FINAL

Report on Carcinogens
Background Document for

Glass Wool Fibers

September 9, 2009

U.S. Department of Health and Human Services
Public Health Service
National Toxicology Program
Research Triangle Park, NC 27709
FOREWORD

The Report on Carcinogens (RoC) is prepared in response to Section 301 of the Public Health Service Act as amended. The RoC contains a list of identified substances (i) that either are known to be human carcinogens or may reasonably be anticipated to be human carcinogens and (ii) to which a significant number of persons residing in the United States are exposed. The Secretary, Department of Health and Human Services (DHHS), has delegated responsibility for preparation of the RoC to the National Toxicology Program (NTP), which prepares the report with assistance from other Federal health and regulatory agencies and nongovernmental institutions.

Nominations for (1) listing a new substance, (2) reclassifying the listing status for a substance already listed, or (3) removing a substance already listed in the RoC are reviewed in a multi-step, scientific review process with multiple opportunities for public comment. The scientific peer-review groups evaluate and make independent recommendations for each substance according to specific RoC listing criteria. This Background Document was prepared to assist in the review of glass wool fibers. The scientific information used to prepare Sections 3 through 5 of this document must come from publicly available, peer-reviewed sources. Information in Sections 1 and 2, including chemical and physical properties, analytical methods, production, use, and occurrence may come from published and/or unpublished sources. For each study cited in the background document from the peer-reviewed literature, information on funding sources (if available) and the authors’ affiliations are provided in the reference section. The draft background document was peer reviewed in a public forum by an ad hoc expert panel of scientists from the public and private sectors with relevant expertise and knowledge selected by the NTP in accordance with the Federal Advisory Committee Act and HHS guidelines and regulations. The document has been finalized based on the peer-review recommendations of the expert panel and public comments received on the draft document. Any interpretive conclusions, comments, or statistical calculations made by the authors or peer reviewers of this document that are not contained in the original citation are identified in brackets [ ].
A detailed description of the RoC nomination review process and a list of all substances under consideration for listing in or delisting from the RoC can be obtained by accessing the 12th RoC at http://ntp.niehs.nih.gov/go/9732. The most recent RoC, the 11th Edition (2004), is available at http://ntp.niehs.nih.gov/go/19914.

Criteria for Listing Agents, Substances or Mixtures in the Report on Carcinogens

U.S. Department of Health and Human Services
National Toxicology Program

The criteria for listing an agent, substance, mixture, or exposure circumstance in the RoC are as follows:

**Known To Be Human Carcinogen:**

There is sufficient evidence of carcinogenicity from studies in humans*, which indicates a causal relationship between exposure to the agent, substance, or mixture, and human cancer.

**Reasonably Anticipated To Be Human Carcinogen:**

There is limited evidence of carcinogenicity from studies in humans*, which indicates that causal interpretation is credible, but that alternative explanations, such as chance, bias, or confounding factors, could not adequately be excluded,

or

there is sufficient evidence of carcinogenicity from studies in experimental animals, which indicates there is an increased incidence of malignant and/or a combination of malignant and benign tumors (1) in multiple species or at multiple tissue sites, or (2) by multiple routes of exposure, or (3) to an unusual degree with regard to incidence, site, or type of tumor, or age at onset,

or

there is less than sufficient evidence of carcinogenicity in humans or laboratory animals; however, the agent, substance, or mixture belongs to a well-defined, structurally related class of substances whose members are listed in a previous Report on Carcinogens as either known to be a human carcinogen or reasonably anticipated to be a human carcinogen, or there is convincing relevant information that the agent acts through mechanisms indicating it would likely cause cancer in humans.

Conclusions regarding carcinogenicity in humans or experimental animals are based on scientific judgment, with consideration given to all relevant information. Relevant information includes, but is not limited to, dose response, route of exposure, chemical structure, metabolism, pharmacokinetics, sensitive sub-populations, genetic effects, or other data relating to mechanism of action or factors that may be unique to a given substance. For example, there may be substances for which there is evidence of carcinogenicity in laboratory animals, but there are compelling data indicating that the agent acts through mechanisms which do not operate in humans and would therefore not reasonably be anticipated to cause cancer in humans.

*This evidence can include traditional cancer epidemiology studies, data from clinical studies, and/or data derived from the study of tissues or cells from humans exposed to the substance in question that can be useful for evaluating whether a relevant cancer mechanism is operating in people.
Executive Summary

Introduction

Glass is an amorphous material produced by solidification from a molten state without crystallization and containing a glass former that can be melted and quenched into a glassy state. Silicon dioxide is the major glass former used for commercial applications. Glass wool refers to fine glass fibers forming a mass resembling wool and most commonly used for insulation and filtration. Glass wool fibers were first introduced into commerce in the 1930s and are now among the world's most extensively used insulating materials. Special-purpose fibers make up a small fraction of the synthetic vitreous fibers (SVFs) market and are used, as the name implies, in specialized applications.

