted T-scores within a mean ± standard deviation (SD) of 50 ± 10. The guardians independently completed the CPRS-48 according to the instruction manual under the direction of trained investigators (++ for methods). Blinding is not reported. Although it is unlikely that the outcome assessors were aware of the fluoride levels in the urine, it is unclear if subjects were selected based on areas with endemic fluoride or if parents were aware of fluoride concentrations in the areas. (NR for blinding). Overall rating for methods and blinding = NR.
    - *Basis for rating:* Probably high risk of bias based on no information provided to indicate that the outcome was blindly assessed.
- ***Selective Reporting:***
    - *Rating:* Definitely low risk of bias (++)
    - *Summary:* All outcomes in the abstract, introduction, and methods are reported in sufficient details.
    - *Basis for rating:* Definitely low risk of bias based on direct evidence that all measured outcomes were reported.
- ***Other potential threats:***
    - *Rating:* Probably low risk of bias (+)
    - *Summary:*
        - *Statistical analyses:* Multiple linear regression models were used to assess the fluoride association with each behavioral outcome. Logistic regression was used to assess the risk of behavioral problems due to fluoride exposure, but what they used to delineate a behavioral problem was not specified. Sensitivity analyses were performed.
        - *Other potential concerns:* None identified.
    - *Basis for rating:* Probably low risk of bias based on indirect evidence that the statistical analyses were appropriate and no other potential threats to risk of bias were identified.
- ***Basis for classification as lower risk-of-bias study overall:*** Probably low risk-of-bias ratings in confounding and exposure. Study strengths include individual exposure measurements, but it is limited by the cross-sectional study design and lack of details on blinding of the outcome assessment. All key confounders were considered in the study design or analysis.

Wang *et al.* (2020b)

Study Details:

- ***Study design*:** Cross-sectional
- ***Population*:** School children aged 7–13 years
- ***Study area:*** Tianjin City, China (possibly a subset of the children from Yu *et al.* (2018))
- ***Sample size:*** 571 school children
- ***Data relevant to the review:*** IQ scores by urine and water fluoride levels.
- ***Reported association with fluoride exposure:*** Yes: Significant correlations between IQ score and water fluoride (adjusted β = −1.587 per 1-mg/L increase) and urinary fluoride (adjusted β = −1.214 per 1-mg/L increase).

Risk of Bias:

- **Author contacts:**
  - Authors were not contacted for additional information because it was not necessary.
- ***Population selection:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Subjects were from a cross-sectional study conducted in 2015, but no citation was provided on this cohort (presumably the Yu *et al.* (2018) cohort). It was noted that the subjects in that cohort were from districts with historically high or normal fluoride levels. Subjects for this study were selected by using a stratified and multistage random sampling approach. Brief description was provided. The study area consisted of three historically high fluoride areas and four nonendemic areas. A flow diagram was provided for inclusion and exclusion, but this detail was given for all children and not by area. Therefore, it cannot be determined if the participation differed by area. However, there was a 93% recruitment rate, and the 13 excluded due to missing data are not likely excluded due to exposure. Detailed characteristics of the study population are provided. Exclusion criteria included: "children who had congenital or acquired diseases affecting intelligence, or a history of cerebral trauma and neurological disorders, or those with a positive screening test history (like hepatitis B virus infection, Treponema palladium infection and Down's syndrome) and adverse exposures (smoking and drinking) during maternal pregnancy, prior diagnosis of thyroid disease, and children who had had missing values of significant factors (2.2%) were also excluded."
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that the exposed groups were recruited using similar methods during the same time frame and that any differences between the exposed groups were accounted for in the statistical analyses.
- ***Confounding:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Study authors noted that the study areas are not exposed to other neurotoxins such as lead, arsenic, or mercury nor were they iodine-deficient. Final models included child's age, child's gender, child's BMI, maternal and paternal education, household income, and low birth weight. Other potential confounders that were considered is unclear as they only noted that the confounders were selected based on current literature. Reasons for exclusion included history of disease affecting intelligence, history of trauma or neurological disorders, positive screening test history,

or exposures such as smoking or drinking during pregnancy. Information was obtained by questionnaire or measurements. Variables such as parental BMI, behavioral and mental health disorders, IQ, and quantity and quality of the caregiving environment were not addressed.

- *Potentially important study-specific confounders:* All key confounders were considered in this study.
  - *Direction/magnitude of effect*: Not applicable.
- *Basis for rating:* Probably low risk of bias because there is direct evidence that the key confounders are taken into account, indirect evidence that the methods for collecting the information were valid and reliable, and co-exposure to arsenic is not an issue in this area.

- ***Attrition:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* A detailed chart of the recruitment process is presented. The study had a 93% recruitment rate and only 2.2% of subjects with missing data for certain covariates were excluded.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that exclusion of subjects from analyses was adequately addressed, and reasons were documented when subjects were removed from the study or excluded from analyses.
- ***Exposure:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Children provided spot urine samples, presumably at the time of examination. Water samples were randomly collected from public water supplies in each village. Fluoride concentrations were analyzed using fluoride ion-selective electrode according to the national standardized method in China. There is no indication if the urine samples accounted for dilution.
    - *Direction/magnitude of effect*: Not accounting for dilution could cause there to be some exposure misclassification. The direction and magnitude would depend on where the differences occurred.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that exposure was consistently assessed using acceptable methods that provide individual levels of exposure.
- ***Outcome:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Assessments of IQ scores were conducted by graduate students at the School of Public Health, Tongji Medical College at the Huazhong University of Science and Technology. Each team member was assigned a single task, meaning that only one person would have conducted the IQ tests. A Combined Raven's Test for Rural China was used. Therefore, the test was appropriate for the study population (++ for method). It was note that the examiner was trained and blind to the exposure (++ for blinding). Overall = ++
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that the outcome was blindly assessed using instruments that were valid and reliable in the study population.

- ***Selective Reporting:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* All outcomes in the abstract, introduction, and methods are reported in sufficient details.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that all measured outcomes were reported.
- ***Other potential threats:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:*
    - *Statistical analyses:* Statistical analyses were appropriate and no other threats to internal validity were identified. Logistic and multivariate regression models accounting for potential confounders were used. Results are presented as betas or odds ratios and 95% confidence intervals. Regression diagnostics were conducted for all models, including examination of multicollinearity, heteroscedasticity, and influential observations. Mediation and interaction analyses were appropriate. The stratified and multistage random sampling approach for subject selection and the fact that selected villages are similar in population and general demographic characteristics helps to ensure that there was no need to account for village-level effects even when the analysis used water samples from the village.
    - *Other potential concerns:* None identified.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that the statistical analyses were appropriate and no other potential threats to risk of bias were identified.
- ***Basis for classification as lower risk-of-bias study overall:*** Definitely or probably low risk-of-bias ratings in confounding, exposure, and outcome. Study strengths include individual exposure measurements but is limited by the cross-sectional study design and lack of accounting for urine dilution. All key confounders were considered in the study design or analysis.

Xiang *et al.* (2003a)

Study Details:

- ***Study design*:** Cross-sectional
- ***Population*:** Children aged 8–13 years
- ***Study area:*** Wamiao and Xinhuai villages located in Sihong County, Jiangsu Providence, China
- ***Sample size:*** 512 school children
- ***Data relevant to the review:*** Comparison of IQ (mean and distribution) between Wamiao County (a severe endemic fluorosis area) and Xinhuai County (non-endemic fluorosis area); additional breakdown of the Wamiao area into 5 water fluoride exposure groups.
- ***Reported association with fluoride exposure:*** Yes: Significant dose-related effect of drinking water fluoride on IQ score based on quintile levels with significantly lower IQ scores observed with water fluoride levels of 1.53 mg/L or higher. Pearson correlation coefficient of −0.164 with urinary fluoride. IQ scores for children in the non-endemic region (100.41 ± 13.21) were

significantly higher than the endemic region (92.02 ± 13.00). The lower-bound confidence limit benchmark concentration (BMCL) of 1.85 mg/L was calculated.

Risk of Bias:

- **Author contacts:**
  - Authors were not contacted for additional information because it was not necessary.
- ***Population selection:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Two villages, Wamiao and Xinhuai, located 64 km apart in Sihong County, Jiangsu Province were selected for this study, which was conducted between September and December 2002. Wamiao is located in a severe fluorosis endemic area, and Xinhuai is located in a non-endemic fluorosis area. Neither village has fluoride pollution from burning coal or other industrial sources. All eligible children in each village were included; children who had been absent from either village for 2 years or longer or who had a history of brain disease or head injury were excluded. In Wamiao, 93% of the children (222 out of 238) were included for the study, while in Xinhuai, 95% were included (290 out of 305). The children in Wamiao were divided into five subgroups according to the level of fluoride in their drinking water: <1.0 mg/L (group A), 1.0–1.9 mg/L (group B), 2.0–2.9 mg/L (group C), 3.0–3.9 mg/L (group D), and >3.9 mg/L (group E). Children in Xinhuai (0.18–0.76 mg F/L in the drinking water) served as a control group (group F). Demographic characteristics are not presented, and statistical analyses are not adjusted, but mean IQ scores are stratified by child's age, child's gender, family income, and parental education.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the exposure groups were similar and were recruited using the same methods within the same time frame, with direct evidence that there was no difference in participation/response rates.
- ***Confounding:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Although information was stated to be collected on personal characteristics, medical history, education levels of the children and parents, family SES, and lifestyle, only child's gender, child's age, family income, and parental education were addressed. Other potential co-exposures, such as arsenic, were not addressed. A separate publication in 2003 [(Xiang *et al.* 2003b), letter to the editor], indicated that blood lead levels were not significantly different between the two areas. Although arsenic was not addressed specifically in this publication, Xiang *et al.* (2013) measured both fluoride and arsenic in the Wamiao and Xinhuai areas. Xinhuai (the low fluoride area) had significantly higher arsenic levels compared to Wamiao (the endemic fluorosis area). This is likely to bias toward the null; however, the study observed a significantly lower IQ score in the endemic fluorosis area. Iodine was tested in a subset of the children and found not to be significantly different between the two groups.
  - *Potentially important study-specific confounders:* Arsenic often occurs in the drinking water along with fluoride in some Chinese populations; however, based on information provided in Xiang *et al.* (2013), arsenic concentrations were higher in the low fluoride area compared to the high fluoride area.

        - *Direction/magnitude of effect*: Presence of arsenic in this study population would potentially bias towards the null.
    - *Basis for rating:* Probably low risk of bias because there is indirect evidence that the key confounders are taken into account, methods used for collecting the information were valid and reliable, and co-exposures to arsenic and lead and iodine deficiency are not attributing to the effect observed in this area.
- ***Attrition:***
    - *Rating:* Definitely low risk of bias (++)
    - *Summary:* Data are complete. IQ results were reported for all 512 children included in the study (222 in the endemic area and 290 in the nonendemic area).
    - *Basis for rating:* Definitely low risk of bias based on direct evidence that there was no attrition.
- ***Exposure:***
    - *Rating:* Probably low risk of bias (+)
    - *Summary:* Exposure was based on drinking water and urinary levels of fluoride. The two study areas were selected to reflect a severe endemic area and a nonendemic area. Drinking water was collected from wells and early-morning spot urine samples were collected from a randomly-selected subsample of children. Both water and urine samples were measured using fluoride ion-selective electrode, but no quality control was discussed. Both absolute and creatinine-adjusted urine results were reported.
        - *Direction/magnitude of effect*: There is potential for exposure misclassification because only current levels were assessed. Migration of subjects in or out of the area was not assessed, but the study authors noted that, if the children had been absent from the village for 2 or more years, they were excluded. Misclassification would likely be non-differential, which could bias the results in either direction.
    - *Basis for rating:* Probably low risk of bias based on indirect evidence that exposure was consistently assessed using well-established methods that directly measured exposure.
- ***Outcome:***
    - *Rating:* Definitely low risk of bias (++)
    - *Summary:* The IQ of each child was measured with the Combined Raven's Test for Rural China (CRT-RC) (++ for methods). The test was stated to be administered to the children independently in a school classroom, in a double-blind manner, under the supervision of an examiner and two assistants, and in accordance with the directions of the CRT-RC manual regarding test administration conditions, instructions to be given, and test environment. (++ for blinding). Overall rating= ++
    - *Basis for rating:* Definitely low risk of bias based on direct evidence that the outcome was blindly assessed using instruments that were valid and reliable in the study population.
- ***Selective Reporting:***
    - *Rating:* Definitely low risk of bias (++)
    - *Summary:* All outcomes outlined in the abstract, introduction, and methods are reported in sufficient detail.

  - *Basis for rating:* Definitely low risk of bias based on direct evidence that all measured outcomes were reported.
- ***Other potential threats:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:*
    - *Statistical analyses:* Data were stated to be analyzed using SAS without reporting the tests conducted. Results provided in the tables indicate that a t-test was conducted, but it was not reported that homogeneity of variance was tested or confirmed. In addition, correlations were tested with Pearson's correlation.
    - A potential concern raised by the NASEM (2020) peer review was the lack of accounting for relationships in exposure between persons from the same village. However, only two villages were included, and the analyses consisted of village-level comparisons; hence, accounting for clustering was not possible. Without controlling for village effects and given the large differences in fluoride concentrations and IQ between villages, the apparent dose-response relationship could be due to a village effect in addition to a fluoride effect. However, the dose-response relationship is still present within the "exposed" village, diminishing the concern for a village-only effect.
    - *Other potential concerns:* None identified.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that statistical analyses were appropriate and that there were no other threats to risk of bias.
- ***Basis for classification as lower risk-of-bias study overall:*** Definitely or probably low risk-of-bias ratings in confounding, exposure, and outcome. Study strengths include individual exposure measurements and outcomes blindly assessed but is limited by the cross-sectional study design and lack of accounting for urine dilution. All key confounders were considered in the study design or analysis, but there is potential for the presence of arsenic to bias toward the null.

Xiang *et al.* (2011)

Study Details:

- ***Study design*:** Cross-sectional
- ***Population*:** Children aged 8–13 years (same population as Xiang *et al.* (2003a))
- ***Study area:*** Wamiao and Xinhuai villages located in Sihong County, Jiangsu Providence, China
- ***Sample size:*** 512 school children
- ***Data relevant to the review:*** Mean IQ scores and odds ratio for having an IQ < 80 presented by serum fluoride quartiles.
- ***Reported association with fluoride exposure:*** Yes: Significant trend on association between quartiles of serum fluoride and children's IQ score < 80 (adjusted ORs for Q1 and Q2; Q1 and Q3; and Q1 and Q4, respectively: 1; 2.22 [95% CI: 1.42, 3.47]; and 2.48 [95% CI: 1.85, 3.32]); significant effects at ≥ 0.05 ppm fluoride.

Risk of Bias:

- **Author contacts:**
  - Authors were not contacted for additional information because it was not necessary.
- ***Population selection:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* The study population is the same as that was used in the Xiang *et al.* (2003a) study, but a few more measurements were available and different analyses were conducted. The comparison population is considered the same as previously based on the study populations being recruited from similar populations, using similar methods, during the same time frame. Demographic characteristics were not provided.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the exposure groups were similar and were recruited using the same methods within the same time frame, with direct evidence that there was no difference in participation/response rates.
- ***Confounding:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* As was noted in the 2003 publication, information was collected on personal characteristics, medical history, education levels in the children and parents, family SES, and lifestyle. In the logistic regression model, age and gender were adjusted in the analysis. In the previous report, no significant associations were observed between groups for family income and parents' education. Urinary iodine and blood lead levels were also stated to be measured and were noted not to be significantly different between the groups. Although the iodine levels were reported in the previous publication, the lead levels were not reported nor were the methods. Lead information is reported in a letter to the editor (Xiang *et al.* (2003b)) and was not significantly different between the areas. Although arsenic was not addressed specifically in this publication, Xiang *et al.* (2013) measured both fluoride and arsenic in the Wamiao and Xinhuai areas. Xinhuai (the low fluoride area) had significantly higher arsenic levels compared to Wamiao (the endemic fluorosis area). This is likely to bias toward the null; however, the study observed a significantly lower IQ score in the endemic fluorosis area and with increasing serum fluoride.
  - *Potentially important study-specific confounders:* Arsenic often occurs in the drinking water along with fluoride in some Chinese populations; however, based on information provided in Xiang *et al.* (2013), arsenic concentrations were higher in the low fluoride area compared to the high fluoride area.
    - *Direction/magnitude of effect***:** Presence of arsenic in this study population would potentially bias toward the null.
  - *Basis for rating:* Probably low of risk bias because there is indirect evidence that the key confounders are taken into account, methods used for collecting the information were valid and reliable, and co-exposures to arsenic and lead and iodine deficiency are not attributing to the effects observed in this area.
- ***Attrition:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Data are reported for all 512 children noted to be included in the study.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that there was no attrition.

- ***Exposure:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Fluoride levels were measured in serum with a fluoride ion-selective electrode. A fasting venous blood sample was used. No details are provided on validation (including correlation with drinking water levels) or QA. Children who did not reside in their village for at least 2 years were excluded. Results were provided in quartiles, but they combined the lower two quartiles with results ranging from <0.05 mg/L to >0.08 mg/L.
    - *Direction/magnitude of effect***:** Serum fluoride may not be the best estimate for exposure. There is potential for exposure misclassification because only current levels were assessed. Migration of subjects in or out of the area was not assessed, but the study authors noted that, if the children had been absent from the village for 2 or more years, they were excluded. Misclassification would likely be non-differential, which could bias results in either direction.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that exposure was consistently assessed using well-established methods that directly measured exposure.
- ***Outcome:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* IQ was assessed as part of the 2003 evaluation. IQ was measured with the Combined Raven's Test for Rural China which is appropriate for this population (++ for methods). Although this study does not provide details, the original study article from 2003 provides specific details. The study authors indicate in the 2003 publication that the tests were conducted in a double-blind manner and these are the same results and population (++ for methods). Overall rating=++
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that the outcome was blindly assessed using instruments that were valid and reliable in the study population.
- ***Selective Reporting:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* All outcomes outlined in the abstract, introduction, and methods are reported in sufficient detail.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that all measured outcomes were reported.
- ***Other potential threats:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:*
    - *Statistical analyses:* Statistical analyses conducted were appropriate for the study. Chi square tests were used to compare categorical variables, and logistic regression was used to evaluate the association between serum fluoride levels and risk of low IQ. A potential concern raised by the NASEM (2020) peer review was the lack of accounting for relationships in exposure between persons from the same village. However, only two villages were included, and the analyses consisted of village-level comparisons; hence, accounting for clustering was not possible. Without controlling for village effects and given the large differences in

fluoride concentrations and IQ between villages, the apparent dose-response relationship could be due to a village effect in addition than a fluoride effect. However, the dose-response relationship is still present within the "exposed" village, diminishing the concern for a village-only effect.

- *Other potential concerns:* None identified.

- *Basis for rating:* Definitely low risk if bias based on direct evidence that the statistical analyses were appropriate and there were no other potential threats to risk of bias identified.

- ***Basis for classification as lower risk-of-bias study overall:*** Definitely or probably low risk-of-bias ratings in confounding, exposure, and outcome. Study strengths include individual exposure measurements with blinding at outcome assessment but is limited by the cross-sectional study design and use of serum concentrations. All key confounders were considered in the study design or analysis, but there is potential for the presence of arsenic to bias toward the null.

Yu *et al.* (2018)

Study Details:

- ***Study design*:** Cross-sectional
- ***Population*:** Children aged 7–13 years
- ***Study area:*** Tianjin City, China
- ***Sample size:*** 2,886 school children
- ***Data relevant to the review:*** IQ for normal (≤ 1 mg/L) versus high (> 1 mg/L) water fluoride; betas for IQ score by water and urine fluoride groupings; ORs by IQ category using water and urine fluoride levels.
- ***Reported association with fluoride exposure:*** Yes: Significant difference (p = 0.036) in mean IQ scores in high (106.4 ± 12.3) versus normal (107.4 ± 13.0) water fluoride areas. Distribution of IQ scores was also significantly different (p = 0.003); every 0.5-mg/L increase in water fluoride (between 3.40 and 3.90 mg/L) was associated with an IQ score 4.29 points lower (95% CI: −8.09, −0.48).

Risk of Bias:

- **Author contacts:**
  - Authors were contacted in September 2018 to obtain additional information for the risk-of-bias evaluation.
- ***Population selection:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* School children (2,886), aged 7–13 years, were recruited from the rural areas of Tianjin City, China. After exclusion, 1,636 children were assigned to the "normal-fluoride" exposure group and 1,250 were assigned to the "high-fluoride" exposure group based on a cut-off water fluoride level of 1.0 mg/L. A multi-stage random sampling technique, stratified by area, was performed to select representative samples among local children who were permanent residents since birth. Detailed characteristics of the study population are provided. Exclusion criteria included: 1) children who had

congenital or acquired diseases affecting intelligence, 2) children with a history of cerebral trauma and neurological disorders, 3) children with a positive screening test history (like hepatitis B virus infection, Treponema palladium infection and Down's syndrome), and 4) children with adverse exposures (smoking and drinking) during maternal pregnancy. A table of characteristics was provided by fluoride level with differences adjusted in the analysis.

- *Basis for rating:* Definitely low risk of bias based on direct evidence that the exposed groups were recruited using similar methods during the same time frame and that any differences between the exposed groups were considered in the statistical analyses.

- ***Confounding:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Demographic data were collected by trained investigators during a face-to-face interview with the recruited children and their parents. Questionnaires were not stated to be validated. The developmental status of the children was further assessed by calculation of BMI, and all measurements were conducted by nurses based on recommended standard methods. Variables that presented differential distribution between the normal-fluoride and high-fluoride exposure groups were adjusted in the linear regression analysis of IQ data and included age, sex, paternal and maternal education levels, and low birth weight. Children exposed to smoking in utero were excluded from the study. Sensitivity analyses were conducted by modifying covariates adjusted in multivariable models among demographics (age and sex); development (BMI); socioeconomics (maternal education, paternal education, and household income); history of maternal disease during pregnancy (gestational diabetes, malnutrition, and anemia); and delivery conditions (hypoxia, dystocia, premature birth, post-term birth, and low birth weight). None of the study sites selected were in areas endemic for iodine deficiency disorders nor were other potential neurotoxins like lead, arsenic, and mercury present. Variables such as parental BMI and behavioral and mental health disorders were not addressed.
  - *Potentially important study-specific confounders:* All key confounders were considered in this study.
    - *Direction/magnitude of effect***:** Not applicable.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that methods of obtaining the information were valid and reliable and direct evidence that all key confounders and co-exposures were addressed.
- ***Attrition:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* There were 1,636 children assigned to the "normal-fluoride" exposure group based on water fluoride, and 1,250 children were assigned to the "high-fluoride" exposure group. Exclusion from the original group of 2,886 children was adequately described. A total of 2,380 children provided urine samples. There is no indication that the data presented excludes any additional children or urine samples, but results do not indicate a sample size for all results.

- *Basis for rating:* Probably low risk of bias based on indirect evidence that exclusion of subjects from analyses was adequately addressed, and reasons were documented when subjects were removed from the study or excluded from analyses.

- ***Exposure:***
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* According to the annual surveillance data from the CDC, the drinking water sources and water fluoride concentrations in each village had remained at stable levels over the past decade. During the investigation, water samples were collected randomly from the public water supplies in each village. Spot (early-morning) urine samples from every child and water samples from each village were collected in pre-cleaned, labeled polythene tubes and transported to the lab within 24 hours while frozen. Samples were stored at −80°C until analysis. Concentrations of fluoride ions (mg/L) were analyzed using the national standardized ion-selective electrode method in China; the detection limit was 0.01 mg/L. Samples were diluted with an equal volume of total ionic strength adjusted buffer (TISAB) of pH 5–5.5 for optimal analysis. Double-distilled deionized water was used throughout the experiment. There is no reporting of any QC methods.
    - *Direction/magnitude of effect*: Spot urine samples may lead to non-differential exposure misclassification. The large population size likely dilutes any potential effects of occasional misclassification. Because the drinking water sources of fluoride had been noted to be stable for the past decade and the children were 13 years or younger, there would only be exposure misclassification if there was a lot of migration between areas.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that exposure was consistently assessed using well-established methods that directly measured exposure.