Glass wool fiber diameters vary within a product but follow an approximately log-normal distribution. The fiber diameter is controlled by the manufacturing process. Fiber diameters vary based on the manufacturing process and the fibers’ intended use. The nominal diameter is an estimate of the average fiber diameter of the product. Insulation wool products typically have nominal diameters of 1 to 10 μm and special-purpose fibers have nominal diameters of 0.1 to 3 μm. The diameters of individual fibers in a glass wool product vary widely around the nominal diameter. Unlike crystalline fibers, such as asbestos, glass fibers do not split lengthwise into fibers with smaller diameters, but only break across the fiber resulting in shorter fibers with the same diameter.

SVFs and other mineral fibers have been classified according to origin (natural vs. manufactured), chemistry (organic vs. inorganic), physical form and morphology (e.g., filaments and wools), or commercial applications (e.g., insulation wools and special-purpose fibers).

Fibers, classified by their physical dimensions, have been basically defined since the late 1950s as being greater than 5 μm long and having a length-to-width (aspect) ratio of at least 3:1 (i.e., the fiber is at least three times longer than its width). WHO defines fibers as being greater than 5 μm long, thinner than 3 μm, and having an aspect ratio of > 3:1.
Fibers have also been examined based upon other characteristics, including biopersistence, retention and clearance rates, and biodurability. The European Union (EU) and Germany have established criteria for labeling and classifying SVFs based on their potential to be hazardous to human health.

**Human Exposure**

The vast majority of SVF produced and used in the United States consists of glass wool used for home and building insulation. Small amounts of glass fibers are produced for special applications such as use in battery separator media, high-efficiency filters, and aircraft insulation. Glass wool is produced by heating the glass to high temperatures, extruding the molten glass to form small streams of glass fibers, and using centrifugal force to attenuate the streams of glass into glass fibers. Finer fibers are formed by flame attenuation. Most general purpose insulation glass wools have nominal diameters ranging from 1 to 10 μm, while special-purpose fibers generally range from 0.1 to 3 μm; however, product bulk samples may have fibers with diameters that are several times greater or smaller than the nominal diameters. ACGIH noted that because of this variation, all wool fiber products contain respirable fibers. The physical properties of fibers affect their likelihood of becoming airborne, with smaller fibers more likely to become airborne. Because of this, the average diameter and length may be smaller, and the percentage of respirable fibers higher, for airborne fibers compared with the bulk product.

Occupational exposure may occur in manufacturing facilities as well as for end-users, such as during installation, removal, fabrication, or otherwise working with glass wool outside the manufacturing environment (end-use). OSHA has estimated that more than 225,000 workers in the United States are exposed to synthetic mineral fibers in manufacturing and end-use applications. General population exposure may occur from exposure to SVFs from insulation and building materials or from fibers in the air near manufacturing facilities or areas near building fires or implosions. Exposure may also occur during do-it-yourself home remodeling activities.
No traditional biological indices of exposure exist for SVFs, although the measurement
of fibers in human lung tissue has been attempted as a means to assess exposure to SVFs.
In addition, a recent study investigated the use of nasal lavage as a biomonitoring method
for SVFs.

Fine mineral fiber emissions are regulated by the EPA, respirable fibers (“particulates not
otherwise regulated”) are regulated by OSHA; ACGIH, NIOSH, and OSHA have set
guidelines for fibers in the air in the workplace.

**Human Cancer Studies**

A number of epidemiological studies have evaluated the relationship between glass wool
exposure and cancer in humans. The studies fall into three main groups: (1) cohort and
case-control studies of workers in SVF manufacture, (2) cohort and case-control studies
of workers exposed in glass wool applications (e.g., insulators and construction workers),
and (3) population-based, case-control studies.

Studies within the SVF manufacturing industry have attempted to distinguish between
exposure to different types of SVF, and the large cohort and nested case-control studies
of workers exposed in plants predominantly engaged in glass wool manufacture are the
most informative. [The principal limitations of the glass wool cohort and case-control
studies of manufacturing workers include potential misclassification of exposure,
particularly for past exposures for which few monitoring data are available, inadequate
length of follow-up in some studies for cancers of longer latency, potential confounding
by smoking or co-exposure to other chemicals, and possible misdiagnosis or inadequate
ascertainment of some cancer outcomes, such as mesothelioma. Studies of workers in
SVF applications (two cohort studies and three case-control studies of respiratory cancer)
and the population-based, case-control studies or cancer registry studies (cancers of the
respiratory and/or gastrointestinal tract, non-Hodgkin’s lymphoma, breast, colon, ovary
and rectum) have generally been unable to distinguish between types of fibers and are
consequently less informative, although intermittent exposures might be higher than
observed among manufacturing workers (IARC 2002). In addition, these studies
generally had small numbers of potentially glass wool-exposed subjects and shorter
follow-up times than studies of manufacturing workers, and thus, limited statistical power to detect long-term effects.]