- ***Outcome:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* IQ scores were measured using the second edition of Combined Raven's Test-The Rural in China (CRT-RC2) for children aged 7–13 years (++ for methods). The test was completed by each participant within 40 minutes according to the instruction manual. For each test, 40 children were randomly allocated to one classroom to take the test independently under the supervision of four trained professionals. There is no mention of whether the evaluators were blinded to the fluoride group of each child (normal vs. high fluoride) or whether there were steps taken to ensure consistency in scoring across the evaluators. It is also not clear if the 40 children randomly assigned to the classroom were specific to the village or if a local center was used. Correspondence with the study authors indicated that the four professionals worked together throughout the examination without knowledge of the child's fluoride exposure (++ for blinding).
  - *Basis for rating:* Definitely low risk of bias based on the direct evidence that the outcome was blindly assessed using instruments that were valid and reliable.

- ***Selective Reporting:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* All outcomes outlined in the abstract, introduction, and methods are reported in sufficient detail.

  - *Basis for rating:* Definitely low risk of bias based on direct evidence that all measured outcomes were reported.
- ***Other potential threats:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:*
    - *Statistical analyses:* Statistical analyses used were appropriate for the study.
    - *Other potential concerns:* None identified.
  - *Basis for rating:* Definitely low risk if bias based on direct evidence that the statistical analyses were appropriate and there were no other potential threats to risk of bias identified.
- ***Basis for classification as lower risk-of-bias study overall:*** Definitely or probably low risk-of-bias ratings in confounding, exposure, and outcome. Study strengths include individual exposure measurements with blinding at outcome assessment but is limited by the cross-sectional study design and lack of accounting for urine dilution. All key confounders including potential co-exposures were considered in the study design or analysis.

Zhang *et al.* (2015b)

Study Details:

- ***Study design*:** Cross-sectional
- ***Population*:** Children aged 10–12 years
- ***Study area:*** Tianjin City, China
- ***Sample size:*** 180 children
- ***Data relevant to the review:*** IQ by control and high fluoride groups; IQ correlations with water, serum, or urinary fluoride levels; betas for IQ with urinary fluoride levels (by genotypes)
- ***Reported association with fluoride exposure:*** Yes: Significant correlation between IQ score and serum fluoride (r = –0.47) and urinary fluoride (r = –0.45); significant difference in IQ score for high-fluoride area (>1 mg/L; 102.33 ± 13.46) compared with control area (<1 mg/L; 109.42 ± 13.30).

Risk of Bias:

- **Author contacts:**
  - Authors were not contacted for additional information because it was not necessary.
- ***Population selection:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary*: Subjects were similar and recruited during the same time frame using the same methods. Authors recruited schoolchildren from a high fluoride area (1.40 mg/L) and a control area (0.63 mg/L) in Tianjin City, China. In accordance with the principles of matching social and natural factors such as educational standard, economic situation, geological environments as much as possible, two areas with different fluoride concentrations in the groundwater were selected by a stratified cluster random sampling of this region. A total of 180 5th grade children aged 10 to 12 years from two primary schools located 18 km apart in the Jinnan District were recruited—Gegu Second

Primary School (from an endemic fluorosis area) and Shuanggang Experimental Primary School (from a non-endemic fluorosis area). The areas are not affected by other drinking water contaminants, such as arsenic or iodine. All subjects were unrelated ethnic Han Chinese and residents in Tianjin with similar physical and mental health status. The authors excluded subjects with known neurological conditions including pervasive developmental disorders and epilepsy. Descriptive statistics of the study population are presented by exposure group in Table 1 of the study. A number of potential differences are taken into account in the statistical analyses.

- *Basis for rating*: Definitely low risk of bias based on direct evidence that the exposure groups were similar and recruited using similar methods during the same time frame.

- **Confounding:**
  - *Rating:* Probably low risk of bias (+)
  - *Summary:* Covariates included in the statistical models were child's age, child's gender, educational levels of parents, drinking water fluoride (mg/L), and levels of thyroid hormones (T3, T4, and TSH). Authors report that the study areas are not affected by other contaminants such as arsenic or iodine and residents were of similar physical and mental health status. Other important confounders (maternal demographics, smoking, reproductive health) were not considered. Covariate data were obtained from a study questionnaire.
  - *Potentially important study-specific confounders:* All key confounders were considered in this study.
    - *Direction/magnitude of effect*: Not applicable.
  - *Basis for rating:* Probably low risk of bias based on indirect evidence that the methods used to collect the information were valid and reliable and direct evidence that key confounders including potential co-exposures were addressed.
- ***Attrition:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Results are complete for the 180 children selected for the study.
  - *Basis for rating:* Definitely low risk of bias based on direct evidence that there was no attrition.
- ***Exposure:***
  - *Rating:* Definitely low risk of bias (++)
  - *Summary:* Drinking water samples (10 mL) were collected from the tube wells of each child's household. Three fasting venous blood samples were also collected. Urine samples were collected in the early morning before breakfast. Fluoride contents in drinking water (W-F), serum (S-F), and urine (U-F) were measured using an ion analyzer EA940 with a fluoride ion-selective electrode (Shanghai constant magnetic electronic technology Co, Ltd, China) according to the China standard GB 7484-87. All reference solutions for the fluoride determinations were double-deionized water. Parallel samples were set for determination and averages were taken. The quantitation limits of this method for W-F, S-F, and U-F were 0.2, 0.012, and 0.5 mg/L, respectively. Recovery rates for this method were in the range of 94.3%–106.4%. The intra- and inter-assay coefficients of variation for fluoride were 2.7% and 6.7%, respectively. Dilution of the urinary fluoride was not addressed.

        - *Direction/magnitude of effect*: Not applicable.
    - *Basis for rating:* Definitely low risk of bias based on direct evidence that the exposure was consistently assessed using well-established methods that directly measured exposure.
- ***Outcome:***
    - *Rating:* Definitely low risk of bias (++)
    - *Summary:* A Combined Raven's Test for Rural China (CRT-RC) was taken to evaluate the IQ of each child (++ for methods). The study report stated that all tests were administered at school by a trained examiner who was masked to participants' drinking water fluoride levels (++ for blinding). Overall rating for methods and blinding=++.
    - *Basis for rating:* Definitely low risk of bias based on direct evidence that the outcome was blindly assessed using instruments that were valid and reliable in the study population.
- ***Selective Reporting:***
    - *Rating:* Definitely low risk of bias (++)
    - *Summary:* All results outlined in the abstract, introduction, and methods sections were reported in sufficient detail.
    - *Basis for rating:* Definitely low risk of bias based on direct evidence that all measured outcomes were reported.
- ***Other potential threats:***
    - *Rating:* Definitely low risk of bias (++)
    - *Summary:*
        - *Statistical analyses:* Statistical methods are very well-documented including testing for normality of the data.
        - *Other potential concerns:* None identified.
    - *Basis for rating:* Definitely low risk if bias based on direct evidence that the statistical analyses were appropriate and there were no other potential threats to risk of bias identified.
- ***Basis for classification as lower risk-of-bias study overall:*** Definitely or probably low risk-of-bias ratings in confounding, exposure, and outcome. Study strengths include individual exposure measurements, outcomes blindly assessed, and assessment of potential key confounders including potential co-exposures.

Appendix 5. Results of Fluoride Meta-analyses

What is the strength of the relationship between exposure to fluoride and children's IQ?

Aim 1. To update existing meta-analyses with additional studies

Approach

The approach used to perform a meta-analysis of the associations between exposure to fluoride and children's IQ levels was outlined in the associated protocol (https://ntp.niehs.nih.gov/go/785076). Details are presented below.

The mean-effect meta-analysis included studies that reported effect estimates as mean outcome measures and included measures of uncertainty such as standard deviation (SD), standard error (SE), 95% CI, and number of subjects (N) for at least one exposed and one reference exposure group. If results from multiple exposure groups were reported within a single study, the highest exposure group was considered the "exposed" group and the lowest exposure group was considered the "reference" group. A sensitivity analysis was performed to evaluate the impact of using any exposed group compared to the reference group (**Figure A-25**). This was accomplished by combining the information from the exposure groups using the approach outlined in the Cochrane Handbook for Systematic Reviews (Higgins *et al.* 2019).

When results were not reported for gender-specific groups or age-specific subgroups (<10, ≥10), they were calculated (if possible) by combining groups, following the approach outlined in the Cochrane Handbook for Systematic Reviews (Higgins *et al.* 2019). Similarly, when only mean effects, Ns, and p-values for differences between groups are reported (Lin *et al.* 1991), SDs were calculated using the SE and t-statistic (assuming equal variances) (Higgins *et al.* 2019).

The meta-analysis pooled the standardized mean difference and corresponding 95% CI using a random-effects model. Heterogeneity was assessed by Cochran's Q test (Cochran 1954) and the I^2 statistic. Forest plots were used to display results and to examine possible heterogeneity between studies. Potential publication bias was assessed by developing funnel plots and performing Egger regression on the estimates of effect size (Begg and Mazumdar 1994, Egger *et al.* 2008, Egger *et al.* 1997). If publication bias was believed to be present, trim-and-fill methods (Duval and Tweedie 2000a, b) were used to estimate the number of missing studies affected by publication bias, assess the effect of those studies on the effect estimate, and predict the impact of the hypothetical "missing" studies. To investigate sources of heterogeneity, subgroup analyses were performed by risk-of-bias evaluation, gender, age group, country, type of intelligence assessment, and type of exposure.

There were 46 studies included in the mean-effect meta-analysis (see **Table A5-1**). **Table A-2** presents information on the studies excluded from the analysis because of missing information on the number of subjects and/or the mean or variance of the outcome. Other studies were excluded because of overlapping study populations. For studies with overlapping populations (i.e., multiple studies that use the same cohort), results were selected with the most information considering the following factors: exposure metric, exposure range, exposure period, number of subjects, and statistical adjustment for potential confounders. Other studies were excluded from the mean-effect meta-analysis because they reported individual-level effects.

Summary Results

Table A5-1. Pooled SMDs and 95% CIs for Children's IQ Score and Exposures to Fluoride				
			Heterogeneity	
Analysis	**Number of Studies**	**SMD (95% CI)**	**p-value**	**I^2**
Overall Effect	46	−0.50 (−0.61, −0.39)	<0.001	89%
Subgroup Analyses				
Risk of Bias				
Lower	9	−0.31 (−0.52, −0.10)	<0.001	87%
Higher	37	−0.56 (−0.68, −0.43)	<0.001	88%
Gender[1]				
Males	12	−0.78 (−0.99, −0.56)	<0.001	75%
Females	11	−0.65 (−0.85, −0.45)	0.001	66%
Age Group				
<10 years[1]	10	−0.55 (−0.79, −0.30)	<0.001	83%
≥ 10 years	11	−0.58 (−0.78, −0.38)	<0.001	76%
Country				
China	31	−0.44 (−0.54, −0.33)	<0.001	86%

Iran	4	−0.68 (−0.99, −0.38)	0.077	56%
Assessment Type				
CRT-RC tests	23	−0.36 (−0.47, −0.26)	<0.001	81%
Non-CRT-RC tests	23	−0.67 (−0.87, −0.47)	<0.001	90%
Raven's tests	10	-0.76 (−1.10, −0.43)	<0.001	91%
Other tests	13	−0.62 (−0.88, −0.35)	<0.001	90%
Exposure Type				
Water fluoride	28	−0.45 (−0.57, −0.34)	<0.001	85%
Dental fluorosis	7	−0.99 (−1.57, −0.41)	<0.001	96%
Other exposures[2]	11	−0.47 (−0.67, −0.27)	<0.001	85%
Sensitivity Analysis				
Any exposure *vs.* reference	46	−0.46 (−0.58, −0.35)	<0.001	92%
Previous Meta-analyses				
Duan *et al.* (2018)	26	−0.52 (−0.62, −0.42)	<0.001	69%
Choi *et al.* (2012)	27	−0.45 (−0.56, −0.34)	<0.001	80%

Notes:
CI = confidence interval; CRC-RC = Combined Raven's Test–The Rural edition in China; SMD = standardized weighted mean difference
[1]An *et al.* (1992) includes 10-year-old children in the <10 age group (7−10 years reported).
[2]Includes iodine (Ren *et al.* 1989 [translated in Ren *et al.* 2008], Lin *et al.* 1991, Wang *et al.* 2001); arsenic (Zhang *et al.* 1998, Wang *et al.* 2007); aluminum (Sun *et al.* 1991); and non-drinking water fluoride (i.e., fluoride from coal burning (Guo *et al.* 1991 [translated in Guo et al. 2008a], Li *et al.* 1994 [translated in Li et al. 2008b], Li *et al.* 1995, Wang *et al.* 1996 [translated in Wang et al. 2008b], Wang *et al.* 2005, Li *et al.* 2009, Bai *et al.* 2014)).

Overall Effect (Main Analysis)

For the group-level exposure meta-analysis, a comparison on the mean outcome measure (IQ score) was conducted across two exposure groups ("exposed" and "reference"). The random-effects pooled SMD estimated from the 46 studies included in the meta-analysis was −0.50 (95% CI: −0.61, −0.39). There was evidence of heterogeneity (I^2 = 89%, p < 0.001; **Table A5-1** and **Figure A5-1**) and publication bias (funnel plot and Egger's test p < 0.001, Begg's test p = 0.08; **Figure A5-2** and **Figure A5-3**). Eliminating publication bias through trim-and-fill analysis continued to support the finding that exposure to fluoride is associated with lower IQ in children, with an adjusted pooled effect estimate of −0.42 (95% CI: −0.54, −0.30) (**Figure A5-4** and **Figure A5-5**).

Aravind *et al.* (2016), Kundu *et al.* (2015), and Razdan *et al.* (2017) studies were excluded from the main analysis due to uncertainties about the way IQ assessments for children were performed in those studies. A sensitivity analysis was conducted that included these studies (**Figure A-35**).

Subgroup Analyses

Risk of Bias

Subgroup analysis by risk-of-bias evaluation showed that exposure to fluoride is associated with lower IQ scores in children for both higher and lower risk-of-bias studies (**Figure A5-6**), with a more severe effect for the higher risk-of-bias studies. The funnel plots and Egger's and Begg's tests of publication bias showed evidence of publication bias only among higher risk-of-bias studies (**Figure A-1**, **Figure A-2**). Eliminating publication bias through trim-and-fill analysis continued to support that exposure to fluoride is associated with lower IQ scores in children, with an adjusted pooled effect estimate of −0.35 (95% CI: −0.50, −0.21) (**Figure A-4**). There was no evidence of publication bias among lower risk-of-bias studies.

Gender

Subgroup analysis by gender showed that exposure to fluoride is associated with lower IQ scores in both males and females (**Figure A5-11)**. There was a slight suggestion of publication bias in the Egger's test for males, but not females (**Figure A-5** and **Figure A-6**). Eliminating publication bias through trim-and-fill analysis continued to support that exposure to fluoride is associated with lower IQ scores in males, with an adjusted pooled SMD estimate of −0.68 (95% CI: −0.90, −0.46) (**Figure A-8**).

Age Group

Subgroup analysis by age group showed that exposure to fluoride is associated with lower IQ scores in children regardless of age group (<10 years or ≥10 years) (**Figure A5-12**). The funnel plots and Egger's and Begg's tests of publication bias showed evidence of publication bias in children younger than 10 years old (**Figure A-9** and **Figure A-10**). Eliminating publication bias through trim-and-fill analysis for studies in children younger than 10 years old continued to support that exposure to fluoride is associated with lower IQ in children, with an adjusted pooled effect estimate of −0.55 (95% CI: −0.79, −0.30) (**Figure A-10**). There was no suggestion of publication bias in the subgroup analyses for children 10 years old and older.

Country

Subgroup analysis by country showed that exposure to fluoride is associated with lower IQ scores in children in China, India, and Iran (**Figure A5-13**), with the largest effect in India. A funnel plot with the SEs of the SMD plotted against the SMD from each study showed slight evidence of publication bias in India (**Figure A-11**). In addition, Egger's and Begg's tests of publication bias revealed evidence of publication bias for studies in India (p < 0.001, **Figure A-12**). Eliminating publication bias through trim-and-fill analysis for studies in India continued to support that exposure to fluoride is associated with

lower IQ in children, with an adjusted pooled effect estimate of −1.49 (95% CI: −2.15, −0.83) (**Figure A-13**). There was no suggestion of publication bias in the subgroup analyses for China or Iran.

Assessment Type

Subgroup analysis by assessment type showed that exposure to fluoride is associated with lower IQ scores in children tested using non-CRT-RC tests than using CRT-RC tests (**Figure A5-14**). The funnel plots and Egger's and Begg's tests of publication bias showed evidence of publication bias only among non-CRT-RC and Raven's tests (**Figure A-15** and **Figure A-16**). Eliminating publication bias through trim-and-fill analysis for studies with Raven's tests continued to support that exposure to fluoride is associated with lower IQ scores in children, with an adjusted pooled SMD estimate of −1.22 (95% CI: −1.68, −0.75) (**Figure A-19** and **Figure A-20**). There was no suggestion of publication bias in the subgroup analysis for studies using CRT-RC or other types of tests.

Exposure Type

Subgroup analysis by exposure type showed that exposure to fluoride is associated with lower IQ scores in children in studies that reported mean effects by fluoride exposure type (**Figure A5-15**). The funnel plots and Egger's test of publication bias showed evidence of publication bias for water fluoride and dental fluorosis (**Figure A-21** and **Figure A-22**). Eliminating publication bias through trim-and-fill analysis continued to support that exposure to fluoride in water is associated with lower IQ scores in children, with an adjusted pooled SMD estimate of −0.42 (95% CI: −0.53, −0.30) (**Figure A-23** and **Figure A-24**). There was no suggestion of publication bias in the subgroup analysis for studies with other exposures or non-drinking water fluoride exposures.

Overall Analysis

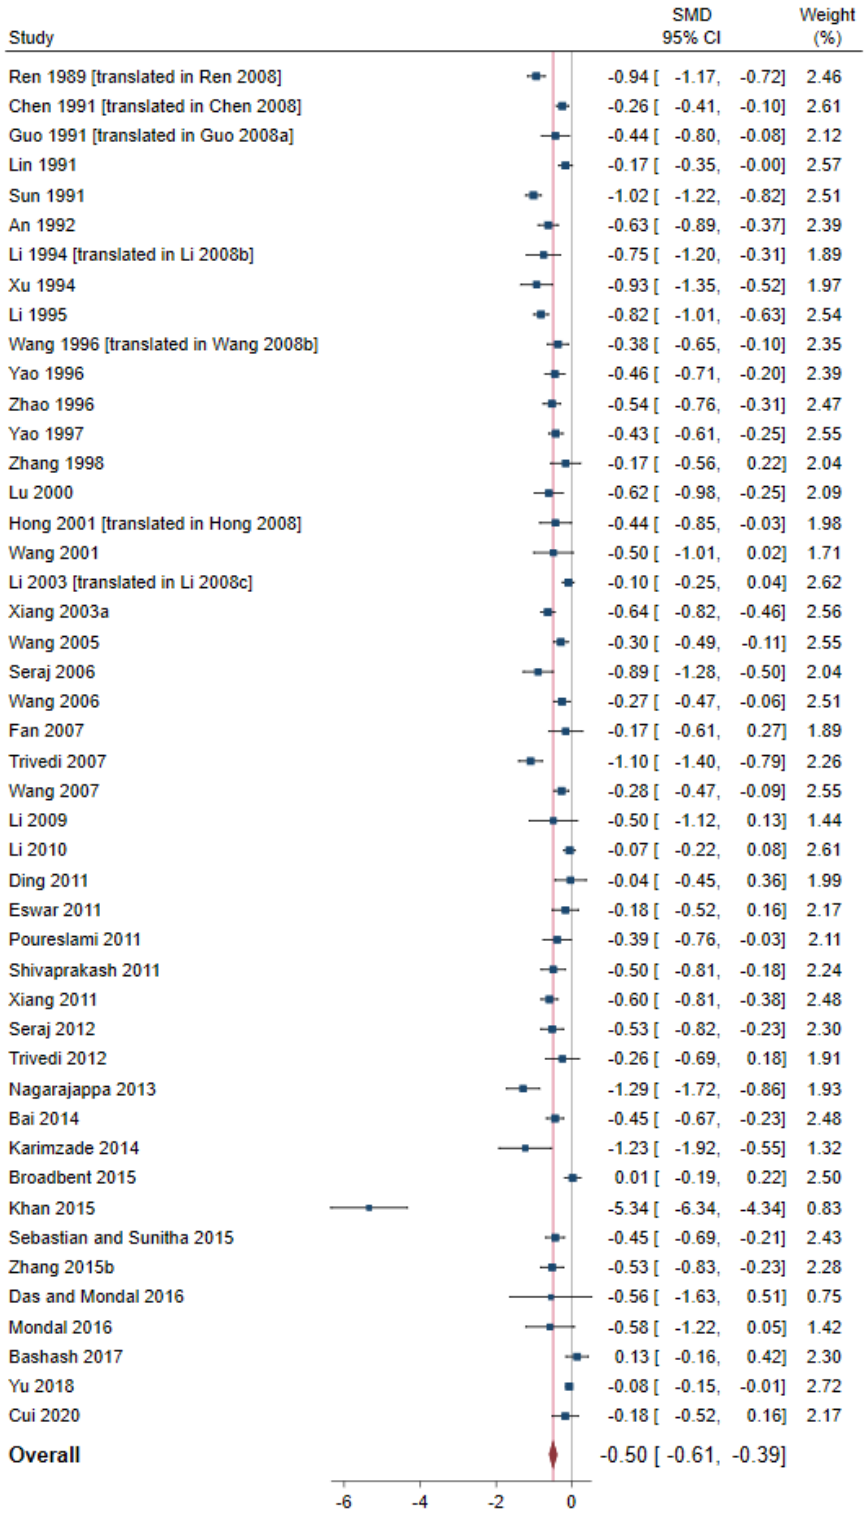

Figure A5-1. Association Between Fluoride Exposure and IQ Scores in Children: Overall Analysis

SMDs for individual studies are shown with solid boxes representing the weight, and the random-effects pooled SMD is shown as a solid diamond. Horizontal lines represent 95% CIs for the study-specific SMDs.

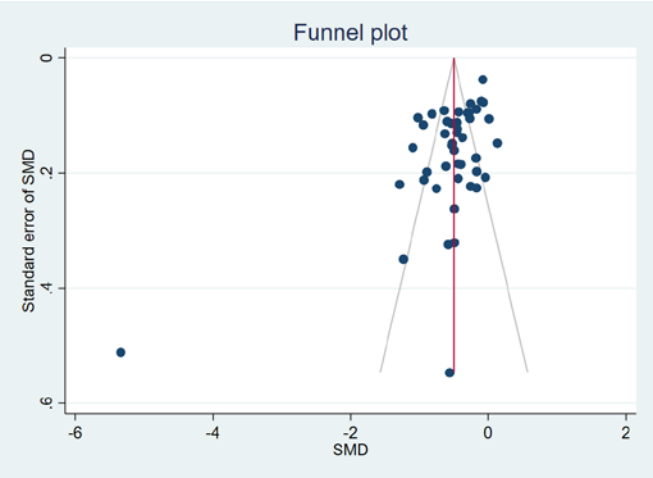

Figure A5-2. Funnel Plot of Included Studies

This funnel plot shows individual studies included in the analysis according to random-effect standardized weighted mean difference (SMD) estimates (x-axis) and the standard error (SE) of each study-specific SMD (y-axis). The solid vertical line indicates the pooled SMD estimate for all studies combined and the dashed lines indicated pseudo 95% confidence limits around the pooled SMD estimate.

Exposure types include water, dental fluorosis, and other exposures (iodine, arsenic, aluminum, and fluoride from coal burning).

Aim 2. To conduct new meta-analyses using individual-level exposure data

Approach

The individual-effect meta-analysis included studies that reported effect estimates as betas and included 95% CIs or SEs (see **Table B-1**). Adjusted effect estimates were used in the meta-analysis. If results from multiple models were reported within a single study, the most adjusted results were selected. The study outcomes were evaluated with respect to a 1-mg/L unit increase in exposure. To ensure consistent units across studies, units of exposure were transformed to mg/L as needed. For Bashash *et al.* (2017), Yu *et al.* (2018), and Till *et al.* (2020), units of exposure were transformed to levels ranging from 0.5 to 1 mg/L. For Cui *et al.* (2018), units of exposure were transformed from 1 log mg/L to 1 mg/L. Cui *et al.* (2018) reported an association between IQ and log-transformed exposure. A sensitivity analysis was performed to evaluate the impact of using Cui *et al.* (2018), since the relationship between IQ and exposure evaluated in this study was not linear (as in the other studies included). Yu *et al.* (2018) reported estimates from piecewise linear regression models, with three estimated ranges for urinary fluoride exposure (low 0.01−1.60 mg/L, medium 1.60−2.50 mg/L, and high 2.50−5.54 mg/L) and two estimated ranges for water fluoride exposure (low 0.20−3.40 mg/L and high 3.40–3.90 mg/L). Because these piecewise effect estimates are likely correlated, study-specific pooled effect estimates were used for urinary and water fluoride exposures for the overall effect meta-analysis. A sensitivity analysis was performed to evaluate the impact of using the pooled estimate rather than the piecewise estimates from Yu *et al.* (2018).

Yu *et al.* (2018) and Wang *et al.* (2020b) used the same study cohort of children recruited in 2015 from the rural areas of Tianjin City, China. Only results from Yu *et al.* (2018) were included in the meta-analysis since Wang *et al.* (2020b) used a subset (n = 571) of the original study population from Yu *et al.* (2018) (n = 2,668). A sensitivity analysis was conducted to evaluate the impact of using the effect estimate from Wang *et al.* (2020b) rather than the pooled effect estimate from Yu *et al.* (2018).

Green *et al.* (2019) and Till *et al.* (2020) used the same cohort of 398 mother-child dyads in the Maternal-Infant Research on Environmental Chemicals (MIREC) cohort that reported drinking tap water in 10 Canadian cities. Both studies reported effect estimates for maternal urinary fluoride (MUF) and water fluoride concentrations. In the Green *et al.* (2019) study, 512 mother-child pairs had MUF data (and all covariates) compared to 398 pairs in Till *et al.* (2020). Water fluoride levels were available for 420 pairs in Green *et al.* (2019) compared to 398 pairs in Till *et al.* (2020). Both references reported effect estimates adjusted for maternal education, maternal race, child's sex, HOME total score, and secondhand smoking status in the child's residence. In addition, Till *et al.* (2020) adjusted for child's age at IQ testing. The age range for study subjects was 3–4 years old. For the main analysis, results from Green *et al.* (2019) were included. A sensitivity analysis was conducted using the water fluoride result for formula-fed children and the MUF result from Till *et al.* (2020) since these are most adjusted compared to Green *et al.* (2019). For fluoride intakes, estimates from both studies were used including total fluoride intake from Green *et al.* (2019) and infant formula intake from Till *et al.* (2020).

In the overall effect analysis, for studies reporting multiple measures of fluoride exposure, results associated with measured or estimated individual-level exposures, biomarker levels (such as urinary fluoride), or fluoride intake were prioritized over results associated with water fluoride concentrations. Subgroup analyses were performed that considered all exposure types. All studies used in these analyses with individual-level effects were lower risk of bias.

The overall effect based on studies with individual-level measures of exposure showed that a 1-unit increase in fluoride exposure was associated with a significantly lower IQ score (beta = −1.40; 95% CI: −2.33, −0.47) (**Table A5-2**). A 1-mg/day increase in fluoride intake resulted in significantly lower IQ score (beta = −3.31; 95% CI: −6.12, −0.50). A 1-mg/L increase in water fluoride also resulted in significantly lower IQ score (beta = −4.77; 95% CI: −9.10, −0.45). The results for fluoride intake and water fluoride, however, are based on two studies and should be interpreted with caution.

There was evidence of moderate heterogeneity (I^2 = 46%, p = 0.101; **Table A5-2**, **Figure A5-16,** and **Figure A5-17**) in studies with individual-level urinary exposure levels. Eliminating publication bias through trim-and-fill analysis continued to support that 1-mg/L increases in individual-level urinary or water fluoride were associated with lower IQ scores, with an adjusted pooled effect estimate of −0.82 (95% CI: −1.81, 0.17) (**Figure A5-19**).

A sensitivity analysis to evaluate the impact of using the piecewise estimates from Yu *et al.* (2018) revealed no significant change in the pooled effect estimate (−1.37; 95% CI: −2.38, −0.37) (**Figure B-1**). A sensitivity analysis to evaluate using estimates from Wang *et al.* (2020b) rather than Yu *et al.* (2018) study also revealed no significant change in the pooled effect estimate (−1.24; 95% CI: −1.94, −0.54) (**Figure B-6**). A sensitivity analysis using the water fluoride result for formula-fed children and the MUF result from Till *et al.* (2020) (rather than Green *et al.* (2019)) suggested no significant change in the overall pooled effect estimate (−1.50; 95% CI: −2.44, −0.57) (**Figure B-11**).

Summary Results

Note: The analyses for publication bias for CRT-RC studies and non-CRT-RC studies include only four and two studies, respectively, and are not shown.

Gender Subgroup Analysis

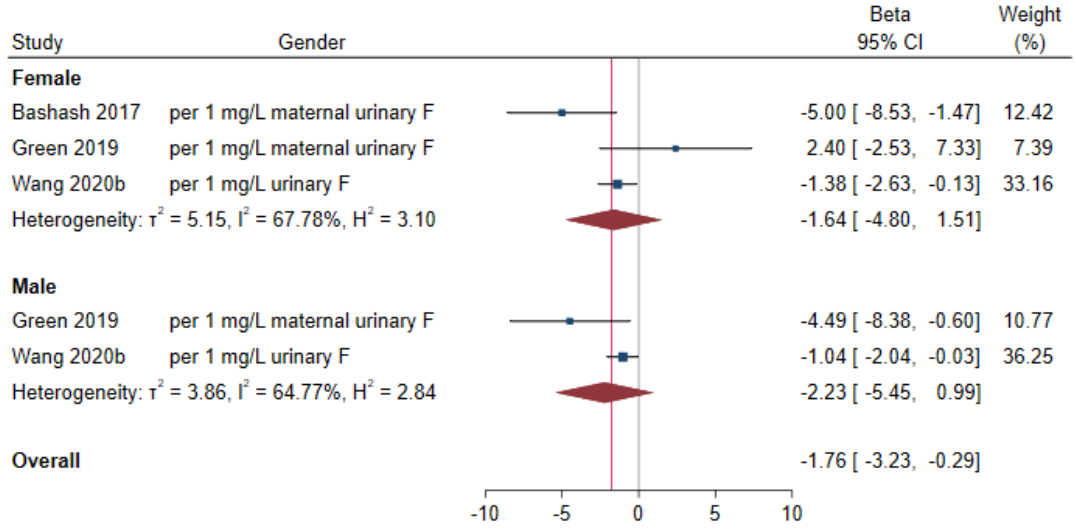

Figure A5-25. Association Between Individual-level Fluoride Exposure and IQ Scores in Children: Effect by Gender

Note: The analysis for publication bias by gender relies on two or three studies each and are not shown.

Dose-response meta-analyses using mean-effect estimates

Approach

For the dose-response meta-analysis using the mean-effect estimates, a one-step approach developed in the protocol (https://ntp.niehs.nih.gov/go/785076) and Crippa *et al.* (2018) was used. The approach uses linear mixed models to analyze all available data, including studies with one nonreference group. For each study, the median or mean fluoride intake for each exposure group was assigned to its corresponding effect estimate. If median or mean intakes by exposure group were not provided, the midpoint of the upper and lower boundaries in every category was assigned as the average intake. If the upper boundary for the highest exposure group was not reported, the boundary was assumed to have the same amplitude as the nearest category. For each study, the SMDs and corresponding SEs are used to compare the differences in mean IQ between the exposed and reference groups. The corresponding SMD for the reference group is set to zero for this analysis. The SMDs and corresponding variances are used to estimate a pooled dose-response curve using a restricted maximum likelihood estimation method. To examine a potential nonlinear relationship between exposure to fluoride and children's IQ levels, quadratic terms and restricted cubic splines were created, and a potential departure from a linear trend was assessed by testing the coefficient of the quadratic term and a second spline equal to zero. Models were compared and best model fit was determined based on the Akaike information criterion (AIC) (Müller *et al.* 2013).

A dose-response meta-analysis using the effect estimates reported in studies with individual-level exposure was considered. However, because of the small number of studies (n = 10), the various types of exposure metrics, and the different types of reported effect estimates that could not be combined, a dose-response meta-analysis of these studies could not be conducted.

Summary Results

Characteristics of the studies that compared mean IQ scores among groups of children with different levels of fluoride exposure are shown in **Table A-1**.

The meta-analysis combining data from 31 studies with fluoride levels in drinking water showed a significantly lower children's IQ score with increasing exposure (**Table A5-3** A5-3). Based on the AIC, the best model fit was achieved when restricted cubic splines with three knots were added to the linear model. However, given the small difference in AICs between the different models, and for ease of interpretability, the linear model results were chosen for the purposes of discussion although results from all models are presented in **Table A5-3.** Based on the linear model, the decrease in mean SMD between exposed and reference groups was −0.14 (95% CI: −0.19, −0.08) (**Table A5-3**). When the analysis was restricted to studies with the "high" group exposed to < 1.5 mg/L fluoride in drinking water (n = 9; 2 lower risk-of-bias studies and 7 higher risk-of-bias studies), the mean SMD became positive and nonsignificant (0.32; 95% CI: −0.57, 1.20). However, when including groups exposed to < 2 mg/L fluoride in drinking water, the mean SMD in children's IQ scores was both negative and statistically significant (SMD = −0.27; 95% CI: −0.36, −0.17) (n = 9; 2 lower risk-of-bias studies and 7 higher risk-of-bias studies).

The meta-analysis combining data from 9 studies with fluoride levels in urine showed a significantly lower children's IQ with increasing exposure (SMD = −0.18; 95% CI: −0.31, −0.05) (**Table A5-3**). Based on AIC, the best model fit was the linear model (**Table A5-3**). There was no improvement in the fit of the model when a quadratic term or restricted cubic splines were added to the linear model (**Table A5-3**). When the analyses were restricted to studies with the "high" group with < 1.5 mg/L fluoride in urine (n = 4; 2 lower risk-of-bias studies and 2 higher risk-of-bias studies), the direction of the effect did not

change, but it was no longer statistically significant (SMD = −0.13; 95% CI: −0.29, 0.03). When the dose-response meta-analysis was extended to include exposed groups with < 2 mg/L urinary fluoride (n = 6; 3 lower risk-of-bias studies and 3 higher risk-of-bias studies), the mean SMD remained negative and not statistically significant (−0.25; 95% CI: −0.71, 0.22).

Dose-Response Meta-analysis Using Mean Effects—Model Selection

Table A5-3. Model Comparison for Dose-response Meta-analysis for Children's IQ Scores (SMDs) and Exposures to Fluoride: Parameter Estimates and Model Fit[1]

Analysis	No. of Studies/ No. of Observations	Linear Model[2]	Quadratic Model[3]	Restricted Cubic Splines Model[4]

Reference[1]	Study Location	Age Range (Years)	Fluoride Exposure		Intelligence Assessment	Overall RoB Rating	Confounders Considered
			Assessment (Metric, Exposure Groups)	Range			
Li *et al.* (2009)[u*]	China	8–12	Urine Endemic fluorosis region caused by coal burning (severe/medium/mild/reference) Degree of dental fluorosis (severe/medium/mild/very mild/suspected/normal)	0.962 ± 0.517 mg/L (reference) 1.235 ± 0.426 mg/L (mild endemic region) 1.670 ± 0.663 mg/L (medium endemic region) 2.336 ± 1.128 mg/L (severe endemic region) 0.867 ± 0.233 mg/L (normal fluorosis) 1.094 ± 0.355 mg/L (suspected fluorosis) 1.173 ± 0.480 mg/L (very mild fluorosis) 1.637 ± 0.682 mg/L (mild fluorosis) 2.005 ± 0.796 mg/L (medium fluorosis) 2.662 ± 1.093 mg/L (severe fluorosis)	Combined Raven's Test for Rural China	Higher	Age; gender
Li *et al.* (2010)	China	7–10	No fluoride measurement Dental fluorosis children/nondental fluorosis children	Not specified	Combined Raven's Test for Rural China	Higher	Gender

Table A-1. Characteristics of Studies Included in the Mean-effect Meta-analysis

Reference[1]	Study Location	Age Range (Years)	Fluoride Exposure		Intelligence Assessment	Overall RoB Rating	Confounders Considered
			Assessment (Metric, Exposure Groups)	Range			
Ding *et al.* (2011)[u*]	China	7–14	Urine Dental fluorosis (questionable/moderate/mild/very mild/normal) Mean urinary fluoride levels (10 groups)	0.80 ± 0.55 mg/L (normal dental fluorosis); 1.11 ± 0.74 mg/L (very mild dental fluorosis); 1.31 ± 0.78 mg/L (mild dental fluorosis); 1.46 ± 0.79 mg/L (moderate dental fluorosis); 1.13 ± 0.73 mg/L (questionable dental fluorosis); 0.26 mg/L (group 1); 0.45 mg/L (group 2); 0.56 mg/L (group 3); 0.66 mg/L (group 4); 0.75 mg/L (group 5); 0.89 mg/L (group 6); 1.08 mg/L (group 7); 1.33 mg/L (group 8); 1.74 mg/L (group 9); 2.96 mg/L (group 10)	Combined Raven's Test for Rural China	Lower	Age; arsenic; iodine; lead; SES; demographics
Eswar *et al.* (2011)[w]	India	12–14	Drinking water High fluoride villages/low fluoride villages	0.29 mg/L (low); 2.45 mg/L (high)	Standard Progressive Matrices	Higher	Age; gender
Poureslami *et al.* (2011)[w]	Iran	7–9	Drinking water Endemic dental fluorosis city/reference city	0.41 mg/L (reference); 2.38 mg/L (endemic)	Persian version of Raven's Matrices Test	Higher	Gender
Shivaprakash *et al.* (2011)[w]	India	7–11	Drinking water Fluorosis severity groups (mild/moderate/severe)/all fluorosis/no fluorosis	<0.5 ppm (no fluorosis); 2.5–3.5 ppm (mild fluorosis); 2.5–3.5 ppm (moderate fluorosis); 2.5–3.5 ppm (severe fluorosis); 2.5–3.5 ppm (all fluorosis)	Raven's Colored Progressive Matrices	Higher	Health factors; SES
Xiang *et al.* (2011)	China	8–13	Serum Quartiles (Q4/Q3/Q2 and Q1)	<0.05 mg/L (Q1 and Q2 reference); 0.05–0.08 mg/L (Q3); >0.08 mg/L (Q4)	Combined Raven's Test for Rural China	Lower	Age; gender; iodine; lead; SES

Table A-1. Characteristics of Studies Included in the Mean-effect Meta-analysis

Reference[1]	Study Location	Age Range (Years)	Fluoride Exposure		Intelligence Assessment	Overall RoB Rating	Confounders Considered
			Assessment (Metric, Exposure Groups)	Range			
Seraj *et al.* (2012)[w]	Iran	6–11	Drinking water High/medium/low fluoride levels	0.8 ± 0.3 mg/L (normal); 3.1 ± 0.9 mg/L (medium); 5.2 ± 1.1 mg/L (high)	Raven's Colored Progressive Matrices	Lower	Age; gender; SES
Trivedi *et al.* (2012)[w]	India	12–13	Ground water High fluoride area/low fluoride area	0.84 ± 0.38 mg/L (low); 2.3 ± 0.87 mg/L (high)	questionnaire prepared by Professor JH Shah	Lower	Gender; SES
Nagarajappa *et al.* (2013)[w]	India	8–10	Drinking water High fluoride area/low fluoride area	0.5 mg/L (low); 2.4–3.5 mg/L (high)	Seguin Form Board Test	Higher	Gender; SES; demographics
Bai *et al.* (2014)[u*]	China	8–12	Urine Coal-burning-borne fluorosis areas (seriously-affected/lightly-affected/reference)	0.54 mg/L (reference); 0.81 mg/L (lightly-affected area); 1.96 mg/L (seriously-affected area)	Chinese Combined Raven Test-C2	Higher	SES
Karimzade *et al.* (2014)[w]	Iran	9–12	Drinking water High fluoride area/low fluoride area	0.25 mg/L (low); 3.94 mg/L (high)	Iranian version of the Raymond B Cattell test	Higher	Gender
Broadbent *et al.* (2015)[w*]	New Zealand	7–13	Drinking water Area with community water fluoridation (high)/area without community water fluoridation (low) Fluoride tablet use (ever/never) Fluoride toothpaste use (always/sometimes/never)	0.0–0.3 mg/L (low); 0.7–1.0 mg/L (high) 0 mg (never used fluoride tablets); 0.5 mg (ever used fluoride tablets) Range not specified for fluoride toothpaste use (always/sometimes/never)	Wechsler Intelligence Scale for Children-Revised	Higher	Gender; SES; low birth weight; breastfeeding
Khan *et al.* (2015)	India	6–11	Drinking water High fluoride areas (Unnao)/low fluoride areas (Tiwariganj) Fluorosis grades (normal/very mild/mild/moderate/severe)	0.19 ppm (Tiwariganj); 2.41 ppm (Unnao) Range not specified by fluorosis grades	Raven's Colored Progressive Matrices	Higher	Health factors; SES
Sebastian and Sunitha (2015)[w*]	India	10–12	Drinking water Low fluoride villages/normal fluoride villages/high fluoride villages	0.40 mg/L (low); 1.2 mg/L (normal); 2.0 mg/L (high)	Raven's Colored Progressive Matrices	Higher	Age; gender; SES

Table A-1. Characteristics of Studies Included in the Mean-effect Meta-analysis

Reference[1]	Study Location	Age Range (Years)	Fluoride Exposure		Intelligence Assessment	Overall RoB Rating	Confounders Considered
			Assessment (Metric, Exposure Groups)	Range			
Zhang *et al.* (2015b)[w*]	China	10–12	Urine, drinking water, serum High fluoride areas/reference	1.10 ± 0.67 mg/L urine; 0.63 (0.58–0.68)mg/L water; 0.06 ± 0.03 serum (reference); 2.40 ± 1.01 mg/L urine; 1.40 (1.23–1.57) mg/L water; 0.18 ± 0.11 serum (high)	Combined Raven's Test for Rural China	Lower	Age; gender; arsenic; iodine; drinking water fluoride; SES; thyroid hormone levels; COMT genotype
Das and Mondal (2016)[u]	India	6–18	Urine, drinking water Dental fluorosis (severe/moderate/mild/very mild/normal)	2.91 ± 1.76 mg/L urine; 0.069 ± 0.021 mg/kg-d drinking water (normal dental fluorosis); 2.50 ± 2.39 mg/L urine; 0.064 ± 0.004 mg/kg-d drinking water (questionable dental fluorosis); 2.58 ± 1.31 mg/L urine; 0.060 ± 0.036 mg/kg-d drinking water (very mild dental fluorosis); 2.95 ± 1.44 mg/L urine; 0.060 ± 0.030 mg/kg-d drinking water (mild dental fluorosis); 4.82 ± 3.57 mg/L urine; 0.099 ± 0.063 mg/kg-d drinking water (moderate dental fluorosis); 3.81 ± 2.51 mg/L urine; 0.093 ± 0.040 mg/kg-d drinking water (severe dental fluorosis)	Combined Raven's Test for Rural China	Higher	–
Mondal *et al.* (2016)[w]	India	10–14	Drinking water High fluoride areas/low fluoride areas	Not reported (low); 0.33–18.08 mg/L (high)	Raven Standard Theoretical Intelligence Test	Higher	SES

Table A-1. Characteristics of Studies Included in the Mean-effect Meta-analysis

Reference[1]	Study Location	Age Range (Years)	Fluoride Exposure		Intelligence Assessment	Overall RoB Rating	Confounders Considered
			Assessment (Metric, Exposure Groups)	Range			
Bashash *et al.* (2017) [u]	Mexico	6–12	Urine	<0.80 mg/L (reference); ≥0.80 mg/L (high)	Wechsler Abbreviated Scale of Intelligence	Lower	Age; gender; weight at birth; parity; gestational age; maternal characteristics (smoking history, marital status, age at delivery, IQ, education, cohort)
Yu *et al.* (2018)[u*,w]	China	7–13	Drinking water High fluoride/normal fluoride Urine (per 0.5-mg/L increment in each range) High/medium/low fluoride ranges	≤1 mg/L (normal); >1 mg/L (high) 0.01–1.60 mg/L (low range urinary); 1.60–2.50 mg/L (medium range urinary); 2.50–5.54 mg/L (high range urinary)	Combined Raven's Test for Rural China	Lower	Age; gender; health factors; SES
Cui *et al.* (2020)[u]	China	7–12	Urine High/medium/low fluoride levels	<1.6 mg/L (low); 1.6–2.5 mg/L (medium); >=2.5 mg/L (high)	Combined Raven's Test	Lower	Gender; arsenic; iodine

Notes:

COMT = catechol-O-methyltransferase; RoB = risk of bias; SES = socioeconomic status

[1]A "w" superscript indicates studies included in the mean effect dose-response meta-analysis using fluoride in water; a "u" superscript indicates studies included in the mean effect dose-response meta-analysis using fluoride in urine; "*" indicates studies included in the mean effect dose-response meta-analysis at levels < 1.5 mg/L.

Table A-2. Studies Excluded from Mean-effect Meta-analysis	
Reference, Country	**Reason for Exclusion**
Qin *et al.* (1990)[translated in Qin *et al.* 2008], China	Missing mean or SD of outcome measure
Yang *et al.* (1994) [translated in Yang *et al.* 2008], China	Overlapping population with Wang *et al.* (2001); Table 2 in Yang *et al.* (1994) seemed incomplete
Wang *et al.* (2005b) [translated in Wang *et al.* 2008a], China	Missing mean or SD of outcome measure
Rocha-Amador *et al.* (2007), Mexico	Missing mean or SD of outcome measure
Liu *et al.* (2000) [translated in Liu *et al.* 2008], China	Overlapping population with Lu *et al.* (2000)
Sudhir *et al.* (2009), India	Missing mean or SD of outcome measure
He and Zhang (2010), China	Missing mean or SD of outcome measure
Kang *et al.* (2011), China	Missing mean or SD of outcome measure
Saxena *et al.* (2012), India	Missing mean or SD of outcome measure
Wang *et al.* (2012), China	Overlapping population with Xiang *et al.* (2003a); used in individual-level meta-analysis
Singh *et al.* (2013), India	Missing mean or SD of outcome measure
Wei *et al.* (2014), China	Missing mean or SD of outcome measure
Choi *et al.* (2015), China	Cognitive functions other than IQ
Kundu *et al.* (2015), India	Unusual IQ scores; used only for sensitivity analysis
Aravind *et al.* (2016), India	Unusual IQ scores; used only for sensitivity analysis
Razdan *et al.* (2017), India	Unusual IQ scores; used only for sensitivity analysis
Cui *et al.* (2018), China	Missing mean or SD of outcome measure; used in individual-level meta-analysis
Green *et al.* (2019), Canada	Missing mean or SD of outcome measure; used in individual-level meta-analysis
Soto-Barreras *et al.* (2019), Mexico	Missing mean or SD of outcome measure
Zhao *et al.* (2019), China	Overlapping population with Yu *et al.* (2018), but smaller sample size
Zhou *et al.* (2019), China	Overlapping population with Yu *et al.* (2018), but smaller sample size
Till *et al.* (2020), Canada	Missing mean or SD of outcome measure; used in individual-level meta-analysis
Wang *et al.* (2020b), China	Missing mean or SD of outcome measure; used in individual-level meta-analysis
Zhao *et al.* (2020), China	Overlapping population with Yu *et al.* (2018), but smaller sample size

Notes:
SD = standard deviation

Table A-3. Characteristics of Studies Included in the Individual-level Meta-analysis

Reference	Study Location	Age Range (Years)	Fluoride Exposure		Intelligence Assessment	Overall RoB Rating	Confounders Considered
			Assessment (Metric, Exposure Groups)	Range			
Ding *et al.* (2011)	China	7–14	Urine	0.10–3.55 mg/L	Combined Raven's Test for Rural China	Lower	Age; arsenic; iodine; lead; SES; demographics
Zhang *et al.* (2015b)	China	10–12	Urine High fluoride area/reference	1.10 ± 0.67 mg/L (reference); 2.40 ± 1.01 mg/L (high fluoride area)	Combined Raven's Test for Rural China	Lower	Age; gender; arsenic; iodine; drinking water fluoride; SES; thyroid hormone levels; COMT genotype

Panel shows the random-effects pooled SMD after filling in to the right using a run estimator. Filling in to the right using a linear estimator or to the left using a linear or a run estimator showed no change in the pooled SMD.