Cancer mortality or incidence has been studied in four cohorts of manufacturing workers: (1) a combined cohort of male and female U.S. SVF manufacturing workers including five plants making mostly glass wool and three making glass wool and filament (Marsh et al. 2001a, Stone et al. 2004), (2) a combined cohort of male and female manufacturing workers in five European glass wool plants (Boffetta et al. 1997, 1999), (3) a cohort of male manufacturing workers in Canada (Shannon et al. 2005), and (4) a cohort of male manufacturing workers in France (Moulin et al. 1986). [The cohorts of manufacturing workers in the United States and Europe are the largest studies and have adequate follow-up to detect cancers with longer latencies (220,700 person-years of exposure in the U.S. cohort and approximately 201,000 person-years of exposure in the European cohort).] In both cohorts, several earlier studies of subcohorts have been conducted, together with two nested case-control studies of respiratory cancer in the U.S. cohort (Marsh et al. 2001a, Chiazze et al. 1992, 1993) and one of lung cancer from part of the European cohort (Gardner et al. 1988).

Reconstruction of glass wool exposures indicated that measurable exposure to respirable glass wool fibers occurred among production workers, and that exposure was higher in the earlier periods of operations. However, as IARC (2002) noted, the concentrations of fibers to which production workers were exposed were generally low.

The potential effect of glass wool exposure on lung and upper respiratory tract cancers has been studied most extensively, due to the structural similarity between glass wool, other SVFs, and asbestos. Findings for respiratory cancers and other tumor sites of interest are discussed below.

**Respiratory cancers**

Statistically significant increases in respiratory cancer mortality were observed among glass wool-exposed workers in unadjusted analyses in the United States (SMR = 1.18, 95% CI = 1.04 to 1.34, $P < 0.05$, lung + larynx, compared with local rates) (Marsh et al. 2001a, Stone et al. 2004).
2001a), European (SMR = 1.27, 95% CI = 1.07 to 1.50, $P$-value not given, lung only, compared with national rates) (Boffetta et al. 1997), and Canadian cohorts (SMR = 1.63, 95% CI = 1.18 to 2.21, $P < 0.05$, lung only, compared with regional rates) (Shannon et al. 2005). Among female workers in the U.S. cohort, no increase in respiratory cancer (trachea, bronchus, and lung) was observed in the whole cohort compared with national or local mortality rates, but in an internal analysis of glass wool-only vs. filament-only–exposed workers, a three-fold increase in these cancers was observed (RR = 3.24, 95% CI = 1.27 to 8.28, Wald $P$-value = 0.014) (Stone et al. 2004). Excesses of lung cancer incidence were observed among the European workers (SIR = 1.28, 95% CI = 0.91 to 1.74, compared with national rates, $P$-value not given) (Boffetta et al. 1999) and Canadian workers (SIR = 1.60, 95% CI = 1.19 to 2.11, $P < 0.05$, compared with regional rates) (Shannon et al. 2005), but not among French workers (SIR = 0.74, 95% CI = 0.24 to 1.72, compared with regional rates) (Moulin et al. 1986).

Attempts were made to control for the effects of smoking and other potentially confounding exposures, including asbestos, formaldehyde, and silica, in the nested case-control study of the U.S. cohort. Adjusting for ever/never smoking (using data obtained from a sample of proxies) reduced the risk of lung cancer mortality among U.S. glass wool workers exposed to respirable fibers (mostly from glass wool) from RR = 1.79 (95% CI = 0.77 to 4.14, $P = 0.17$) to RR = 1.37 (95% CI = 0.55 to 3.42, $P = 0.50$).

(Formaldehyde exposure was also independently associated with lung cancer in this cohort, but models for glass wool and lung cancer adjusting for both formaldehyde and smoking were not presented.) [The European, Canadian, and French studies had few data on potentially confounding exposures.]