Attachment B. Subgroup and Sensitivity Analyses (Aim 2)

Table B-1. Characteristics of Studies Included in the Individual-level Meta-analysis

Reference	Study Location	Age Range (Years)	Fluoride Exposure		Intelligence Assessment	Overall RoB Rating	Confounders Considered
			Assessment (Metric)	Range			
Ding *et al.* (2011)	China	7–14	Urine	0.10−3.55 mg/L	Combined Raven's Test for Rural China	Lower	Age; arsenic; iodine; lead; SES; demographics
Zhang *et al.* (2015b)	China	10–12	Urine	1.10 ± 0.67 mg/L (reference); 2.40 ± 1.01 mg/L (high fluoride area)	Combined Raven's Test for Rural China	Lower	Age; gender; arsenic; iodine; drinking water fluoride; SES; thyroid hormone levels; COMT genotype
Bashash *et al.* (2017)	Mexico	6–12	Urine	0.18−2.8 mg/L	Wechsler Abbreviated Scale of Intelligence	Lower	Age; gender; weight at birth; parity; gestational age; maternal characteristics (smoking history, marital status, age at delivery, IQ, education, and cohort)
Cui *et al.* (2018)	China	7–12	Urine	0.8−2.0 mg/L	Combined Raven's Test for Rural China	Lower	Age; maternal education; smoking in family member; stress; anger; dopamine receptor-2 polymorphism
Yu *et al.* (2018)	China	7–13	Urine, drinking Water	0.01−5.54 mg/L (urine) 0.20−3.90 mg/L (water)	Combined Raven's Test for Rural China	Lower	Age; gender; maternal education; paternal education; low birth weight

Table B-1. Characteristics of Studies Included in the Individual-level Meta-analysis

Reference	Study Location	Age Range (Years)	Fluoride Exposure		Intelligence Assessment	Overall RoB Rating	Confounders Considered
			Assessment (Metric)	Range			
Green *et al.* (2019)	Canada	3–4	Maternal urine, maternal fluoride intake, drinking water	0.51 ± 0.36 mg/L (urine) 0.54 ± 0.44 mg/day (maternal daily fluoride intake) 0.31 ± 0.23 mg/L (water)	Wechsler Primary and Preschool Scale of Intelligence-III	Lower	Gender; city; maternal education; race/ethnicity; HOME score; prenatal secondhand smoke exposure
Till *et al.* (2020)	Canada	3–4	Residence (fluoridated/nonfluoridated cities), maternal urine, infant fluoride intake from formula, drinking water	0.64−0.70 mg/L (fluoridated), 0.38−0.42 mg/L (nonfluoridated) (urine) 0.12−0.34 mg/day (fluoridated), 0.02−0.08 mg/day (nonfluoridated) (infant formula fluoride intake) 0.58 mg/L (fluoridated), 0.13 mg/L (nonfluoridated) (water)	Wechsler Primary and Preschool Scale of Intelligence-III	Lower	Age; gender; maternal education; maternal race; HOME total score; second-hand smoke status in the child's house
Wang *et al.* (2020b)	China	7–13	Urine, drinking water	0.01−5.54 mg/L (urine) 0.20−3.90 mg/L (water)	Combined Raven's Test for Rural China	Lower	Age; gender; body mass index; maternal education; paternal education; household income; low birth weight

NIEHS/DNTP Response to the

REVIEW OF THE REVISED NTP MONOGRAPH ON THE SYSTEMATIC REVIEW OF FLUORIDE EXPOSURE AND NEURODEVELOPMENTAL AND COGNITIVE HEALTH EFFECTS: A LETTER REPORT

The National Academies of
SCIENCES • ENGINEERING • MEDICINE

THE NATIONAL ACADEMIES PRESS
Washington, DC
www.nap.edu

The National Toxicology Program (NTP) and the Division of the National Toxicology Program (DNTP) at the National Institute of Environmental Health Sciences (NIEHS) appreciates the comments provided by the National Academies of Sciences, Engineering, and Medicine (NASEM) Committee in its review of the September 2020 revised draft of the NTP Monograph on the Systematic Review of Fluoride Exposure and Neurodevelopmental and Cognitive Health Effects.

The NASEM Committee reviews of the draft NTP monographs on fluoride (September 2019 and September 2020) determined that, "Overall the revised monograph seems to include a wealth of evidence and a number of evaluations that support its main conclusion, but the monograph falls short of providing a clear and convincing argument that supports its assessments…" Thus, we have removed the hazard assessment step and added "State of the Science" to the title to indicate the change. The monograph was retitled the "NTP Monograph on the State of the Science Concerning Fluoride Exposure and Neurodevelopmental and Cognitive Health Effects: A Systematic Review" and underwent additional peer review by five external experts. The prepublication 2022 NTP Monograph includes consideration of comments from that external peer review and from key stakeholders across HHS in addition to the NASEM Committee's comments.

In addition, the prepublication 2022 NTP Monograph removes the meta-analysis that was added at the NASEM Committee's request following their review of the 2019 draft NTP Monograph. The meta-analysis is being prepared as a separate journal publication, taking into consideration the NASEM Committee's comments on the 2020 draft NTP Monograph.

The NIEHS/DNTP separated the NASEM Committee Letter Review comments that were applicable to the prepublication 2022 NTP Monograph from the comments that are focused on the meta-analysis because these are now two separate, distinct evaluations. For each set of comments, NIEHS/DNTP prepared responses and described changes made in response to the comments. The NASEM Committee's comments and responses that were directly relevant to the meta-analysis are in the document titled "Sup01_Meta-analysis" (see Word file Sup01_Meta-analysis – NASEM_comments_on_meta-analysis_only_and_NIEHS_DNTP_response.docx) and are not included in this document. In particular, the section titled "*Evaluation of the Meta-Analysis*" is not included here.

This document contains a subset of the overall NASEM Committee's comments and NIEHS/DNTP responses that are related to the prepublication 2022 NTP Monograph. For clarity, the complete text from the NASEM Letter Review, with the exception of the meta-analysis relevant comments, have been included in the pages that follow and is formatted in black text. The responses begin with the word "**Response**," are formatted in blue font, and are interspersed within the original NASEM Committee text.

Mary S. Wolfe, PhD
Deputy Division Director for Policy
Director, Office of Liaison, Policy, and Review National Toxicology Program
111 T.W. Alexander Drive Keystone Building, MD A2-03 Research Triangle
Park, NC 27709

Dear Dr. Wolfe,

At your request, the National Academies of Sciences, Engineering, and Medicine (the National Academies) convened the Committee to Review the Revised NTP Monograph on Fluoride Exposure and Neurodevelopmental and Cognitive Health Effects. The committee was asked to determine whether substantive concerns raised in the National Academies 2020 report *Review of the Draft NTP Monograph: Systematic Review of Fluoride Exposure and Neurodevelopmental and Cognitive Health Effects* have been sufficiently addressed by revisions of the monograph and whether the evidence presented by NTP in the revised monograph supports its conclusions. Overall, the committee appreciates the efforts to revise the monograph to address concerns previously raised. Although the monograph is much improved in many important ways, the committee still has concerns as expressed in the comments in this letter report.

Given the strong views of water-fluoridation advocates who are concerned with preventing dental caries and their systemic sequelae and the equally strong views of antifluoridation advocates who contend that fluoride exposure poses a threat to health, preparing a report that can withstand the scrutiny of both sides is extremely challenging. The report must present its methods clearly, document the results transparently, and provide the rationale for conclusions in such a way that even those who disagree with them will appreciate that the process by which they were derived is clear and was implemented without error. The question is not whether this committee or the multiple audiences come to the same conclusions but rather whether the methods and analysis documented in the monograph support NTP's conclusions.

According to the committee's task statement, the committee's primary focus was "to determine whether the evidence as presented by NTP in its revised monograph supports its conclusions." As documented in this letter report, the committee had difficulty in following various aspects of the reported methods, identified a few worrisome remaining inconsistencies, was not able to find some key data used in the meta-analysis, and had concern about the wording of some conclusions. Even though the evidence provided appears to show consistent indications of an association between exposure to high fluoride concentrations and cognitive deficits in children, the monograph falls short of providing a clear and convincing argument that supports its assessment. It also needs to emphasize that much of the evidence presented comes from studies that involve

relatively high fluoride concentrations and that the monograph cannot be used to draw conclusions regarding low fluoride exposure concentrations (less than 1.5 mg/L), including those typically associated with drinking water fluoridation.

Sincerely,

David A. Savitz, *Chair* Committee to Review the Revised NTP Monograph on the Systematic Review of Fluoride Exposure and Neurodevelopmental and Cognitive Health Effects

REVIEW OF THE REVISED NTP MONOGRAPH ON THE SYSTEMATIC REVIEW OF FLUORIDE EXPOSURE AND NEURODEVELOPMENTAL AND COGNITIVE HEALTH EFFECTS: A LETTER REPORT

In 2019, the National Toxicology Program (NTP) released the draft monograph *Systematic Review of Fluoride Exposure and Neurodevelopmental and Cognitive Health Effects* (NTP 2019a).[1] The draft monograph summarized the findings of the systematic review and concluded that "fluoride is *presumed to be a cognitive neurodevelopmental hazard to humans*. This conclusion is based on a consistent pattern of findings in human studies across several different populations showing that higher fluoride exposure is associated with decreased IQ or other cognitive impairments in children" (NTP 2019a, p. 59). Given the controversies surrounding the risks and benefits associated with fluoride exposure and to ensure the integrity of its evaluation, NTP asked the National Academies of Sciences, Engineering, and Medicine (the National Academies) to review the draft monograph.

The National Academies committee that was convened to address the request identified deficiencies in the analysis of various aspects of some of the studies and in the analysis, summary, and presentation of the data in the draft monograph (NASEM 2020). The committee provided many suggestions for improvement and concluded that NTP had not adequately supported its conclusions. It noted that the committee's finding did not mean that NTP's conclusions were incorrect; rather, further analysis or reanalysis would be needed to support the conclusions. Taking the committee's suggestions into consideration, NTP revised the draft monograph.

STATEMENT OF TASK AND COMMITTEE APPROACH

NTP asked the National Academies to review the revised monograph (NTP 2020a) to ensure that it was responsive to the committee's recommendations and, more important, adequately supported its conclusions. Attachment A provides the verbatim statement of task. The committee that reviewed the draft monograph was reconvened to review the revised monograph; Attachment B provides biographic information on the committee.

To complete its task, the committee held several virtual meetings, one of which included a public session at which NTP provided an overview of the changes that had been made in the draft monograph. The committee reviewed the revised monograph, including the newly added appendixes with details of lower risk-of-bias studies and the meta-analysis; NTP responses to the committee's recommendations; the revised protocol; and public comments submitted to the committee. It is important to note that the committee did not conduct its own independent evaluation of the evidence, nor did it conduct a data audit; both were outside its scope. The committee reviewed the revised monograph and determined whether the evidence as presented in it supported NTP's main conclusion that "fluoride is *presumed to be a cognitive neurodevelopmental hazard to humans*" (NTP 2020a, p. 80). Each section below provides the committee's assessment of NTP responses to substantive issues previously raised (NASEM 2020) regarding methods, animal evidence, human evidence, and communication. Attachment C summarizes the substantive issues previously raised and NTP's responses. The committee

[1] Referred to hereafter as the draft monograph. The revised version released in 2020 is referred to as the revised monograph.

provides many recommendations for improving the revised monograph and has highlighted in boldface, italics some particularly critical ones, but all are important to address.

METHODS

In its previous review, the committee raised several issues associated with the general methods of NTP's systematic review process. The issues were concerning because they decreased the transparency of the process and the probability of reproducing the findings and did not align with some general best practices for systematic review. The committee finds that NTP has addressed many of the issues regarding methods in its revisions of the draft monograph but notes that some further improvements would be useful. A brief overview of suggested improvements is provided below; other methodologic issues raised in the previous review that are not discussed here have been adequately addressed in the revised monograph. The committee considers the remaining issues related to the systematic review methods to be minor with the exception of the comment below concerning NTP's process for upgrading and downgrading the body of evidence (NTP 2020b, Table 5).

First, the role of the Office of Health Assessment and Translation (OHAT) handbook (NTP 2015, 2019b,c) has been explicitly added to the revised monograph. Two statements in the revised monograph—on pp. ii and 6 (footnote)—describe the OHAT handbook as a source of general systematic review methods that are selected and tailored to the project in the prespecified protocol. Although the statement clarifies the general role of the handbook, the committee finds that it does not address the committee's previous recommendation to set the expectation for how closely the process described in the handbook will be followed in the protocol and in the eventual systematic review. For example, the handbook section "Key Questions and Analytical Framework" that guides development of the population, exposure, comparator, and outcomes (PECO) statement is not included in the fluoride protocol or the revised monograph. As the committee recommended in its previous review, NTP should treat each systematic review protocol as a stand-alone document that contains all the information necessary for understanding of the planning and conduct of the review, and these expectations should be explicitly stated in the protocol. The committee did not find that revisions of the protocol adequately addressed this recommendation.

Response: Agree (change made)

- We appreciate the desire of the Committee for more specificity in the protocol with respect to laying out all aspects of the systematic review; however, we respectfully submit that the detail provided in the protocol followed for both the systematic review and meta-analysis are well within, and in many aspects exceed, standard practice in the field. We added the following text to the *Methods* section of the prepublication 2022 NTP Monograph to further clarify the role of the OHAT handbook.

  "The protocol served as the complete set of methods followed for the conduct of this systematic review. The OHAT Handbook for Conducting a Literature-Based Health Assessment (http://ntp.niehs.nih.gov/go/38673) is a source of general systematic review methods that were selected and tailored in developing this protocol. Options in the OHAT handbook that were not specifically referred to in the protocol were not part of the methods for the systematic review."

Second, several recommendations in the committee's previous review that might have increased the overall transparency of the monograph do not appear to have been addressed, such as reporting the excluded studies at the title and abstract step (also recommended in the OHAT handbook) and adding to the protocol clear definitions for each factor that contributes to increasing or decreasing confidence in the body of evidence and key considerations that warrant upgrading or downgrading the body of evidence (NTP 2020b, Table 5, p. 18). ***The committee found that such omissions decrease the reproducibility and transparency of the systematic review process and should be viewed as a deficiency that should be addressed.***

Response: Agree (change made)

- Figure 2 (titled "Study Selection Diagram") in the prepublication 2022 NTP Monograph has been transformed into an interactive Tableau® figure (https://hawcproject.org/summary/visual/assessment/405/Figure-2/). The list of studies excluded at the title and abstract stage can now be accessed through this interactive Tableau® figure. The section of the prepublication 2022 NTP Monograph titled "*Confidence Rating: Assessment of Body of Evidence*" has been expanded to provide short descriptions and key considerations for each factor considered for downgrading or upgrading confidence in the human body of evidence.

Third, NTP has added text to the revised monograph regarding the use of the SWIFT-Active Screener tool to priority-rank studies for screening and to set stopping rules. However, the committee recommends that a more detailed explanation of some terminology be added to eliminate any confusion that might arise given the novelty of the use of such tools. For example, the term *percent recall* might lack consistent interpretation, and it would be helpful to define it to clarify the implications of stopping at a set recall, such as 98% estimated recall, and the implication of the potential number of missed studies at the set stopping point.

Response: Agree (change made)

- We call attention to the Committee of text on pg. 22 of the 2020 draft NTP Monograph that discusses the SWIFT-Active screening process and implications for stopping at 98% with respect to possible studies missed. We assume that the Committee means to refer to the term "predicted recall," as the term "percent recall" is not found in the 2020 draft NTP Monograph. In the *Evaluation of SWIFT-Active Screener Results* section of the prepublication 2022 NTP Monograph, the use of the term "predicted recall" has been supplemented with a layman description of the concept.

ANIMAL EVIDENCE

The committee appreciates that NTP agrees that there were problems with the risk-of-bias analyses of the animal studies, and it agrees with NTP's decision that devoting further effort to refining the analyses is not worthwhile but has concerns regarding the reasons provided by NTP for not reanalyzing any of the animal data. NTP provided the following reasons in the revised monograph: "(1)…a more critical risk-of-bias assessment would result in fewer relevant animal studies judged to be of high quality; (2)…the highest quality experimental animal study reviewed for this monograph (McPherson et al. 2018) did not find effects of fluoride on learning, memory or motor activity in the critical ≤20 ppm in drinking water concentration range; and (3)…[there are] a large number of human epidemiology studies directly addressing neurobehavioral and cognitive effects of fluoride in children" (NTP 2020a, p. 58). Although the committee agrees with the first reason to the extent that a reanalysis would probably not find any low risk-of-bias studies, it is inappropriate for NTP to highlight one specific study (McPherson et al. 2018) as a rationale for not reassessing all the animal literature. Regarding the third reason, the committee disagrees that a large number of epidemiologic studies generally negates the value of animal studies in hazard determination. Instead, NTP should clarify that a large number of relevant epidemiologic studies can be used as a primary source of evidence to support a conclusion in its hazard identification scheme for integrating human and animal data to reach a final rating of the overall evidence.

Response: Disagree (no change)

- The reasons cited in the 2020 draft NTP Monograph for not reanalyzing the animal data have been removed from the prepublication 2022 NTP Monograph. We appreciate the Committee's objection to citing one high quality study as part of the reason to not carry further reviews of the experimental animal literature. Note that the significance of McPherson et al. (2018) in this context is that it was performed at the NIEHS specifically to address deficiencies in prior studies identified in the NTP 2016 systematic review of the animal literature. We also respectfully disagree that the 2020 draft NTP Monograph implies that "a large number of epidemiologic studies generally negates the value of animal studies in hazard determination" as is indicated in the Committee's comments. The prepublication 2022 NTP Monograph does not state or imply that epidemiological studies negate the value of animal studies.

In the revised monograph, NTP has added a disclaimer about the animal evidence but left the original discussion unchanged. ***The committee strongly recommends that NTP not publish the monograph with the original text that states that evidence of effects on activity or motor function invalidate observations of learning or memory deficits.*** If taken out of context, that text could be interpreted incorrectly or raise questions about the scientific validity of the monograph more generally. For example, Yang et al. (2018) was grouped with studies that were classified as high risk of bias because in addition to finding learning deficits by using the Morris water maze, it found open-field effects. However, the Morris water maze data are highly unlikely to be affected by the minor open-field differences found in that study not only because swimming is different from ambulation and rearing but because there were no differences among groups in learning the task over 5 days of testing. Differences emerged only on retesting 10 and 20 days later and then were not significant on days 30, 40, and 50. It is implausible that rats with any kind of activity effect would learn the Morris water maze equally well, show deficits on only some retest days, and then fail to show further deficits because of an open-field effect. That example shows that the monograph

overgeneralizes concerns about activity without examining the learning data in sufficient depth to determine their validity. Instead, the monograph dismisses all data on the basis of a sweeping indictment that no learning differences can be used if activity differences are found. That view is not scientifically justifiable.

The committee strongly recommends that NTP revise the monograph text that states that a change in motor activity necessarily complicates interpretation of learning and memory tests and that the absence of an evaluation of motor activity is automatically problematic.[2] First, the mere observation of a change in motor activity does not automatically undermine a learning and memory effect, nor does the absence of statements about the general health of the animals undercut validity, as the monograph asserts. Second, the absence of a motor-activity test does not necessarily invalidate a learning and memory effect if the test has an internal control for activity. The central issue is whether the learning and memory method alone or in combination with other indexes dissociates learning from performance in a way that allows a correct interpretation of animal learning and memory.

Response: Agree (change made)

- We agree with the Committee's recommendation, and this information has been removed from the prepublication 2022 NTP Monograph.

[2] Text that needs to be edited includes p. 58, last paragraph, lines 4–7, and p. 59, last paragraph, lines 4–13.

HUMAN EVIDENCE

The committee provided many suggestions in its previous report (NASEM 2020) to address deficiencies that it identified in the analysis of the human evidence provided in the draft monograph (NTP 2019a). The headings in this section represent the overarching concerns that the committee raised in its previous report, and the text provides the committee's assessment of NTP's responses to the concerns and the revisions made in the draft monograph.

Potential for Biased Selection of Studies

NTP has done excellent work in responding to concerns about a potentially biased selection of studies. The expansion of the literature search to include several Chinese databases strengthens NTP's review and strengthens the overall process that it has used to support its conclusions. In a few respects, NTP could improve the process even further, and these are discussed below.

First, the databases that NTP chose for searching the Chinese literature were selected on the basis of their covering "studies previously identified from other sources" (NTP 2020b, p. 6). Although that approach might be appropriate, it would have been helpful for NTP to provide a few brief details about the quality or scope of the two new Chinese databases. For example, NTP chose such databases as PubMed and BIOSIS for a reason—for example, fairly extensive coverage of journals or some quality-control standards. Do the same reasons or qualities also apply to the CNKI and Wanfang databases? ***NTP should also address the concern that selecting databases on the basis of studies already identified might perpetuate, rather than ameliorate, biases resulting from the initial search.***

Response: Disagree (no change)

- We recognize the desire of the Committee for further information on the databases selected. Details were added to the *Supplemental Chinese Database Literature Search* section of the prepublication 2022 NTP Monograph to further explain the rationale for our approach. We searched for and were unable to find definitive guidance on the most comprehensive, highest quality, or otherwise most appropriate non-English-language databases for health studies of fluoride. Therefore, we chose databases (CNKI and Wanfang) that identified non-English-language studies that we were aware of—"seed" studies previously identified from other resources. It is standard practice to use seed studies to test search strings and explore the value of databases. An informationist requires some means of judging whether a database has the appropriate content. Note that the CNKI and Wanfang databases are large and recognized by information scientists in the United States. We recognize that the coverage, scope, and completeness of the various search engines providing access to the Chinese literature is somewhat opaque. Therefore, we explored more than 15 databases to identify databases that indexed the seed studies. The CNKI and Wanfang databases contained the highest proportion of seed studies (>50%).
- We found this the most effective approach to ensure that databases selected were able to identify at least some references that were appropriate to the topic. Preliminary searches were performed on all of the databases considered, understanding that optimization of search strings would then be necessary for each database. Further optimization of the search string was only applied to databases where at least one previously identified seed study was found. We find it unlikely that not finding seed studies would make it more likely that these databases contained potentially missing studies. Therefore, we respectfully disagree with the Committee's concern that this approach may have further perpetuated a potential bias in our

initial search.

- Furthermore, we took steps to ensure that a consistent peer-review standard was applied to the included human studies identified in the CNKI and Wanfang databases and to all of the relevant human studies published in non-English languages. An epidemiologist fluent in Chinese and an informationist conducted searches for publicly available information on peer-review practices of all non-English language journals (n = 30) in which human studies were published that had been included as relevant for this review. If publicly available information was not available on peer-review practices, we contacted the journals in Chinese and requested additional information. Through this process, we confirmed that 28 out of the 30 non-English journals in which relevant human studies were published have peer-review practices (described on the website, listed in a major bibliographic database with known peer-review standards, and/or confirmed directly). Publicly available details of the peer-review procedures of two journals (Chinese Primary Health Care and Lit Inf Prev Med, renamed Preventive Medicine Tribune) were limited and we did not receive responses to our inquiries. There were only three relevant studies that were published in these journals (Yao et al. 1996; Yao et al. 1997; and Hong et al. 2001[a]) and we had previously rated all of them as high risk-of-bias studies. A note was added to the rationale for the "other potential threats to internal validity" risk-of-bias question for each of these studies in the Health Assessment and Workspace Collaborative (HAWC) to reflect that they were published in a journal with an unclear peer-review process.

Second, the monograph states that "newly-retrieved human references were reviewed to identify studies that might impact conclusions with priority given to identifying and translating null studies" (NTP 2020a, p. 10). It is somewhat understandable that NTP would want to focus on null studies because these studies would most likely affect NTP's conclusions. However, that statement provides questionable justification, given NTP's primary mission—an unbiased review of the literature, which means including all relevant studies whether positive or negative. ***NTP needs to consider all eligible studies identified in the new literature search.***

Response: Agree (change made)

- We accepted this suggestion and have taken additional steps to translate and extract data from all non-English language studies identified from the Chinese database searches that were not included previously. As a result, eight additional studies have been incorporated into the systematic review (six on IQ in children, one on other neurodevelopmental or cognitive effects in children, and one on cognitive effects in adults). All eight are high risk-of-bias studies, and the addition of these eight studies has not resulted in any changes to the confidence ratings or any substantive updates to discussions in the monograph. We have updated the text in the *Literature Search* section to reflect that the search of Chinese databases was conducted to identify studies that may have been missed in previous searches because non-English-language studies are not always indexed in the main databases used for

[a]Yao L, Zhou J, Wang S, Cui K, Lin F. 1996. Analysis of TSH levels and intelligence of children residing in high fluorosis areas. Lit Inf Prev Med 2(1): 26-27.

Yao Y. 1997. Comparative assessment of the physical and mental development of children in endemic fluorosis area with water improvement and without water improvement. Lit Inf Prev Med 3(1): 42-43.

this systematic review.

Lack of Independence of Studies

NTP recognizes that the monograph evaluates and describes multiple publications from the same study. It also indicates some uncertainty about a few publications that cannot be attributed to a parent study, given insufficient published details. The revised monograph states that it addressed the independence issue, but the exact process used for selection of a single publication remains unclear, and in the meta-analysis, two reports on the same population are inappropriately included as described below. It would be useful for the monograph to identify clearly which publications were derived from which study to minimize concerns about potential selection bias;

doing so would also help to define the publications selected for the meta-analysis. NTP might consider editing the monograph to differentiate studies from publications or papers. That revision can be achieved by restricting the term *study* to the original body of research conducted with a defined population during a specified time and using the terms *publications* and *papers* to refer to the published work drawn from a study.

Response: Disagree (edited for clarity)

- We assure the Committee that all attempts were made to determine when a single study population was the source material for more than one report. In the prepublication 2022 NTP Monograph, we have added details to clearly define the approach used in the document, and we have gone through the monograph to ensure that appropriate distinctions are made. “Study population” refers to a defined population on which an original body of research was conducted. The published work drawn from that original body of research is often referred to as a “study.” In addition, IQ studies and studies on other neurodevelopmental effects in children that report on the same study populations have now been identified in Tables 6 and 7 of the monograph. Also note that the prepublication 2022 NTP Monograph clarifies that the terms “study” and “publication” are used interchangeably to refer to a published work drawn from an original body of research conducted on a defined population.

Inconsistent Application of Risk-of-Bias Criteria

In response to the committee's concern regarding the risk-of-bias assessment, NTP has added Appendix 4, which provides its rationale for classifying studies relative to their estimated risk of bias. The new appendix is helpful and adds transparency, but inconsistencies remain in the application of risk-of-bias criteria to individual studies, particularly in NTP's evaluation of how various studies handled major confounders, co-exposures, and outcomes. An example concerns the handling of co-exposure to arsenic and lead. According to the protocol, a cross- sectional study is rated as having a probably low risk of bias on confounding if there is direct evidence that appropriate adjustments for arsenic and lead were made; the monograph requires the studies to address arsenic and lead, if applicable. Barberio et al. (2017) did not adjust for arsenic and lead, nor did the authors discuss co-exposures; however, it was rated as having a probably low risk of bias. The committee also identified several studies whose classification changed in revisions in the draft monograph without any justification provided (Sudhir et al.
2009; Trivedi et al. 2012; Das and Modal 2016).

Response: Agree (change made)

- We recognize the Committee's continued concerns over the consistent application of the risk-of-bias criteria. While a top priority to us as well, it is important to emphasize to the Committee that the risk-of-bias criteria laid out in the protocol are not an algorithm or a scoring system. Each study describes a unique set of circumstances. We apply the risk-of-bias criteria to individual studies and specifically look across studies to ensure that the criteria are consistently applied, with the understanding that scientific judgement is needed, and risk-of-bias judgements are made on a case-by-case basis.
- Barberio et al. (2017) used data from the Canadian Health Measures Survey which consists of a nationally representative sample of Canadians. Because most Canadians (~89%) receive water from municipal water supplies, which monitor for levels of lead and arsenic, we assumed that co-exposure to lead and arsenic in drinking water was not applicable to this study (which follows the guidance in the protocol). However, we agree that this reasoning should have been more explicitly explained, and we have added further details to the confounding risk-of-bias domain discussion for this study in *Appendix E* of the prepublication 2022 NTP Monograph (previously *Appendix 4* in the 2020 draft NTP Monograph).
- Below, we provide justifications for why the three studies identified by the Committee changed in risk-of-bias classification. Many of the changes occurred after implementing the Committee's recommendations from the first peer review with regard to risk of bias. However, because the 2020 draft NTP Monograph was still in draft form, we consider that if the reasoning for the risk-of-bias ratings was clearly explained in the appendix, reasons for changing ratings of individual studies between drafts was not appropriate.
    - Sudhir et al. 2009 – From the 2019 draft NTP Monograph to the 2020 draft NTP Monograph, the confounding rating changed from *probably high risk of bias* to *probably low risk of bias*. Because of this rating change, the overall risk-of-bias status of the study changed from high to low risk of bias. The change in the confounding rating is based on the use of groundwater quality maps to identify areas where arsenic could be a concern. The following explanation of this approach was added to the 2020 draft NTP Monograph: "*In order to identify areas of China, India, and Mexico where arsenic is a concern, groundwater quality maps were evaluated*

(https://www.gapmaps.org/Home/Public#) (Podgorski and Berg 2020). If no arsenic measurements were available for the area, the arsenic groundwater quality predictions from the global arsenic 2020 map were used (Podgorski and Berg 2020). If an area had less than 50% probability of having arsenic levels greater than 10 µg/L (the WHO guideline concentration), the area was considered not to have an issue with arsenic that needed to be addressed by the study authors."

- Trivedi et al. 2012 – From the 2019 draft NTP Monograph to the 2020 draft NTP Monograph, the confounding and exposure assessment ratings changed from *probably high risk of bias* to *probably low risk of bias*. Because of these rating changes, the overall risk-of-bias status of the study changed from high to low risk of bias. The change in the confounding rating is based on the use of groundwater quality maps to identify areas where arsenic could be a concern. The change in the exposure assessment rating is based on additional information obtained via author inquiry regarding the availability of groundwater fluoride levels and urine fluoride levels for all children for which IQ was assessed. Additional details are provided in *Appendix E* of the prepublication 2022 NTP Monograph.
- Das and Modal 2016 – From the 2019 draft NTP Monograph to the 2020 draft NTP Monograph, the outcome assessment rating changed from *probably low risk of bias* to *probably high risk of bias*. Because of this rating change, the overall risk-of-bias status of the study changed from low to high risk of bias. The change is based on the determination that the study authors administered the Combined Raven's Test for Rural China (CRT-RC) on an Indian population; however, this test is validated in a Chinese population not an Indian population and there is no information provided to indicate it was validated in the study population.

Evaluation of Confounding Insufficient, Difficult to Understand, or Applied Inconsistently

The revised monograph articulates a formal approach for assessing confounding by defining what it considers to be key confounders (that is, children's age, sex, and socioeconomic status) and other potential confounders. The addition of Appendix 4 makes it easier to follow how individual studies were assessed for risk of bias and confounding, but the committee still considers NTP's evaluation of confounding insufficient and sometimes inconsistently applied.
For example, Cui et al. (2020), which was rated as having a probably high risk of bias for confounding and was included with the lower risk-of-bias studies, presented a univariate comparison of IQ by high vs low fluoride exposure without any adjustment for confounders. According to the protocol, the study should have been rated as having a definitely high risk of bias for confounding and included with the higher risk-of-bias studies.

Response: Disagree (no change)

- We have re-evaluated risk of bias due to potential confounding. After further review, we would like to clarify to the Committee that Cui et al. (2020) did not meet the protocol's definition for *definitely high risk of bias* due to confounding, which requires direct evidence that important covariates, known confounders, and co-exposures differed between the groups and were not taken into account. Therefore, it is appropriate for the Cui et al. (2020) study to receive a *probably high risk of bias* rating for the confounding domain. As stated in *Appendix E* of the prepublication 2022 NTP Monograph (previously *Appendix 4* of the 2020 draft NTP Monograph), the *probably high risk of bias* rating is based on "indirect evidence" that age was not addressed as a confounder, and it may be related to both IQ and exposure. If there was direct evidence that age differed by exposure or IQ level, the study would have received a *definitely high risk of bias* rating, and the study would have been considered high risk of bias overall.

An example of inconsistent application of criteria to classify confounding is the adjustment for smoking and lead exposure. Specifically, Broadbent et al. (2015) is rated as having a probably high risk of bias on confounding, but other studies, such as Trivedi et al. (2012), were not similarly ranked.

Response: Disagree (no change)

- We respectfully disagree that this is a compelling example of inconsistent application of criteria to classify confounding. The primary reason the confounding domain in Broadbent et al. (2015) was rated *probably high risk of bias* was that it did not address age (a key confounder for all studies), and there was indirect evidence that age was not addressed as a confounder and that it may be related to both IQ and exposure (IQ was measured in children with an age range of 7-13 years with no information on the ages in the different groups or similarities between the groups), which justifies a rating of *probably high risk of bias* for confounding. Although Trivedi et al. (2012) also did not directly address age, they provided indirect evidence that children living in low and high fluoride villages were of similar ages based on the grades included in the study population (6^{th} and 7^{th} grade), which justifies a rating of *probably low risk of bias* for confounding.

Another example of inconsistent application of confounding assessment concerns Valdez- Jimenez et al. (2017); here, the issue was the unbalanced and unexplained demographic characteristics of the study population.

Response: Disagree (no change)

- We are unable to respond directly, as we find the exact concern unclear. Please note that Valdez-Jimenez et al. (2017) was rated *probably high risk of bias* for confounding in the 2020 draft NTP Monograph (and in the prepublication 2022 NTP Monograph) primarily based on indirect evidence that there was a potential for co-exposure with arsenic that was not addressed.

In Appendix 4, NTP attempted to clarify the direction and magnitude of bias due to confounding, although supporting text is often unclear. For several studies, NTP added a paragraph on the potential direction of bias due to lack of adjustment for arsenic exposure but then provided an argument to justify its absence as a confounder (see, for example, Sudhir et al. 2009). As noted, the committee did not conduct a full audit but examined some illustrative papers and still found reasons for concern.

Response: Disagree (edited for clarity)

- **Response:** The sub-bullet "Direction/magnitude of effect" text in *Appendix E* of the prepublication 2022 NTP Monograph (previously *Appendix 4* in the 2020 draft NTP Monograph) explains the conceptual impact of potential confounding concerns. In Sudhir et al. (2009), for example, the "Direction/magnitude of effect" text explains that the presence of arsenic would potentially bias away from the null if arsenic were present along with fluoride, and the text before and after this sub-bullet clearly states that arsenic is not considered an issue in this study. In *Appendix E* of the prepublication 2022 NTP Monograph, the "Direction/magnitude of effect" sub-bullet text has been revised to clearly state that the impacts on direction/magnitude of effect are conceptional concerns that depend on whether the specific issue applied. If a potential confounder is not considered an issue in a study, this determination is clearly stated in the "Direction/magnitude of effect" sub-bullet.

Possibility of Exposure Misclassification

The revised monograph addresses methodologic issues concerning potential exposure misclassification in light of the various types of exposure measures—for example, child and mother spot urines, serum, drinking water, urine, and residence—considered in the studies. Specifically, Appendix 4 addresses the potential direction and magnitude of bias due to exposure misclassification, if applicable. Thus, the committee's prior concerns regarding exposure misclassification appear to have been adequately addressed.

Response: Agree (no change requested)

- We appreciate the Committee's positive feedback.

Need for Further Consideration of Blinding

In its previous review, the committee recommended that NTP consider more carefully the effect of not intentionally blinding outcome assessors when evaluating the human studies. In its response, NTP indicated that when authors did not directly provide evidence of examiner blinding, it contacted the authors for information. It is unclear how the risk-of-bias information has been updated regarding blinding on the basis of any new information that was received. Specifically, Health Assessment and Workspace Collaborative records identify only whether and when authors were contacted but not what information was obtained or how it might have changed risk-of-bias ratings.

Response: Disagree (edited for clarity)

- Please note that the risk-of-bias rating explanations provided in HAWC and *Appendix E* in the prepublication 2022 NTP Monograph (previously *Appendix 4* of the 2020 draft NTP Monograph) previously noted whether an author responded and whether the response provided affected the risk-of-bias rating. To provide information more clearly on author inquiries and how information provided by the authors was used in the risk-of-bias analysis, we have also made updates to the HAWC study profiles for each human study and to *Appendix E*. Please note the following:
    - When author inquiries were conducted, they are noted in the study profiles (e.g., "Author was contacted in September 2017 to obtain information for RoB assessment").
    - If the author did not respond, it is noted in the study profile (e.g., "No response was received to email request for clarification").
    - If the author responded and provided additional information that informed a rating decision in the risk-of-bias analysis, it is now noted in the study profiles and *Appendix E* which risk-of-bias questions were impacted (e.g., "Additional information provided by the authors informed the rating decision for the following risk-of-bias domains: Detection [outcome assessment]"). Additional details on the information provided by authors can be found in the risk-of-bias explanation rating in HAWC and *Appendix E* (e.g., "*Correspondence with the study authors indicated that the outcome assessors were blind to the children's fluoride status*").

NTP also stated that it "verified that the lower risk-of-bias studies did not provide direct evidence of imprecision or lack of blinding" (NTP 2020c). However, that approach assumes that authors will always reveal in their manuscripts a lack of blinding and other weaknesses in their study design. A more conservative approach would be to assume that there was no blinding of outcome assessors unless it was specified in the manuscript and that a designation of probably high risk of bias for this criterion (at a minimum) would be more appropriate when the blinding status was not explicitly stated. That approach would follow the one described in the protocol in which NTP states that "studies should be considered 'probably high RoB' unless specific direct or indirect evidence of blinding is provided" (NTP 2020b, p. 13).

Response: Disagree (no change)

- We appreciate the Committee's recommendation regarding assessor blinding; however, it fails to account for the standard practice of considering both direct and indirect evidence and

judging the two types of evidence accordingly. We respectfully stand by our decision to consider risk of bias from assessor blinding as "definitely high" if there is direct evidence of lack of assessor blinding and "definitely low" if there is direct evidence of assessor blinding. Direct evidence is the strongest evidence and justifies the "definite" ratings. We also consider indirect evidence of whether assessors were blind to the exposure status of individuals when assessing outcomes. For example, in studies with a cross-sectional design in which exposure and outcome were measured simultaneously, it was considered more likely that the outcome assessor did not know the exposure status of individuals when assessing outcome. Therefore, simultaneous measurement of exposure and outcome was considered indirect evidence of assessor blinding and was rated *probably low risk of bias* if the outcome was otherwise assessed appropriately. Further, we would like to clarify that, if authors do not report information regarding blinding of outcome assessors, a rating of *not reported* is applied, which is equal to a *probably high risk of bias* rating in concern—effectively, in the absence of information, the default rating is *probably high risk of bias*. Study authors are then contacted for missing information and the rating is only changed if authors provide additional details indicating whether assessors were blind to exposure status.

Appendix 4 in the revised monograph outlines details of each lower risk-of-bias study and includes outcome-assessor blinding, if known, and any information gathered from direct contact with manuscript authors. In several cases in which assessor blinding was not known, risk of bias for confidence in the outcome assessment was considered low because of the cross-sectional design in which exposure and outcome were measured simultaneously or when all children resided in the same geographic area. The committee considers that an acceptable approach.
However, in studies in which children were tested in schools or other facilities in areas where low and high fluoride concentrations of different localities were being compared (see, for example, Cui et al. 2018), there is an increased risk of bias because examiners might make assumptions about children in the different areas. A designation of probably high risk of bias (at a minimum) would be more appropriate in those cases given the approach described in the protocol noted above.

Response: Disagree (no change)

- As mentioned in our previous response, simultaneous measurement of exposure and outcome was considered indirect evidence of assessor blinding and was rated *probably low risk of bias* if the outcome was otherwise assessed appropriately.
- To address the Committee's specific concern about Cui et al. (2018), we state in *Appendix E* of the prepublication 2022 NTP Monograph (previously *Appendix 4* of the 2020 draft NTP Monograph) that, "*Blinding or other methods to reduce bias were not reported. Although it was unlikely that the outcome assessor would have knowledge of the child's urine fluoride levels, there was potential that they would know whether the child was from an endemic or non-endemic area if the IQ tests were conducted at the child's school, and there was no information provided on how the IQ tests were administered.*" Also, in response to an author inquiry, the study author noted that the cross-sectional nature of the study with outcome and exposure assessed at the same time made the outcome assessors effectively blind to the exposure. We acknowledge in *Appendix E* of the prepublication 2022 NTP Monograph that there is still potential for knowledge of the area by the outcome assessor, but overall, we determined that there was sufficient indirect evidence of assessor blinding to support a rating of *probably low risk of bias* for blinding.

Flawed Measures of Neurodevelopmental and Cognitive Outcome

The committee raised a concern in its previous review about studies that were classified as having lower risk of bias when measurement of a neurodevelopmental or cognitive outcome was flawed. NTP's response indicated that it did not change the draft monograph but verified that the lower risk-of-bias studies did not provide direct evidence of imprecision in their outcome measurement. However, the committee remains concerned about the application of the protocol definitions to rate studies. For example, Barberio et al. (2017) assessed outcomes that rely on parent or child self-report of diagnosis of learning disability or attention deficit hyperactivity disorder. According to the protocol, that study would be rated as either probably or definitely high risk-of-bias because the method was not listed in Table 6 (NTP 2020b, p. 21), but NTP failed to address whether there is direct evidence that a self-reported diagnosis has been validated as a reliable outcome measure. That evidence would allow one to distinguish which category (probably or definitely high risk of bias) would be most appropriate. ***Because the outcome measure is critical for the interpretation of the findings, the committee recommends that NTP apply its criteria in a more consistent manner and specifically address whether there is direct evidence of the sensitivity and precision of self-reported neurodevelopmental outcomes.***

Response: Disagree (no change)

- We recognize the Committee's continued concern on risk of bias for outcome assessment tools. However, the Committee may be misunderstanding the definition of direct evidence and the different types of evidence needed for each situation. Direct evidence is required for either a *definitely low risk of bias* or *definitely high risk of bias* rating. Direct evidence that the neurodevelopmental or cognitive function outcome was assessed using well-established, validated assessment methods and direct evidence that assessors were blind to exposure status are required for a *definitely low risk of bias* rating on outcome. Similarly, direct evidence that the outcome assessment method was imprecise or insensitive or direct evidence of a lack of assessor blinding is required for a *definitely high risk of bias* rating on outcome. We consider self-reporting of a learning disability to be an insensitive method (as stated in *Appendix E* of the prepublication 2022 NTP Monograph, previously *Appendix 4* of the 2020 draft NTP Monograph), but in the absence of direct evidence that the outcome assessment method is an insensitive or imprecise method (i.e., a known, previous demonstration that the instrument was not reliable in the study subjects or similar population), we consider this concern to result in *probably high risk of bias* for outcome assessment and not *definitely high risk of bias*.

Lack of Rigorous Statistical Review

The committee recognizes that NTP made substantial efforts to improve the statistical reviews of the lower risk-of-bias studies. Each study was reviewed by a senior statistician, and summaries of the analytic methods were added to the study descriptions in Appendix 4 in the section "Other potential threats." However, the summaries provided for a few publications were only a single sentence—"Statistical analyses used were appropriate for the study" (Sudhir et al. 2009; Barberio et al. 2017; Bashash et al. 2017, 2018)—and two other summaries mentioned only log-transformations (Choi et al. 2015) or that tests of normality were performed (Zhang et al. 2015). For those

publications, NTP should have provided more evidence to support its conclusion that the analyses were appropriate. It is also concerning that NTP assumed that the analyses in Soto-Barreras et al. (2019) were appropriate despite few details provided in the manuscript regarding their methods.

Response: Disagree (edited for clarity)

- We appreciate the Committee's continued concerns over the adequacy of the statistical approaches used in some of the publications reviewed in the 2020 draft NTP Monograph. We have expanded our comments concerning the statistical methods used in the low risk-of-bias studies in *Appendix E* of the prepublication 2022 NTP Monograph (previously *Appendix 4* in the 2020 draft NTP Monograph).

The committee also finds that NTP did not adequately address the issue of clustering. Most of the attention to clustering pertained to the examples provided in the committee's previous review. Although it was important for NTP to review those examples, they were meant to highlight the issue and were not meant to serve as a comprehensive list of problematic studies. In fact, when reviewing Appendix 4 in the revised monograph, the committee found several other studies whose analyses failed to account for clustering. Of most concern are the studies that used fluoride concentration measured at the community level as the exposure—see, for example, Seraj et al. (2012), Till et al. (2020), Trivedi et al. (2012), and Wang et al. (2012). When everyone in a community is subject to the same exposure, the standard error of the difference in means between high-exposure and low-exposure groups increases multiplicatively by the square root of a variance inflation factor (VIF) equal to [1 + (n - 1)r], where n is the number of persons in each community and r is the correlation in outcomes (such as IQ score) between members of the same community (Murray 1998; Donner and Klar 2000; Feng et al. 2001). The same phenomenon occurs in randomized control trials that assign treatment to groups of persons. Thus, unless within-community clustering is accounted for in the analysis—for example, through a random- effects model—standard-error estimates will be too small and confidence intervals (CIs) too narrow. Those errors could have a substantial effect on the meta-analysis, which requires valid estimates of within-study variability. The same issue applies to analyses that use community- level exposure to estimate slopes in a regression model. For individual-level exposures, such as urinary fluoride concentration, the VIF is probably smaller than one would see for community- level exposures because some communities might contain people in multiple exposure groups.

Response: Agree (change made)

- **Response:** The potential impact of clustering is addressed in multiple ways in the prepublication 2022 NTP Monograph, that expand previous discussion and analysis. We have revised text in *Appendix E* of the prepublication 2022 NTP Monograph (previously *Appendix 4* in the 2020 draft NTP Monograph) to clearly specify which low risk-of-bias studies addressed clustering when that was a feature of the study design or statistical analysis. We have also reached out to the study authors to request additional information as suggested by the comment and addressed the impact of any information provided. As suggested by the Committee, lack of accounting for clustering has little impact in studies with individual-level exposure levels (e.g., urinary fluoride levels) that also account for many important confounders that often capture the cluster (city) effect.
- The potential impact of clustering is illustrated by Bashash et al. (2017) who accounted for clustering at the cohort level by using cohort as a fixed effect in the models. In addition, the

models accounted for many important confounders, which are also likely to reflect the cohort effects. The similarity between the unadjusted and the adjusted effect estimates β (95% CI)=(−2.37 [(−4.45, −0.29)] and −2.50 ([−4.12, −0.59)], respectively) reflects the minimal impact of accounting for the cohort effect.

- In addition, for the studies referenced in the comment (Seraj et al. 2012; Till et al. 2020; Trivedi et al. 2012; Wang et al. 2012), the number of clusters is relatively small. In such cases, there is "typically not enough information to accurately estimate group-level variation. As a result, multi-level models in this setting typically gain little beyond classical varying-coefficient models" (Gelman and Hill 2006).
- The above response applies to the prepublication 2022 NTP Monograph, additional response specific to the meta-analysis will be released when the manuscript is published.

However, it is still important to account for clustering in the analysis because one would expect most people in a community to be in the same exposure group. ***NTP should note specifically whether each study applied an analytic approach that addressed clustering when that was a feature of the design***.

In the case of Green et al. (2019), NTP learned from the investigators that accounting for city-level clustering via a random-effects model "showed similar results to the main model." More details should be provided regarding the similarity of results because although overall conclusions might not have changed, the results of the meta-analysis could be affected by incorrect exposure-effect or standard-error estimates.

Response: Agree (change made)

- We have revised text in *Appendix E* of the prepublication 2022 NTP Monograph (previously *Appendix 4* in the 2020 draft NTP Monograph) to clearly specify which low risk-of-bias studies addressed clustering when that was a feature of the study design or statistical analysis.
- In the case of Green et al. (2019), we contacted the study authors and received the results from models using city as a random intercept. The overall adjusted effect estimates with city as a fixed effect and with city as a random effect were not significantly different from each other: β (95% CI) =−1.95 (−5.19, 1.28) and −2.20 (−5.39, 0.98), respectively.

The statistical review conducted by NTP also failed to identify a study that did not properly account for the sampling design. Yu et al. (2018) used a hierarchical stratified sampling design but did not indicate that sampling weights were used in the analysis. Thus, both point estimates (means and regression coefficients) and standard errors were likely biased (Lohr, 2019). ***NTP should examine the studies included in the meta-analysis in greater depth to determine whether each study properly accounted for its design because not doing so could invalidate the meta-analysis results***.

Response: Agree (change made)

- To address the part of the comment we agree with "***NTP should examine the studies included in the meta-analysis in greater depth to determine whether each study properly accounted for its design"***, we revised text in *Appendix E* of the prepublication 2022 NTP

Monograph (previously *Appendix 4* in the 2020 draft NTP Monograph) to note specifically whether studies accounted for the sampling strategy. In cases where the publication used stratified or clustered sampling designs but did not mention whether the sampling strategy was accounted for in the analysis (e.g., Cui et al. 2018, 2020; Yu et al. 2018), we contacted study authors to specifically ask for this information. If they responded, we updated the information in *Appendix E* (noting that the information came from correspondence with the authors). If authors did not respond, we noted that we contacted them but did not receive a response.

- A detailed response to the Committee's critique of the meta-analysis is provided in "Sup01_Meta-analysis".

Need to Juxtapose Results of Broadly Comparable Studies

In its previous review, the committee expressed concern about selective consideration and presentation of results from the various studies. That approach can convey inaccurate impressions regarding consistency unless the findings are derived from studies that are comparable or aligned with respect to study population, exposure measurement, and outcome ascertainment. Some text in the revised monograph continues to be impressionistic and haphazard in citing various findings from studies and does not provide a clear rationale for why some findings are reported and others are not. The committee notes that reporting findings that are most or least supportive of a finding does not necessarily indicate bias and that this issue might be more editorial than substantive in that the text is not the basis for drawing conclusions. However, it does constitute a concern with transparent communication.

Response: Agree (change made)

- **Response:** We appreciate the Committee's comments on this point and have carefully re-evaluated the information presented in the monograph. We have detected an imbalance in the presentation toward highlighting flaws and limitations in the studies and have attempted to address this in the prepublication 2022 NTP Monograph. In a few instances, we have added details to the main data table summarizing the results of the IQ studies in children (Table 6) to account for all outcomes reported.

The critical information regarding comparison of study results comes from the new meta-analysis, which seeks to extract and integrate comparable findings from selected studies as discussed further below. The overall approach appears to be sound in comparing mean IQ scores for the most and least highly exposed to fluoride even though the absolute fluoride concentrations are not comparable among studies. ***Because the meta- analysis is so critical to the conclusions that are drawn, NTP should provide the data that were used from each study to enable the reader to understand and evaluate what was done***.

The values that were used to determine the standardized mean differences (SMDs) could not be found in the revised monograph, nor was there a figure that showed the pattern of results from studies restricted to the lower exposure ranges. . A more detailed assessment of the meta-analysis is provided in the next section.

Response: Disagree (no change)

- A detailed response to the Committee's critique of the meta-analysis is provided in "Sup01_Meta-analysis". However, we take issue with the Committee's assertion that the meta-analysis is critical to the conclusions drawn. Indeed, we reached the same hazard conclusions in the 2019 draft NTP Monograph, which lacked a meta-analysis, as we did in the 2020 draft NTP Monograph, in which we included a meta-analysis at the Committee's recommendation. Because of the extensive comments on the meta-analysis, and consistent with the original decision to not perform one because of the uncertainty over the precision of the findings of many of the high risk-of-bias studies, we have removed the meta-analysis from the prepublication 2022 NTP Monograph and will pursue publishing it separately.

Evaluation of the Meta-Analysis

Note: The NASEM Committee's comments in the "Evaluation of the Meta-Analysis" section are not reproduced here as they are not directly relevant to the prepublication 2022 NTP Monograph. See "Sup01_Meta-analysis" for the meta-analysis-relevant comments and responses.

COMMUNICATION

Overall, NTP has done a good job of identifying and extracting the underlying epidemiologic information that it needs to evaluate the possible neurodevelopmental effects of fluoride. With a few exceptions, the major problem with the report is not related to missing or misinterpreted information, but rather with how the underlying research and its evaluations are presented by NTP. As detailed in many of the preceding comments, NTP's protocols and its evaluations of the research are sometimes difficult to follow. As NTP is aware, the issue of fluoride toxicity and safety is highly contentious. To be widely accepted, any analysis concerning the issue needs to be performed and presented with exceptional care and with exceptional clarity. Overall, the revised monograph seems to include a wealth of evidence and a number of evaluations that support its main conclusion, but the monograph falls short of providing a clear and convincing argument that supports its assessment, given the lack of details in several places and the lack of clarity on several substantive issues.

Much of the evidence presented in the report comes from studies that involve relatively high fluoride concentrations. Little or no conclusive information can be garnered from the revised monograph about the effects of fluoride at low exposure concentrations (less than 1.5 mg/L). ***NTP therefore should make it clear that the monograph cannot be used to draw any conclusions regarding low fluoride exposure concentrations, including those typically associated with drinking-water fluoridation***. Drawing conclusions about the effects of low fluoride exposures (less than 1.5 mg/L) would require a full dose–response assessment, which would include at a minimum more detailed analyses of dose–response patterns, models, and model fit; full evaluations of the evidence for supporting or refuting threshold effects; assessment of the differences in exposure metrics and intake rates; more detailed analyses of statistical power and uncertainty; evaluation of differences in susceptibility; and detailed quantitative analyses of effects of bias and confounding of small effect sizes. Those analyses fall outside the scope of the NTP monograph, which focuses on hazard identification and not dose– response assessment. ***Given the substantial concern regarding health implications of various fluoride exposures, comments or inferences that are not based on rigorous analyses should be avoided.***

Response: Disagree (no change)

- The Committee correctly states that the data driving the hazard conclusions in the 2019 and 2020 draft NTP Monographs primarily reflect high exposures (i.e., >1.5 mg/L in drinking water, along with other fluoride sources including food, beverages, and oral hygiene products). The extent to which community artificial water fluoridation contributes to high fluoride exposures is not addressed in the prepublication 2022 NTP Monograph, although some studies evaluated individuals with high fluoride exposures that were associated at least in part with community water fluoridation (e.g., Green et al. 2019). Both the 2019 and 2020 versions of the draft NTP Monograph concluded that the findings concerning children's IQ, where exposures were equivalent to or below 1.5 mg/L, were inconsistent and therefore unclear.

NTP CONCLUSION

As noted above, the committee focused on determining whether the evidence as presented in the revised monograph supported NTP's main conclusion that "fluoride is *presumed to be a cognitive neurodevelopmental hazard to humans*" (NTP 2020a, p. 80). The revised monograph is

much improved from the initial draft that the committee reviewed. The addition of the meta-analysis substantially increases the support for NTP's main conclusion. However, the committee is still concerned about the presentation of the data, the methods, and the analyses in the revised monograph and finds that the monograph falls short of providing a clear and convincing argument that supports its assessment. The committee urges NTP to improve the clarity of the document. The monograph has great importance in the discussion about effects of fluoride on neurodevelopmental and cognitive health effects and will likely influence exposure guidelines or regulations. Thus, it is extremely important for it to be able to withstand scientific scrutiny by those who have vastly different opinions on the risks and benefits associated with fluoride exposure. ***The committee strongly recommends that NTP improve the revised monograph by seriously considering the suggestions that are provided in this letter report to improve its clarity and transparency.***

Response: Agree (change made)

- We agree with and appreciate the Committee's statements concerning the importance of this assessment and consider that the prepublication 2022 NTP Monograph has been improved in clarity and transparency through responses to the Committee's criticisms of earlier drafts.

ATTACHMENT A STATEMENT OF TASK

An ad hoc committee of the National Academies of Sciences, Engineering, and Medicine will review the revised National Toxicology Program (NTP) *Monograph on Systematic Review of Fluoride Exposure and Neurodevelopmental and Cognitive Health Effects*. The committee will consider whether NTP's revisions have addressed the substantive concerns raised in the National Academies 2020 report *Review of the Draft NTP Monograph: Systematic Review of Fluoride Exposure and Neurodevelopmental and Cognitive Health Effects*. The primary focus of the committee will be to determine whether the evidence as presented by NTP in its revised monograph supports its conclusions.

BIOGRAPHIES

David A. Savitz (NAM) (*Chair*) is professor of epidemiology and associate dean for research of the Brown University School of Public Health, with joint appointments in obstetrics and gynecology and pediatrics at the Alpert Medical School. He was vice president of research at the university from 2013 to 2017. His epidemiologic research has addressed a wide array of important public-health issues, including environmental hazards in the workplace and community, reproductive-health outcomes, and environmental influences on cancer. He has worked extensively on health effects of nonionizing radiation, pesticides, drinking-water treatment byproducts, and perfluorinated compounds. Before joining Brown University, Dr.
Savitz held appointments as the Charles W. Bluhdorn Professor of Community and Preventive Medicine at Mount Sinai School of Medicine and professor at the University of North Carolina School of Public Health. He was president of the Society for Epidemiologic Research and the Society for Pediatric and Perinatal Epidemiologic Research and was a North American regional councilor for the International Epidemiological Association. Dr. Savitz was elected to the National Academy of Medicine in 2007. He received an MS in preventive medicine from Ohio State University and a PhD in epidemiology from the University of Pittsburgh Graduate School of Public Health.

Germaine M. Buck Louis is dean of the College of Health and Human Services of George Mason University. Her research has addressed a mixture of environmental exposures, including endocrine disruptors, stress, diet, and physical activity in relation to a spectrum of reproductive outcomes in men and women. She was an early pioneer in the application of the exposome research paradigm for understanding environmental influences on human fecundity and fertility impairments. Before joining the university, Dr. Louis was the director of the Division of Intramural Population Health Research in the Eunice Kennedy Shriver National Institute of Child Health and Human Development of the National Institutes of Health, where she led population- health scientists in

designing research aimed at enhancing the health and well-being of fetuses, pregnant women, children, and young adults. She has served the National Academies, Pan American Health Organization, US Environmental Protection Agency, and World Health Organization in various roles. She is a former president of the Society of Pediatric and Perinatal Epidemiologic Research and of the Society for Epidemiologic Research and has served on the boards of the American College of Epidemiology and the International Society for Environmental Epidemiology. Dr. Louis received a PhD in epidemiology from the State University of New York at Buffalo.

Kevin M. Crofton is principal and consultant at R3Fellows, LLC. Previously, he worked for more than 35 years as a developmental neurotoxicologist in the US Environmental Protection Agency (EPA) Office of Research and Development. Dr. Crofton has also served as an adjunct associate professor at Duke University, the University of North Carolina, and North Carolina State University. His research interests include developmental neurotoxicity with an emphasis on the consequences of endocrine disruption for neurodevelopment. He recently received the EPA Distinguished Career Service Award. Dr. Crofton received an MS in toxicology from Miami University and a PhD in toxicology from the University of North Carolina at Chapel Hill.

Akhgar Ghassabian is an investigator and assistant professor in the Departments of Pediatrics, Population Health, and Environmental Medicine of the New York University (NYU) School of Medicine. Her research focuses on identifying environmental exposures that contribute to the etiology of developmental disabilities in childhood. Before joining NYU, Dr. Ghassabian was the intramural research training award fellow at the Eunice Kennedy Shriver National Institute of Child Health and Human Development of the National Institutes of Health. During her doctoral and postdoctoral training, Dr. Ghassabian was involved in birth-cohort studies in Europe and in the United States. She was a collaborator on European epidemiologic consortia examining the effect of nutrition and air pollution on children's neurodevelopment. Dr. Ghassabian was the recipient of the Rubicon Award from the Netherlands Organization for Scientific Research in 2014 and the Robin/Guze Young Investigator Award from the American Psychopathological Association in 2019. She obtained an MD from Tehran University of Medical Sciences and a PhD in epidemiology from Erasmus University Rotterdam, the Netherlands.

Judith B. Klotz is an affiliate faculty member in the Department of Environmental and Occupational Health of the Drexel University Dornsife School of Public Health and an adjunct associate professor in the Department of Epidemiology of the Rutgers School of Public Health. She is a member of the Health Effects Committee of the New Jersey Drinking Water Quality Institute and of the Public Health Standing Committee of the Science Advisory Board, both advisory groups of the New Jersey Department of Environmental Protection. She served as environmental scientist and program manager in environmental health and in cancer surveillance in the New Jersey Department of Health from 1984 to 2003 and focused especially on toxic substances in drinking water and the environmental epidemiology of cancer and reproductive outcomes. Dr. Klotz has served on several National Academies committees, including the Committee on Fluoride in Drinking Water and the Committee on the Review of the Styrene Assessment in the National Toxicology Program 12th Report on Carcinogens. She received an MS in genetics from the University of Michigan and a DrPH in environmental health sciences from Columbia University.

Juleen Lam is an assistant professor in the Department of Health Sciences of the California State University, East Bay. She is also an affiliate researcher in the Department of Obstetrics, Gynecology and Reproductive Sciences of the University of California, San Francisco, School of

Medicine. Her research interests are in environmental epidemiology, evaluation of population exposures to environmental contaminants, assessment and communication of environmental risks, and reproductive and developmental health. She specializes in analysis of environmental- health data and development and application of risk-assessment methods. Dr. Lam has been involved in the development of systematic review methods for environmental-health data and has had a pivotal role in implementing, publishing, and disseminating these approaches in academic and government settings. She is a member of the US Environmental Protection Agency Board of Scientific Counselors Chemical Safety for Sustainability Subcommittee. She served on the National Academies Committee to Review DOD's Approach to Deriving an Occupational Exposure Limit for TCE. She received an MS in environmental engineering management from George Washington University and an MHS in biostatistics and PhD in environmental-health policy from the Johns Hopkins University Bloomberg School of Public Health.

Pamela J. Lein is a professor of neurotoxicology in the Department of Molecular Biosciences of the University of California, Davis, School of Veterinary Medicine. Her research interests are in how environmental stressors interact with genetic susceptibilities to influence the risk and severity of neurodevelopmental disorders and neurodegeneration. Because altered patterns of connectivity are associated with neurologic deficits, her research focuses on investigating how environmental contaminants, chemical convulsants, and inflammation perturb neuronal connectivity as determined by using biochemical, morphogenic, and electrophysiologic end points. Her group is also developing biomarkers of organophosphate neurotoxicity and testing novel therapeutic approaches for protecting against the neurodegenerative effects associated with neurotoxic proconvulsants. Dr. Lein was a member of the National Academies Committee to Review Report on Long-Term Health Effects on Army Test Subjects. She received an MS in environmental health from East Tennessee State University and a PhD in pharmacology and toxicology from the State University of New York at Buffalo.

Michael L. Pennell is associate professor in the Division of Biostatistics in the College of Public Health of Ohio State University. His research interests are in nonparametric Bayes, first hitting time models for survival analysis; design and analysis of group randomized trials; joint modeling outcomes of different scales; statistical methods in toxicologic risk assessment; and statistical applications in biomedical research, including cancer control, pathology, and veterinary medicine. Dr. Pennell has served as an ad hoc member of the US Environmental Protection Agency (EPA) Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA) Scientific Advisory Panel, the EPA Science Advisory Board on trichloroethylene and Libby amphibole asbestos, and the Chemical Safety Advisory Subcommittee for 1-bromopropane. He served on the National Academies Committee to Evaluate the IRIS Protocol for Inorganic Arsenic. He received an MS and a PhD in biostatistics from the University of North Carolina at Chapel Hill.

Craig Steinmaus is an associate adjunct professor of epidemiology at the University of California, Berkeley (UCB). He is also a public-health medical officer III in the California Environmental Protection Agency (CalEPA) and is the UCB director of the Arsenic Health Effects Research Group. He is a board-certified physician with over 12 years of patient-care experience. His epidemiologic research has involved studies of drinking-water contaminants with a focus on early-life exposure and other factors conferring susceptibility. He also teaches graduate courses on epidemiology, causal inference, and systematic review at UCB and at the University of California, San Francisco. Dr. Steinmaus has served on several study sections of the National Institutes of Health and Centers for Disease Control and Prevention and is a full member of the Cancer, Heart, and Sleep Epidemiology, A study section. His work in the CalEPA water toxicology section has involved systematic reviews and risk assessments of drinking-water agents, including nitrate, arsenic, copper, perchlorate, fluoride, chromium, and trihalomethanes. He received an MD from the University of California, Davis, School of Medicine and an MPH in environmental-health sciences from UCB.

Charles V. Vorhees is a professor in the University of Cincinnati College of Medicine. He is co-director of the Animal Behavior Core and program director of the Teratology Training Program. He is on the graduate faculty of the graduate programs in neuroscience and molecular and developmental biology. His research focuses on brain development and behavior. He was a founding member of the Neurobehavioral Teratology Society in 1977 and was elected president in 1984–1985 and 2012–2013. Dr. Vorhees has served on multiple scientific advisory committees for the US Food and Drug Administration, US Environmental Protection Agency, and National Institutes of Health. He was on the National Academies Subcommittee on Reproductive and Developmental Toxicants. Dr. Vorhees obtained an MA and a PhD in neurobiology from Vanderbilt University.

Kimberly Yolton is a professor in Cincinnati Children's Hospital Medical Center (CCHMC) and the University of Cincinnati College of Medicine and director of research in the Department of General and Community Pediatrics. She is a developmental psychologist and epidemiologist with over 25 years of experience in studying the effects of prenatal and early-life exposures on neurobehavior from infancy through childhood and directs the longitudinal Health Outcomes and Measures of the Environment (HOME) Study. She was formerly the director of a follow-up clinic serving high-risk infants and young children and has extensive experience with infants and children who were prenatally exposed to substances of abuse, who were born prematurely or at low birth weight, or who come from disadvantaged home environments. She was involved in the initial development of the NICU Network Neurobehavioral Scale (NNNS), a specialized neurobehavioral assessment tool used with healthy and high-risk newborns, and conducts frequent training on the proper administration, scoring, and interpretation of the instrument for research and clinical purposes. She has been affiliated with the National Institutes of Health– funded Neonatal Research Network for over 25 years at two sites as an examiner, Gold Standard reviewer for intelligence testing, follow-up principal investigator, and steering-committee member. She often collaborates with investigators regarding neurobehavioral assessment and staff training strategies to acquire the most appropriate outcome measures with the highest standards of reliability and validity. She earned a PhD in child development and developmental psychology from Ohio State University and completed a 3-year National Research Service Award in Pediatric Environmental Health at CCHMC.

ATTACHMENT C

This attachment summarizes the substantive issues raised in the committee's previous report (NASEM 2020) concerning the general systematic review methods and the evaluation of the human evidence. Because NTP decided to base its conclusions on the human evidence, it did not re-evaluate the animal evidence to address the committee's previous concerns. Instead, it added a disclaimer to the revised monograph and left the original text unchanged. For that reason, the committee's concerns regarding the animal evidence are not listed here.

Committee Issue on Methods and Communication	NTP Response
NTP added foreword to monograph and text to protocol to clarify relationship.	
NTP added text to protocol and monograph to clarify literature search strategy and to clarify assessment of animal data.	
Absence of exclusion–inclusion criteria from protocol	No information provided.
Lack of justification for some decisions SWIFT-Active screener to justify approach.	NTP added information to the monograph on
Inconsistencies between protocol and monograph concerning critical confounders to evaluate.	NTP clarified text in protocol and monograph
Communication concerning how monograph can be used (or not) to inform water fluoridation concentrations	No information provided.

Committee Issue on Evaluation of Human Evidence	NTP Response
Potential for Biased Selection of Studies	NTP conducted supplemental searches of Chinese databases and identified additional studies.
NTP revised the monograph to indicate the multiple publications on the same population. However, when conducting the meta-analysis, NTP included more than one publication for a single study population in at least one case.	
Inconsistent Application of Risk-of Bias Criteria	NTP added Appendix 4.
Evaluation of Confounding Insufficient, Difficult to Understand, or Applied Inconsistently	NTP revised text to identify clearly key confounders that applied to all study populations. NTP added Appendix 4.
Possibility of Exposure Misclassification	NTP added Appendix 4.
Need for Further Consideration of Failure to Blind Examiners	NTP added Appendix 4.
Flawed Measures of Neurodevelopmental and Cognitive Outcomes	NTP verified lower risk-of-bias studies that did not provide direct evidence of imprecision or lack of blinding.
NTP examined studies identified by committee and included discussion in Appendix 4.	

Need to Juxtapose Results across Broadly Comparable Studies	NTP conducted subgroup analyses as part of meta-analysis to address heterogeneity in the data and further analyze consistency of data.
Need to Consider Conducting Meta-Analysis meta-analysis using individual-level exposure data.	NTP updated meta-analyses and conducted new
Lack of Support for Conclusion that Effects Occur at Higher Fluoride Doses	NTP conducted dose–response analysis as part of meta-analysis.

ATTACHMENT E ACKNOWLEDGMENT OF REVIEWERS

This consensus letter report was reviewed in draft form by persons chosen for their diverse perspectives and technical expertise. The purpose of this independent review is to provide candid and critical comments that will assist the National Academies of Sciences, Engineering, and Medicine in making each published report as sound as possible and to ensure that it meets institutional standards of quality, objectivity, evidence, and responsiveness to the study charge. The review comments and draft manuscript remain confidential to protect the integrity of the deliberative process.
We thank the following for their review of this report:

Ana Navas-Acien, Columbia University **David Bellinger**, Harvard Medical School **Weihsueh Chiu**, Texas A&M University
David Dorman, North Carolina State University **Jayanth Kumar**, California Department of Public Health **Karen Robinson**, Johns Hopkins University

Although the reviewers listed above provided many constructive comments and suggestions, they were not asked to endorse the conclusions or recommendations of this report, nor did they see the final draft before its release. The review of the report was overseen by **Jonathan Samet** (NAM), Colorado School of Public Health, who was responsible for making certain that an independent examination of the report was carried out in accordance with institutional procedures and that all review comments were carefully considered. Responsibility for the final content rests entirely with the authoring committee and the National Academies.

NIEHS/DNTP Response to the

REVIEW OF THE REVISED NTP MONOGRAPH ON THE SYSTEMATIC REVIEW OF FLUORIDE EXPOSURE AND NEURODEVELOPMENTAL AND COGNITIVE HEALTH EFFECTS: A LETTER REPORT

The National Academies of
SCIENCES • ENGINEERING • MEDICINE

THE NATIONAL ACADEMIES PRESS
Washington, DC
www.nap.edu

The National Toxicology Program (NTP) and the Division of the National Toxicology Program (DNTP) at the National Institute of Environmental Health Sciences (NIEHS) appreciates the comments provided by the National Academies of Sciences, Engineering, and Medicine (NASEM) Committee in its review of the September 2020 revised draft of the NTP Monograph on the Systematic Review of Fluoride Exposure and Neurodevelopmental and Cognitive Health Effects.

The NASEM Committee reviews of the draft NTP monographs on fluoride (September 2019 and September 2020) determined that, "Overall the revised monograph seems to include a wealth of evidence and a number of evaluations that support its main conclusion, but the monograph falls short of providing a clear and convincing argument that supports its assessments…" Thus, the NTP removed the hazard assessment step and added "State of the Science" to the title to indicate the change. The monograph was retitled as "NTP Monograph on the State of the Science Concerning Fluoride Exposure and Neurodevelopmental and Cognitive Health Effects: A Systematic Review" and underwent additional peer review by five external experts. The prepublication 2022 NTP Monograph includes consideration of comments from that external peer review and from key stakeholders across HHS in addition to the NASEM Committee's comments.

In addition, the prepublication 2022 NTP Monograph removed the meta-analysis that was added at the NASEM Committee's request following its review of the September 2019 draft NTP Monograph. The meta-analysis is being prepared as a separate journal publication, taking into consideration the NASEM Committee's comments on the September 2020 draft NTP Monograph.

The NIEHS/DNTP separated the NASEM Committee Letter Review comments that were applicable to the prepublication 2022 NTP Monograph from the comments that are focused on the meta-analysis because these are now two separate, distinct evaluations. For each set of comments, NIEHS/DNTP prepared responses and described changes made in response to the comments. The NASEM Committee's comments and responses that were directly relevant to the prepublication 2022 NTP Monograph are in the document titled "Sup01_Monograph" (see Word file Sup01_Monograph_NASEM_comments_on_monograph_only_Feb_2021_and_NIEHS_ DNTP_ response.docx) and are not included here.

This document contains a subset of the overall NASEM Committee's comments and NIEHS/DNTP responses that are related to the meta-analysis. Therefore, all of the comments from the "Evaluation of the Meta-Analysis" section are included, along with the portion of meta-analysis-relevant comments from the "Lack of Rigorous Statistical Review" and "Need to Juxtapose Results of Broadly Comparable Studies" sections. For clarity, the complete text from comments relevant to the meta-analysis from the NASEM Letter Review have been included in the pages that follow and is formatted in black text. Formatting has been applied to aid in reading and page numbers have been added starting with "Sup01_Meta-analysis." The responses begin with the word "Response," are formatted in blue font, and are interspersed within the original NASEM Committee text.

Lack of Rigorous Statistical Review

Note: The NASEM Committee's comment in the first paragraph of this section is on the prepublication 2022 NTP Monograph and is not reproduced here as it is not directly relevant to the meta-analysis. See "Sup01_Monograph" for the monograph-relevant comments and responses.

The committee also finds that NTP did not adequately address the issue of clustering. Most of the attention to clustering pertained to the examples provided in the committee's previous review. Although it was important for NTP to review those examples, they were meant to highlight the issue and were not meant to serve as a comprehensive list of problematic studies. In fact, when reviewing Appendix 4 in the revised monograph, the committee found several other studies whose analyses failed to account for clustering. Of most concern are the studies that used fluoride concentration measured at the community level as the exposure—see, for example, Seraj et al. (2012), Till et al. (2020), Trivedi et al. (2012), and Wang et al. (2012). When everyone in a community is subject to the same exposure, the standard error of the difference in means between high-exposure and low-exposure groups increases multiplicatively by the square root of a variance inflation factor (VIF) equal to [1 + (n - 1)r], where n is the number of persons in each community and r is the correlation in outcomes (such as IQ score) between members of the same community (Murray 1998; Donner and Klar 2000; Feng et al. 2001). The same phenomenon occurs in randomized control trials that assign treatment to groups of persons. Thus, unless within-community clustering is accounted for in the analysis—for example, through a random- effects model—standard-error estimates will be too small and confidence intervals (CIs) too narrow. Those errors could have a substantial effect on the meta-analysis, which requires valid estimates of within-study variability. The same issue applies to analyses that use community-level exposure to estimate slopes in a regression model. For individual-level exposures, such as urinary fluoride concentration, the VIF is probably smaller than one would see for community-level exposures because some communities might contain people in multiple exposure groups.

However, it is still important to account for clustering in the analysis because one would expect most people in a community to be in the same exposure group. ***NTP should note specifically whether each study applied an analytic approach that addressed clustering when that was a feature of the design***.

In the case of Green et al. (2019), NTP learned from the investigators that accounting for city-level clustering via a random-effects model "showed similar results to the main model." More details should be provided regarding the similarity of results because although overall conclusions might not have changed, the results of the meta-analysis could be affected by incorrect exposure-effect or standard-error estimates.

Note: The NASEM Committee's comments in the three paragraphs above are relevant to both the prepublication 2022 NTP Monograph and meta-analysis and are therefore included here. See "Sup01_Monograph" for the monograph-relevant responses.

Response: Agree (change made)

- We have revised text in Appendix E of the prepublication 2022 NTP Monograph (previously Appendix 4 in the September 2020 draft NTP Monograph) to note specifically whether each low risk-of-bias study applied an analytic approach that addressed clustering when that was a feature of the study design. We have also reached out to the study authors to request additional information and addressed the impact of any information provided.
- For the studies referenced in the comment (Seraj et al. 2012; Till et al. 2020; Trivedi et al. 2012; Wang et al. 2012), the number of clusters in each is relatively small. In such cases, there is "typically not enough information to accurately estimate group-level variation. As a result, multi-level models in this setting typically gain little beyond classical varying-coefficient models" (Gelman and Hill, 2006). For these studies and all low risk-of-bias studies, in the *Other potential threats* domain in Appendix E of the prepublication 2022 NTP Monograph, we now discuss whether clustering was specifically addressed and/or whether there were other factors that may have increased or reduced our concern for clustering-related bias.
- As suggested by the Committee, lack of accounting for clustering has little impact in studies with individual-level exposure measures (e.g., urinary fluoride levels) that also account for many important covariates that often capture the cluster (city or cohort) effect. The minimal impact of clustering is illustrated by Bashash et al. (2017) who accounted for clustering at the cohort level by using cohort as a fixed effect in the linear regression models. In addition, these models adjusted for many important covariates, which are also likely to reflect the cohort effects. The minimal impact of clustering is reflected in the similarity between the unadjusted and adjusted effect estimates (β [95% CI] = −2.37 [−4.45, −0.29] and −2.50 [−4.12, −0.59], respectively).
- In the case of Green et al. (2019), we contacted the study authors and received the results from models using city as a random intercept. The authors shared that the overall adjusted effect estimates with city as a fixed effect and with city as a random effect were not significantly different from each other (β [95% CI] = −1.95 [−5.19, 1.28] and −2.20 [−5.39, 0.98], respectively).

  To be responsive to the Committee's comment, we added a sensitivity analysis to the meta-analysis manuscript using the effect estimate from the random-effect models from both Bashash et al. (2017) and Green et al. (2019) to assess the impact of accounting for clustering. The results of that new sensitivity analysis compared to the main overall effect estimate have been added to eTable 6 (see excerpt of eTable 6 below).

  Excerpt of eTable 6. Regression Slopes Meta-analysis

Analysis	Number of Studies	Beta (95% CI)	Heterogeneity	
			p-value	I^2
Overall Estimate				
Full-scale IQ	9	−1.81 (−2.80, −0.81)	<0.001	77%
Sensitivity Analysis *using estimates from random effect models for Green et al. (2019)[113] and Bashash et al. (2017)[112]*				
Full-scale IQ	9	−1.80 (−2.80, −0.80)	<0.001	76%

- In summary, for 12 of the 13 low risk-of-bias studies included in the meta-analysis, the potential impact of clustering was considered minimal due to use of individual-level data and/or adjustment for important covariates (including cohort or city) or similarities between study areas with respect to certain characteristics (e.g., SES). In one of these 12 low risk-of-bias studies (Xiang et al. 2003a), clustering at the village level was not considered in the analytic approach; however, only two villages were compared. A dose-response relationship was observed with the unexposed village as the reference, and a dose-response relationship was observed within the "exposed" village. The dose-response relationship within the "exposed" village suggests that the effect is not driven by between-village differences only, thus reducing the concern for the effect being biased due to lack of accounting for the differences between the two villages and likely minimizing the impact on the effect estimates. In summary, the potential impact of clustering was considered minimal and unlikely to appreciably bias the observed effect estimates.
- In the remaining low risk-of-bias study (Trivedi et al. 2012), comparative analyses did not account for clustering of children within the high- and low-fluoride villages (six villages in total). The study did not use individual exposure levels and did not account for clustering; therefore, the lack of these considerations is likely to bias the standard error of the difference in mean IQ levels between the high- and low-fluoride villages. This bias is likely to make the differences appear stronger than they actually are; however, the clustering bias is not considered sufficient to fully account for the reported differences. Therefore, the lack of accounting for clustering was not considered a major concern, as it would not likely change the nearly 5-point difference in IQ scores reported in the study between the high- and low-fluoride villages. The study is considered low risk of bias overall because it has low potential for bias for the three key risk-of-bias questions (confounding, exposure characterization, and outcome assessment), and clustering was not considered a major concern.

  To be responsive to the Committee's comment, we added a sensitivity analysis to the meta-analysis manuscript that excluded Trivedi et al (2012) from the *mean-effects meta-analysis* (both the overall effect analysis and the low risk-of-bias subgroup analysis) to assess the impact of clustering. Excluding Trivedi et al. (2012) did not change the results appreciably. The results of this sensitivity analysis compared to the main overall effect estimate are shown below.

  Excerpt of eTable 3. Sensitivity Analyses for Mean-effects Meta-analysis: Pooled SMDs and 95% CIs for Children's IQ Score and Exposures to Fluoride

Analysis	Number of Studies	Beta (95% CI)	Heterogeneity	
			p-value	I^2
Overall Estimates				
Overall effect	55	−0.46 (−0.55, −0.37)	<0.001	87%
Low risk of bias	10	−0.22 (−0.39, −0.05)	<0.001	83%
Sensitivity Analyses excluding Trivedi et al. (2012)[40]				
Overall effect	54	−0.46 (−0.56, −0.37)	<0.001	87%
Low risk of bias	9	−0.22 (−0.40, −0.04)	<0.001	85%

The statistical review conducted by NTP also failed to identify a study that did not properly account for the sampling design. Yu et al. (2018) used a hierarchical stratified sampling design but did not indicate that sampling weights were used in the analysis. Thus, both point estimates (means and regression coefficients) and standard errors were likely biased (Lohr, 2019). ***NTP should examine the studies included in the meta-analysis in greater depth to determine whether each study properly accounted for its design because not doing so could invalidate the meta-analysis results***.

Response: Agree (change made)

- We agree with the first part of the recommendation that says we should examine whether the studies properly accounted for sampling design, and we address this part of the comment in the final bullet of this response.
- However, we disagree that using effect estimates from studies that did not properly account for the sampling design invalidates the results of the meta-analysis. The purpose of the meta-analysis is to combine results from multiple studies with a variety of features to examine the data collectively and more precisely quantify the overall (pooled) association. The meta-analysis also allows for exploration of sources of heterogeneity through stratified analyses. Our risk-of-bias assessment carefully considered failures to account for sampling strategy or clustering in determining study-specific potential for bias. Our analyses stratify results by risk-of-bias status to evaluate the potential impact on the overall effect estimates from studies that have high potential for bias versus studies that have low potential for bias.
- We also performed new sensitivity analyses excluding the results from the studies that did not account for complex sampling strategies (Yu et al. 2018; Zhang et al. 2015b) and the pooled effect estimate for full-scale IQ did not change appreciably (see excerpt of eTable 6 below).
- We also performed new sensitivity analyses using unadjusted effect estimates when available. The results showed that including unadjusted effect estimates in the meta-analysis did not change the results appreciably (see excerpt of eTable 6 below).
- While the true tradeoff between bias and uncertainty is unknown, including some unadjusted or insufficiently adjusted effect estimates can still be informative and lead to a more precise pooled estimate due to the number of studies (Higgins et al. 2019).

Excerpt of eTable 6. Regression Slopes Meta-analysis

Analysis	Number of Studies	Beta (95% CI)	Heterogeneity	
			p-value	I^2
Overall Estimate				
Full-scale IQ	9	−1.81 (−2.80, −0.81)	<0.001	77%
Sensitivity Analyses				
Excluding Yu et al. (2018)[3] and Zhang et al. (2015b)[110]				
Full-scale IQ	7	−1.76 (−2.90, −0.62)	<0.001	82%
Using unadjusted estimates from Bashash et al. (2017),[112] Cui et al. (2018),[76] Green et al. (2019)[113], Yu et al. (2018)[3]				
Full-scale IQ	9	−1.82 (−2.81, −0.83)	<0.001	76%

- To address the part of the comment we agree with "***NTP should examine the studies included in the meta-analysis in greater depth to determine whether each study properly accounted for its design"***, we revised text in Appendix E of the prepublication 2022 NTP Monograph (previously Appendix 4 in the September 2020 draft NTP Monograph) to note specifically whether studies accounted for the sampling strategy. In cases where the publication used stratified or clustered sampling designs but did not mention whether the sampling strategy was accounted for in the analysis (e.g., Cui et al. 2018, 2020; Yu et al. 2018), we contacted study authors to specifically ask for this information. If they responded, we updated the information in Appendix E (noting that the information came from correspondence with the authors). If authors did not respond, we noted that we contacted them but did not receive a response.

Need to Juxtapose Results of Broadly Comparable Studies

Note: The NASEM Committee's comment in the first paragraph of this section is on the prepublication 2022 NTP Monograph and is not reproduced here as it is not directly relevant to the meta-analysis. See "Sup01_Monograph" for the monograph-relevant comments and responses.

The critical information regarding comparison of study results comes from the new meta-analysis, which seeks to extract and integrate comparable findings from selected studies as discussed further below. The overall approach appears to be sound in comparing mean IQ scores for the most and least highly exposed to fluoride even though the absolute fluoride concentrations are not comparable among studies. ***Because the meta- analysis is so critical to the conclusions that are drawn, NTP should provide the data that were used from each study to enable the reader to understand and evaluate what was done***.

Note: This comment was about conclusions made on the 2020 draft NTP Monograph, but because it mentions the meta-analysis, we have responded here. While we appreciate the Committee's support of the methods used in the meta-analysis, we strongly disagree with the Committee's assertion that the meta-analysis is critical to the conclusions drawn in the monograph. NTP reached the same hazard conclusions in the 2019 draft NTP Monograph, which lacked a meta-analysis, as we did in the 2020 revision in which we included a meta-analysis at the Committee's recommendation.

With removal of the hazard assessment from the 2020 draft NTP Monograph, our focus shifted to providing a qualitative confidence assessment of the relevant literature of fluoride exposure and neurodevelopmental and cognitive health effects in children and adults which is presented in the prepublication 2022 NTP Monograph. In contrast, the updated meta-analysis manuscript provides a quantitative assessment of the studies examining fluoride exposure and IQ in children. After considering the scope and nature of the NASEM Committee's comments, we determined that without the hazard assessment section to integrate these two assessments, the confidence assessment of the complete evidence base on neurodevelopmental and cognitive health effects in children and adults is a broad and distinct issue from the specific focus of the meta-analysis on IQ in children. It is our view that the topic is of such high public health importance that the

integration of the confidence assessment of the complete evidence base on neurodevelopmental and cognitive health effects would be better done as a collective effort by the public health community in a larger conversation about the appropriate method and timing of population exposures to fluoride to benefit oral health.

The values that were used to determine the standardized mean differences (SMDs) could not be found in the revised monograph, nor was there a figure that showed the pattern of results from studies restricted to the lower exposure ranges. A more detailed assessment of the meta-analysis is provided in the next section.

Response: Agree (change made)

- At the Committee's suggestion, we have added eTable 2 (excerpt provided below), which presents the specific results used from each study including the values used to determine the standardized mean differences (SMDs). Specifically, eTable 2 presents means, standard deviations, sample sizes, regression slopes with 95% confidence intervals, and exposure levels. The source of the results (e.g., table, figure) from each study publication is also listed.
- The results of the studies restricted to lower exposure ranges are presented in eTable 4, eTable 5, eFigure 17, and eFigure 18, which are all provided in supplemental materials.

Evaluation of the Meta-Analysis

The committee found the meta-analysis to be a valuable addition to the monograph and acknowledges the tremendous amount of work that was required. The meta-analysis applied

standard, broadly accepted methods, and the data shown in Figure A5-1 and the related evaluations are especially informative (NTP 2020a, p. 235). As noted in the revised monograph, 44 of the 46 studies represented in that figure had effect estimates to the left of zero—results that indicate an association between higher fluoride exposures and lower IQ. Those results highlight the marked consistency in the current epidemiologic literature on fluoride and childhood IQ. The subgroup analyses also add considerable strength to the monograph. Despite those improvements, there are areas in which further clarification or revision is needed. Because the revised monograph provides the first opportunity to review and comment on the meta-analysis, the committee offers more detailed suggestions here than in the other sections of this letter report.

One area that needs attention is data transparency. Although the results of each study in the meta-analysis are presented in figures, it is difficult to understand where each of the data points comes from and what each data point represents. Many of the publications used in the meta- analysis provide a number of results or present results in several ways. For example, Bashash et al. (2017) provide results for both child and maternal urinary fluoride concentrations. It is difficult to determine which results were selected for the overall meta-analysis or for each subgroup analysis. In addition to the figures in the revised monograph, ***NTP should add a table that provides more information on each study result, including the actual result used from each study (SMDs, regression coefficients, and CIs), any data that NTP might have used to calculate the results (for example, means, standard deviations, and sample sizes), and other key information (for example, exposure concentrations of the high- and low-fluoride groups, the method used to assess exposure and outcome, which populations overlap, and information obtained from study authors).*** Table A-1 includes some of that information but does not include the actual results that NTP selected for the meta-analysis. Overall, adding a table that includes the critical information on each study result would allow readers to identify which result from each study was used and support a better understanding of why NTP selected the results that it did for inclusion in the meta-analysis.

Response: Agree (change made)

- We have updated Table A-1 (now called Table 1. Characteristics of Studies Included in the Meta-analysis) (excerpt provided below) and added eTable 2 (excerpt provided below).
- As requested by the Committee, eTable 2 presents the specific results from each study that were used in each meta-analysis (i.e., the *mean-effects meta-analysis*, the *dose-response mean-effects meta-analysis*, and the *regression slopes meta-analysis*). This includes the actual values from each study that were used to calculate the SMDs, regression slopes, and confidence intervals. Specifically, eTable 2 presents the study design, study location, age range of children, assessment (metric and exposure groups), fluoride exposure levels for each group, means, standard deviations, sample sizes, and regression slopes with 95% confidence intervals. The source of the results (e.g., table, figure) from each study publication is also listed.
- Table 1. Characteristics of Studies Included in the Meta-analysis (excerpt provided below) includes the study design, study location, age range of children, exposure assessment (metric and exposure groups), fluoride exposure levels for each group, intelligence assessment, the overall risk of bias rating, and covariates that were adjusted for in the statistical models.

- In addition, the complete study details are available and downloadable in Excel format from HAWC, a publicly accessible online database. All of the information suggested in the comment is available in HAWC including results (e.g., SMDs, CIs), data for calculations (means, SDs, sample sizes), other key information (e.g., exposure concentrations), and the full study risk-of-bias assessment (see https://hawcproject.org/assessment/405/ for information related to the meta-analysis along with the complete details of the prepublication 2022 NTP Monograph).

As part of its meta-analysis, NTP presents several subgroup and sensitivity analyses. The committee finds them very informative; several are directly responsive to some of the committee's previous concerns. However, ***NTP should also include subgroup or sensitivity analyses that respond to the committee's concerns about blinding, complex sampling designs, and statistical analyses that account for clustered study designs.*** Those analyses would

include subgroup analyses that separate studies that did and did not blind the outcome assessors, a sensitivity analysis that omits studies with complex sampling designs that did not mention the use of sampling weights, and a sensitivity analysis that omits studies that used community-level exposures but did not account for clustering. Alternatively, NTP could perform a sensitivity analysis in which the standard errors of the studies that did not account for clustering are multiplied by an estimate of the VIF. Other subgroup analyses that should be considered are ones that compare prenatal and postnatal exposures. The additional subgroup or sensitivity analyses noted could help to alleviate some of the committee's current concerns.

Response: Agree (change made)

- We conducted additional sensitivity analyses to address all three concerns raised by the Committee: blinding, complex sampling designs, and clustering (the latter two are also addressed in previous responses). Several additional sensitivity analyses are shown in the table below, with one excluding Cui et al. (2018) to respond to the Committee's concerns about blinding. To address the Committee's concerns about complex sampling designs, we conducted a sensitivity analysis excluding Yu et al. (2018) and Zhang et al. (2015b). To address the Committee's concerns about clustering, we performed three sensitivity analyses—one using the unadjusted effect estimates and one using the estimates from the random effect models from Bashash et al. (2017) and Green et al. (2019) (see excerpt of eTable 6 below), and one excluding Trivedi et al. (2012) from the *mean-effects meta-analysis* (see excerpt of eTable 3 below).
- The additional sensitivity analyses had minimal impact on the pooled effect estimate for full-scale IQ (results shown in excerpts below).

Excerpt of eTable 6. Regression Slopes Meta-analysis

Analysis	Number of Studies	Beta (95% CI)	Heterogeneity p-value	Heterogeneity I^2
Overall Estimate				
Full-scale IQ	9	−1.81 (−2.80, −0.81)	<0.001	77%
Sensitivity Analyses				
Excluding Cui et al. (2018)[76]				
Full-scale IQ	8	−1.89 (−3.03, −0.74)	<0.001	80%
Excluding Yu et al. (2018)[3] and Zhang et al. (2015b)[110]				
Full-scale IQ	7	−1.76 (−2.90, −0.62)	<0.001	82%
Using unadjusted estimates from Bashash et al. (2017),[112] Cui et al. (2018),[76] Green et al. (2019)[113], Yu et al. (2018)[3]				
Full-scale IQ	9	−1.82 (−2.81, −0.83)	<0.001	76%
Using estimates from random effect models for Green et al. (2019)[113] and Bashash et al. (2017)[112]				
Full-scale IQ	9	−1.80 (−2.80, −0.80)	<0.001	76%

Excerpt of eTable 3. Sensitivity Analyses for Mean-effects Meta-analysis: Pooled SMDs and 95% CIs for Children's IQ Score and Exposures to Fluoride

Analysis	Number of Studies	Beta (95% CI)	Heterogeneity	
			p-value	I^2
Overall Estimates				
Overall effect	55	−0.46 (−0.55, −0.37)	<0.001	87%
Low risk of bias	10	−0.22 (−0.39, −0.05)	<0.001	83%
Sensitivity Analyses excluding Trivedi et al. (2012)[40]				
Overall effect	54	−0.46 (−0.56, −0.37)	<0.001	87%
Low risk of bias	9	−0.22 (−0.40, −0.04)	<0.001	85%

Another major concern of the committee in its first review was that NTP might have been including multiple results from a given study population. In its meta-analysis protocols (NTP2020b, p. 83), NTP implies that only one result from each population was used. The section of the meta-analysis of "individual-level exposure data" (NTP 2020a, Appendix 5, p. 246) includes a good discussion of two overlapping sets of publications (Yu et al. 2018/Wang et al. 2020 and Green et al. 2019/Till et al. 2020) and the process used to select one result from each set.

However, NTP appears to have included at least one set of overlapping publications—Xiang (2003) and Xiang (2011) (Figure A5-1)—in the overall meta-analysis of mean effects. ***NTP should review all its analyses to ensure that overlapping publications are not included in any single meta-analysis***. That exercise is especially important given that the issue of "double counting" was a substantive concern of the committee in its first review.

Response: Agree (change made)

- We agree with the Committee that, according to our protocol, we should not have included a set of overlapping populations from Xiang et al. (2003) and Xiang et al. (2011) in the same meta-analysis. Therefore, we have removed the Xiang et al. (2011) assessment of IQ associated with serum fluoride levels from the meta-analyses.
- We further reviewed all the analyses and found no other overlapping populations used in a single meta-analysis.

Another issue involves the overall organization of the meta-analysis protocols and results. Information on the meta-analysis protocols and information on the meta-analysis results are presented in several places. That approach forces the reader to go back and forth between sections and between documents to determine what was done or to obtain a clear picture of the meta-analysis findings. For example, some methods are described in the protocol, some in the revised monograph (NTP 2020a, pp. 48-51), and some in Appendix 5. In addition, NTP presents an exhaustive set of forest plots, funnel plots, Egger and Begg test results, and trim and fill plots and results. NTP can be applauded for developing so many data displays and being so transparent here. However, much of the information is not that helpful, and it is difficult to wade through it, given the sheer volume. Some of the information could be eliminated, summarized, or presented more succinctly or at least provided in a separate

document, website, or appendix.
Overall, some coalescing and reorganization of the meta-analysis protocols and results would make the meta-analysis easier to follow and easier to interpret.

Response: Agree (change made)

- We have considered this comment when presenting the meta-analysis results. All forest plots, funnel plots, Egger and Begg test results, trim-and-fill plots, and sensitivity analyses results are presented in supplemental materials, and the number of meta-analysis figures has been appropriately reduced from 103 to 27.

NTP provides a reasonably thorough and appropriate evaluation of publication bias. ***In addition to what it has presented, it should mention the weaknesses of the tests used to evaluate that bias***. One weakness is that the evaluation of the funnel plot involves mostly a subjective interpretation, which can be especially troublesome when the number of studies is small. Another weakness is the possibility that positive results from the funnel plot and the Egger and Begg tests might be caused by something other than publication bias. In addition, NTP uses the phrase "eliminating publication bias" when it refers to the results of the trim and fill analyses (see, for example, NTP 2020a, p. 49). However, because the tests for publication bias are not 100% specific, it is not known exactly what is being eliminated by the trim and fill process. The committee suggests that a better phrase might be "adjusting for possible publication bias." In summary, acknowledging the weaknesses of the tests that were used to evaluate publication bias would make the report more transparent.

Response: Agree (change made)

- We agree with the Committee's overall comment that, "NTP provides a reasonably thorough and appropriate evaluation of publication bias."
- We also agree with the Committee's recommendation to use the phrase "adjusting for possible publication bias" instead of "eliminating publication bias" and revised the language throughout the manuscript.
- Finally, we agree that the limitations of the tests used to evaluate publication bias should be mentioned and have added the following to the *Discussion* section:

  "There are also several limitations to the existing approaches for evaluating potential for publication bias. The funnel plot asymmetry is a subjective assessment and is recommended only when at least 10 studies are included in the meta-analysis.[64] Furthermore, the Egger regression test and Begg's rank tests[25-27] may suffer from inflated type I power and limited power in certain situations.[65]"

NTP notes that 44 of the 46 studies (96%) in its meta-analysis of childhood IQ have effect estimates to the left of zero. That finding should be emphasized more, and its meaning with respect to evaluating and quantifying heterogeneity should be mentioned. To assess heterogeneity, NTP primarily used the Cochran's Q test. However, heterogeneity can also be assessed by providing a count or percentage of the number of studies to the right or left of the null value. Some would consider that a much simpler, more intuitive, and perhaps more useful

way of assessing heterogeneity, especially in light of the marked differences between the studies in design, study populations, exposure and outcome assessment methods, and statistical analyses. Although that approach should not be used as the sole basis of conclusions, it can be a useful first step in exploring why heterogeneity might exist. For example, Figure A5-1 appears to show that Broadbent et al. (2015) and Bashash et al. (2017) are two major contributors to the heterogeneity seen in the overall meta-analysis, and they should be clearly identified in the monograph. NTP does note that there were two studies with effect estimates to the right of the null (NTP 2020a, p. 49, last full paragraph), but a key reference (Bashash et al. 2017) is missing.

Response: Agree (change made)

- We agree with the Committee's suggestion and have revised the *Results* section to emphasize the large number of studies that show effect estimates to the "left of zero" (i.e., to the left of null), as follows:

  "*The pattern of results across the 55 studies was consistent; 52 (95%) reported an inverse association with SMDs ranging from −5.34 (95% CI: −6.34, −4.34) to −0.04 (95% CI: −0.45, 0.36)*".

- We have revised the *Results* section to include clear references to the studies with effect estimates to the right of the null, as follows:

  "*The three studies with a non-negative association reported SMD estimates of 0.01 (95% CI: −0.19, 0.21),[6] 0.01 (95% CI: −0.19, 0.22),[38] and 0.13 (95% CI: −0.16, 0.42).[5]*"

In addition to identifying the studies, NTP should explore whether there might be an obvious or likely reason for the results of those two studies to tend to differ from the results of the others. For example, the Bashash et al. (2017) result used in the meta-analysis of SMDs appears to be for the cross-sectional evaluation of children's urinary fluoride concentrations. However, the study also presents prospective results that use maternal prenatal urinary fluoride concentrations, and, unlike the cross-sectional results, the prospective results indicate a fairly strong adverse relationship—a relationship that is much more consistent with that in the other studies used in the meta-analysis. ***The rationale for choosing one result over the other should be provided because such decisions can affect the results of the meta-analysis***.

Response: Agree (change made)

- As mentioned in a previous comment, we have added a new table, eTable2 (excerpt provided below), which clearly indicates which results were used from each publication and in which analysis they were used (i.e., *mean-effects meta-analysis* or *regression slopes meta-analysis*). In the example of Bashash et al. (2017), the cutoff based on the children's urinary fluoride concentrations (CUF) (0.80 mg/L) was used to determine the reference and exposed groups needed in the *mean-effects meta-analysis*. The estimate from the association between individual-level maternal urinary fluoride (MUF) concentrations and IQ was used in the *regression slopes meta-analysis*.

- In response to this comment, we have added text to the supplemental materials to identify likely reasons that the results from three studies (Bashash et al. 2017, Broadbent et al. 2015, and Green et al. 2019) differ from the results of the other studies, as follows:

"The three studies with non-negative associations reported SMD estimates of 0.01 (95% CI: −0.19, 0.21),[113] 0.01 (95% CI: −0.19, 0.22),[25] and 0.13 (95% CI: −0.16, 0.42).[112] Two of the three studies with non-negative SMDs compare mean IQs in children living in fluoridated vs. non-fluoridated areas in Canada,[113] or in New Zealand.[25] No other studies included in the main mean-effects meta-analysis made comparisons between fluoridated vs. non-fluoridated areas. In both studies, levels of fluoride in water were low, even in communities with fluoridated drinking water, likely limiting the power to detect an effect.

In Bashash et al.,[112] the SMD compares mean IQ scores in children with urinary fluoride levels below vs. above 0.80 mg/L in Mexico.[112] Unlike other studies in the mean-effects meta-analysis which compared mean IQ scores between fluoridated vs. non-fluoridated areas, or areas with high vs. low fluoride exposures (see eTable 2), the Bashash et al.[112] study was not designed to measure fluoride exposure by geographical area. However, since the mean IQ scores were provided in the manuscript for children with urinary fluoride levels below vs. above 0.80 mg/L, we included them in this analysis. It's worth noting that there was no significant difference when comparing MUF levels between the groups of children with urinary fluoride levels above or below 0.80 mg/L, however when children's IQs were regressed against MUF, a statistically significant inverse association was found."

Excerpt of eTable 2. Study Characteristics and Study-specific Effect Estimates Included in the Meta-analyses and Sensitivity Analyses

Reference[a] *Study Design*	Study Location	Age Range (Years)	Assessment (Metric, Exposure Groups)	Fluoride Exposure Levels	Mean-effects Meta-analysis N, Mean (SD) [Reference] [Exposed]	Dose-response Mean-effects Meta-analysis N, Mean (SD) [Reference] [Exposed]	Regression Slopes Meta-analysis Slope (SE) or 95% CI per Unit Change Fluoride	Source
Bashash et al. (2017)[112,me, u, rs] *Prospective Cohort*	Mexico	6–12	Maternal urine Reference/high fluoride levels (based on children urinary fluoride)	<0.80 mg/L (reference) ≥0.80 mg/L (high)	77, 95.37 (10.31) 112, 96.80 (11.16)	77, 95.37 (10.31) 112, 96.80 (11.16)	−2.50 (−4.12, −0.59) per 0.5 mg/L maternal urinary F	Abstract, Table 3
Razdan et al. (2017)[73,sa] *Cross-sectional*	India	12–14	Drinking water Low/high fluoride levels	0.6 ppm (low) 4.99 ppm (high)	69, 38.61 (6.34) 75, 13.95 (5.14)			Table 2
Valdez Jiménez et al. (2017)[74sa] *Prospective Cohort*	Mexico	Infancy	Maternal urine, drinking water	Urine: 1.9 ± 1.0 mg/L (1st trimester) 2.0 ± 1.1 mg/L (2nd trimester) 2.7 ± 1.1 mg/L (3rd trimester) Water: 2.6 ± 1.1 mg/L (1st trimester) 3.1 ± 1.1 mg/L (2nd trimester) 3.7 ± 1.0 mg/L (3rd trimester)			Bayley MDI: −19.05 (8.9) per 1 log10 mg/L maternal urinary F (1st trimester) −19.34 (7.46) per 1 log10 mg/L maternal urinary F (2nd trimester)	Table 2, Table 4
Cui et al. (2018)[76,rs] *Cross-sectional*	China	7–12	Urine	Boys: 1.3 (0.9–1.7)[d] mg/L Girls: 1.2 (0.9–1.6)[d] mg/L			−2.47 (−4.93, −0.01) per 1 log urinary F	Table 2
Yu et al. (2018)[3,me, w, u*, rs] *Cross-sectional*	China	7–13	Maternal urine Low/medium/high fluoride ranges Drinking water Normal/high fluoride	Urine: 0.01–1.60 mg/L (low) 1.60–2.50 mg/L (medium) 2.50–5.54 mg/L (high) Water: ≤1 mg/L (normal) >1 mg/L (high) Overall: 0.01–5.54 mg/L (urine) 0.20–3.90 mg/L (water)	1636, 107.40 (13.00) 1250, 106.40 (12.30)	1636, 107.40 (13.00) 1250, 106.40 (12.30)	0.36 (−0.29, 1.01) per 0.5 mg/L maternal urinary F	Table 1, Table 3

Finally, ***NTP should review the process it used to exclude study results from its meta-analysis***. For example, Table A-2 says Green (2019) was excluded because of "missing mean or SD of outcome measure; used in individual level meta-analysis." However, means and SDs are available (Green 2019, Table 1), and at least two other studies (Ding 2011; and Zhang 2015) are used in both the mean-effect and individual-level meta-analyses.

Response: Agree (change made)

- We have revised the mean-effects meta-analyses and the mean-effects dose-response meta-analyses to include SMDs calculated from the means and standard deviations in Green et al. (2019). We also agree with the Committee that Ding et al. (2011) and Zhang et al. (2015) were correctly included in both the mean-effects and regression slopes meta-analyses.
- We have further reviewed our process and assessed whether any other information was excluded when it should have been included, as described in Appendix 6 of the protocol. We found no other instances where we excluded information when it should have been included.
- The studies that were included in the mean-effects and regression slopes meta-analyses are noted with superscript letters in the first column of Table 1 (excerpt provided below). The footnote to the table defines the superscript letters as follows:

  "An "me" superscript indicates that the studies included in the mean-effects meta-analysis; an "o" superscript indicates a study included in "other" exposures mean-effects meta-analysis (see Table 2 footnote); a "w" superscript indicates studies included in the mean-effects dose-response meta-analysis using fluoride in water; a "u" superscript indicates studies included in the mean-effects dose-response meta-analysis using fluoride in urine; "" indicates studies included in the mean-effects dose-response meta-analysis at levels < 1.5 mg/L; an "rs" superscript indicates studies included in the regression slopes meta-analysis.*"

  Excerpt of eTable 1. List of Excluded Studies from Mean-effects Meta-analysis

Reference, Country	Reason for Exclusion
Qin et al. (1990)[45] [translated in Qin et al. 2008], China	Missing mean or SD of outcome measure
Yang et al. (1994)[47] [translated in Yang et al. 2008], China	Overlapping population with Wang et al. (2001)[49]; Table 2 in Yang et al. (1994)[47] seemed incomplete
Wang et al. (2005b)[50] [translated in Wang et al. 2008a], China	Missing mean or SD of outcome measure
Rocha-Amador et al. (2007)[52], Mexico	Missing mean or SD of outcome measure
Liu et al. (2000)[53] [translated in Liu et al. 2008] , China	Overlapping population with Lu et al. (2000)[55]
Sudhir et al. (2009)[56], India	Missing mean or SD of outcome measure
He and Zhang (2010)[57], China	Missing mean or SD of outcome measure
Xiang et al. (2011)[58], China	Overlapping population with Xiang et al. (2003a)[59]
Saxena et al. (2012)[60], India	Missing mean or SD of outcome measure
Wang et al. (2012)[61], China	Overlapping population with Xiang et al. (2003a)[59]

Excerpt of relevant sections of Table 1. Characteristics of Studies Included in the Meta-analysis

Reference[a] *Study Design*	Study Location	Age Range (Years)	Fluoride Exposure		Intelligence Assessment	Overall RoB Rating	Confounders Considered
			Assessment (Metric, Exposure Groups)	Levels			
Ding et al. (2011)[32me, u*, rs] *Cross-sectional*	China	7–14	Dental fluorosis (normal/ questionable/very mild/mild/moderate) Urine Mean urinary fluoride levels (10 groups)	0.80 ± 0.55 mg/L (normal) 1.13 ± 0.73 mg/L (questionable) 1.11 ± 0.74 mg/L (very mild) 1.31 ± 0.78 mg/L (mild) 1.46 ± 0.79 mg/L (moderate) 0.26 mg/L (group 1) 0.45 mg/L (group 2) 0.56 mg/L (group 3) 0.66 mg/L (group 4) 0.75 mg/L (group 5) 0.89 mg/L (group 6) 1.08 mg/L (group 7) 1.33 mg/L (group 8) 1.74 mg/L (group 9) 2.96 mg/L (group 10) 0.10–3.55 mg/L	Combined Raven's Test for Rural China	Low	Age; arsenic; iodine; lead; SES; demographics
Zhang et al.(2015b)[33me, w*, u, rs] *Cross-sectional*	China	10–12	Urine, drinking water, serum Reference/high fluoride areas	Urine: 1.10 ± 0.67 mg/L (reference) 2.40 ± 1.01 mg/L (high) Water: 0.63 (0.58–0.68) mg/L (reference) 1.40 (1.23–1.57) mg/L (high) Serum: 0.06 ± 0.03 (reference) 0.18 ± 0.11 (high)	Combined Raven's Test for Rural China	Low	Age; sex; arsenic; iodine; drinking water fluoride; SES; thyroid hormone levels; COMT genotype
Bashash et al. (2017)[5me, u, rs] *Prospective Cohort*	Mexico	6–12	Maternal urine Reference/high fluoride (based on children urinary fluoride)	<0.80 mg/L (reference) ≥0.80 mg/L (high)	Wechsler Abbreviated Scale of Intelligence	Low	Age; sex; weight at birth; parity; gestational age; maternal characteristics (smoking history, marital status, age at delivery, IQ, education, cohort)
Yu et al. (2018)[11me, w, u*, rs] *Cross-sectional*	China	7–13	Maternal urine Low/medium/high fluoride ranges Drinking water Normal/high fluoride	Urine: 0.01–1.60 mg/L (low) 1.60–2.50 mg/L (medium) 2.50–5.54 mg/L (high) Water: ≤1 mg/L (normal) >1 mg/L (high) Overall: 0.01–5.54 mg/L (urine) 0.20–3.90 mg/L (water)	Combined Raven's Test for Rural China	Low	Age; sex; health factors; SES
Green et al. (2019)[6me, w*, u*, rs] *Prospective Cohort*	Canada	3–4	Maternal urine, drinking water, maternal fluoride intake Nonfluoridated/fluoridated area	Urine: 0.40 ± 0.27 mg/L (nonfluoridated) 0.69 ± 0.42 mg/L (fluoridated) Water: 0.13 ± 0.06 mg/L (nonfluoridated) 0.59 ± 0.08 mg/L (fluoridated) Intake: 0.30 ± 0.26 mg/day (nonfluoridated) 0.93 ± 0.43 mg/day (fluoridated) Overall: 0.51 ± 0.36 mg/L (urine) 0.54 ± 0.44 mg/day (intake) 0.31 ± 0.23 mg/L (water)	Wechsler Primary and Preschool Scale of Intelligence-III	Low	Sex; city; maternal education; race/ethnicity; HOME score; prenatal secondhand smoke exposure

Notes:
COMT = catechol-O-methyltransferase; RoB = risk of bias; SES = socioeconomic status; HOME = Home Observation for Measurement of the Environment
[a]An "me" superscript indicates that the studies included in the *mean-effects meta-analysis*; an "o" superscript indicates a study included in "other" exposures mean-effects analysis (see Table 2 footnote); a "w" superscript indicates studies included in the *mean-effects dose-response meta-analysis* using fluoride in water; a "u" superscript indicates studies included in the *mean-effects dose-response meta-analysis* using fluoride in urine; "*" indicates studies included in the *mean-effects dose-response meta-analysis* at levels < 1.5 mg/L; an "rs" superscript indicates studies included in the *regression slopes meta-analysis*.
[b]Additional exposure regions including iodine levels were not included in the analysis.
[c]Additional exposure regions including arsenic levels were not included in the analysis.
[d]Median (q1−q3).

The committee identified several minor points concerning the meta-analysis, and these are provided below.

- NTP notes that pooled SMDs and pooled relative risks were considered significantly different when their 95% CIs did not overlap (NTP 2020b, p. 85). That approach can provide many false-negative results because significant differences can occur when CIs overlap.

Statistical significance should instead be determined by hypothesis tests, such as those described in Altman and Bland (2003).

Response: Agree (change made)

- Although we consider the stated approach for comparison of confidence intervals to be a widely used and accepted approach in the scientific community (Schenker and Gentleman 2001), we have taken the Committee's recommendation and have not used the overlap between confidence intervals for formal significance testing in describing our results. While we acknowledge that the method of examining overlap can be more conservative (i.e., rejects the null hypothesis less often), the method is still reliable at correctly detecting significant differences when the confidence intervals clearly do not overlap (Schenker and Gentleman 2001).

Almost all the forest and funnel plots are difficult to see because they are too narrow. They should be expanded horizontally. An example of a forest plot that is much easier to read is Figure 2 in Choi et al. (2012).

Response: Agree (change made)

- We agree with the Committee's suggestion and have revised the forest plot for the *mean-effects meta-analysis*, which appears as Figure 2 (shown below). We have also revised four additional figures that were too narrow and difficult to see due to the large number of studies included. These figures present the forest plots of the meta-analyses stratified by risk of bias, country, IQ assessment type, and exposure, and these are included in the supplemental materials.

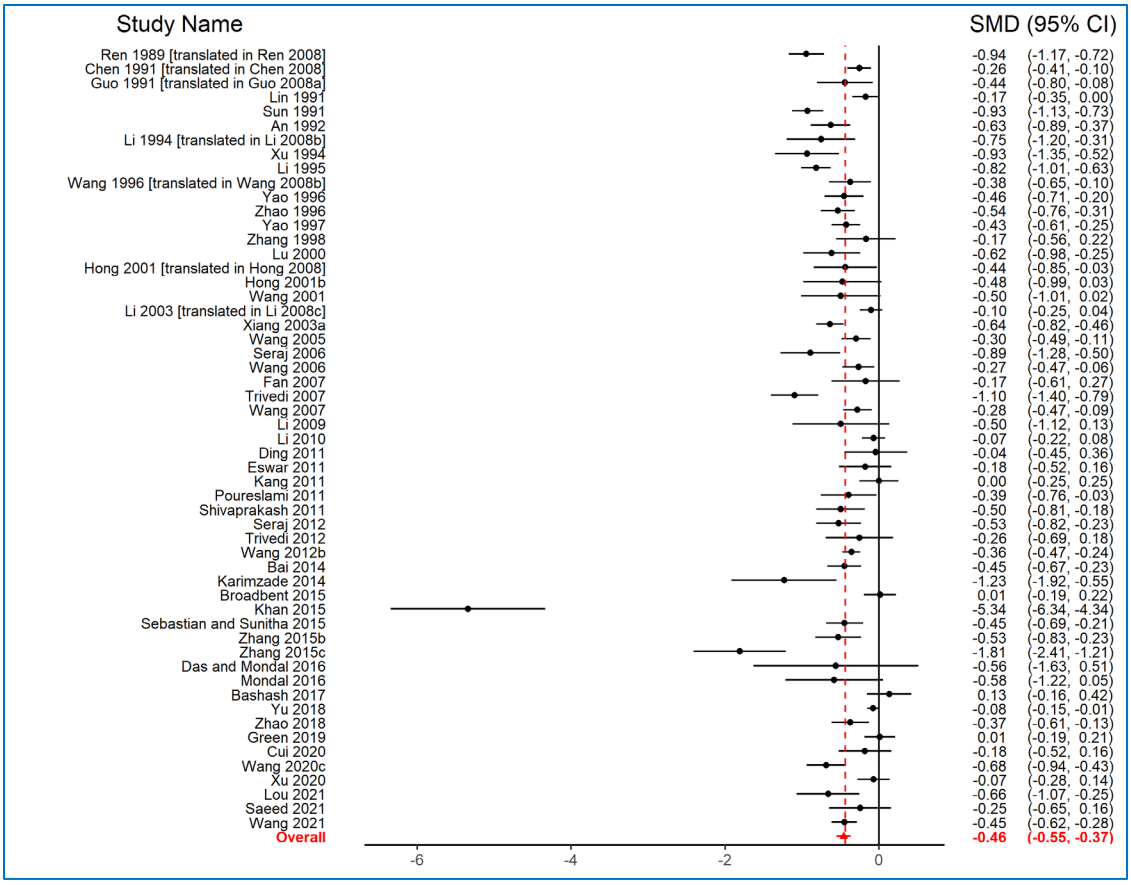

Figure 2. Association Between Fluoride Exposure and IQ Scores in Children

Forest plot for random-effects meta-analysis of the association between fluoride exposure and child's IQ scores. Effect size is expressed as the standardized weighted mean difference for heteroscedastic population variances (SMD). The random-effects pooled SMD is shown as a solid triangle. Horizontal lines represent 95% CIs for the study specific SMDs.

- Labeling the Aim 2 meta-analysis as a "meta-analysis using individual-level exposure data" is somewhat misleading because it is not clear that all the studies used in it involved individual exposure data. Some might have used ecologic exposure data or the types of clustered exposure data discussed above. Aim 2 actually appears to be a meta-analysis of regression slopes, and labeling it as such would be more appropriate.

Response: Agree (change made)

- We followed the Committee's suggestion and relabeled "meta-analysis using individual-level exposure data" to be the "*regression slopes meta-analysis*."
- The change is reflected throughout the *Methods*, *Results*, and *Discussion* sections of the manuscript as well as the *Results* section of the supplemental materials.

- NTP notes that the pooled SMD in its main meta-analysis after applying the trim and fill method is -0.42 (95% CI: -0.54, 0.30) (NTP 2020a, p. 49). NTP should confirm that the CI is correct and that the upper confidence limit is not -0.30.

Response: Agree (change made)

- We corrected the typo in the meta-analysis manuscript to reflect the negative upper limit of the confidence interval. However, since that time, the literature search in the manuscript was updated and this number is no longer relevant.
- The revised trim-and-fill analysis for the *mean-effects meta-analysis* is reflected in the *Results* section as follows:

  "*Adjusting for possible publication bias through trim-and-fill analysis suggested the imputation of seven additional studies to the right side, with an adjusted pooled SMD of –0.36 (95% CI: −0.46, −0.26)*".

- If possible, NTP should summarize its meta-analysis results for SMDs by putting the results in a format that is easier to interpret. For example, if the typical standard deviation for a commonly used IQ test is 15 IQ points, a pooled SMD of -0.50 would be expected to represent about a 7.5-point decrease in IQ. Expressing the major results as estimated IQ points, rather than as just SMDs, would make the results easier for people unfamiliar with SMDs to interpret.

Response: Disagree (no change)

- We agree that this suggestion would make the results easier to interpret. However, we disagree that the suggested approach would appropriately convert the pooled SMD estimate to estimated IQ points. As opposed to the 15 IQ points suggested, the multiplier for the pooled SMD would more appropriately be the standard deviation in the denominator of the pooled SMD from the meta-analysis. This is specific to the meta-analysis and not the same as the standard deviation of the IQs in the population for which the IQ tests were designed. Because the meta-analysis includes studies with different study populations, we decided not to convert the SMDs to IQ points. Therefore, we have not presented the results in the format suggested by the Committee.

- The rationale for excluding the PhD thesis by Thomas from the NTP review of meta-analysis should be provided.[3.]

Response: Disagree (no change)

- We were confused as to why this was recommended by the NASEM Committee for two reasons: (1) our protocol states that unpublished, non-peer-reviewed papers were not included in the systematic review, and (2) the work related to fluoride exposure during pregnancy and children's IQ in the ELEMENT cohort was later published by Bashash (2017) in a peer-reviewed journal and is included in the meta-analysis.
- In addition, the study flow diagram has been updated to an interactive version that provides a list of reasons why studies were excluded. It will be included when the manuscript is submitted for publication, which will allow readers to identify decisions for specific studies.