Several studies evaluated exposure-response relationships for respiratory cancers. In the U.S. cohort and case-control studies, no clear exposure-response relationships with duration of exposure or cumulative exposure were observed. An association between average intensity of exposure was observed in an unadjusted model but not in models adjusted for smoking or other confounders or in weighted-exposure models (Marsh et al. 2001a, Stone et al. 2001, Youk et al. 2001). There was a modest trend towards increased risk with longer time since first hire in the U.S. but not the European cohort. Similarly, in
the nested case-control studies of lung cancer among the U.K. subgroup of the European cohorts, no clear exposure-response relationships with lung cancer were observed, with the exception of a statistically significant increase among glass wool and/or superfine fiber-exposed workers after 10 to 19 years since first hire in the case-control study of the U.K. subcohort by Gardner et al. (1988) (RR = 2.0, confidence intervals not given, 17 cases). In the Canadian cohort, there was some evidence of a trend towards increased risk with longer duration of employment, time since first hire, and year of hire (Shannon et al. 2005).

Statistically significant increases in lung cancer risk were found among insulation installers in Germany (OR = 1.48, 95% CI = 1.17 to 1.88, 304 cases) and among combined insulation installers and electrical insulation fitters with either 20 or more years (OR = 1.69, 95% CI = 1.01 to 2.81, 61 cases) or 30 or more years (OR = 2.03, 95% CI = 1.04 to 3.95, 47 cases) of potential exposure (Bruske-Hohlfeld et al. 2000). However, no increases in lung cancer risk were found in other studies of construction and application workers or in the population-based, case-control studies of lung cancer. [In general, glass wool exposure cannot be distinguished from other SVF exposure in these studies, and few attempts to adjust for smoking and other confounders were conducted.]

*Mesothelioma*

Only one death from mesothelioma was observed among glass wool-exposed workers in the European cohort (Boffetta et al. 1997). Marsh et al. (2001b) observed seven possible deaths from malignant mesothelioma among the glass wool- or glass wool + filament-exposed workers, but a review of pathology reports or medical records, which were available for only three of these cases, showed that at least two of them were possible misdiagnoses. An earlier case-control study by Rödelsperger et al. (2001) reported a three-fold increase in risk of mesothelioma among mixed SVF-exposed individuals after adjustment for asbestos and other potential confounders (OR = 3.08, 95% CI = 1.17 to 8.07, $P < 0.05$, 55 cases), and a two-fold increase in pleural mesothelioma incidence (SIR = 2.13, 95% CI = 1.35 to 3.20, 23 cases) was observed among a cohort of construction workers by Engholm et al. (1987), but confounding by asbestos might have occurred in these studies.
Upper respiratory and upper gastrointestinal cancers

Marsh et al. (2001a) did not report these cancers separately for the glass wool-exposed workers, but no increases in these cancers were observed in the combined (glass wool- and filament-exposed) cohort (SMR for larynx = 1.01, 95% CI = 0.68 to 1.45, 29 deaths; SMR for buccal cavity and pharynx = 1.11, 95% CI = 0.85 to 1.42, 63 deaths). In the European cohort, a small increase in buccal cavity + pharyngeal mortality and incidence (SMR = 1.47, 95% CI = 0.71 to 2.71, 10 deaths; SIR = 1.31, 95% CI = 0.65 to 2.34, 11 cases), and in laryngeal mortality and incidence (SMR = 1.08, 95% CI = 0.29 to 2.75, 4 deaths, and SIR = 1.68, 95% CI = 0.55 to 3.93, 5 cases), was observed among glass wool-exposed workers (Boffetta et al. 1997, 1999). Moulin et al. (1986) reported a statistically significant excess of “upper respiratory and alimentary tract” cancers in the French cohort (SIR = 2.18, 95% CI = 1.31 to 3.41, 19 cases, including one unexposed production worker and one maintenance worker). In a hospital-based, case-control study, Marchand et al. (2000) reported small increases in both laryngeal cancers (OR = 1.33, 95% CI = 0.91 to 1.95, 133 cases) and hypopharyngeal cancers (OR = 1.55, 95% CI = 0.99 to 2.41, 99 cases; each analysis adjusted for smoking, age, and alcohol intake) among men ever exposed to “mineral wools.” When a 15-year latency period was used, the risks of laryngeal and hypopharyngeal cancer increased (OR = 1.5, 95% CI = 1.03 to 2.22, and 1.65, 95% CI = 1.05 to 2.58, respectively, cases not specified). No significant interaction with asbestos exposure was observed, but few subjects were exposed to mineral wools and not to asbestos.

Other cancer sites

No statistically significant excesses of other tumors have been reported in the largest cohort mortality or incidence studies of production workers or construction workers. [Note that some studies did not report data for all cancer sites.] A number of elevated risks (SMRs or SIRs above 1.0) have been reported for a number of sites in single studies, but only for the following cancer sites in more than one cohort study (excluding earlier studies of subcohorts or earlier follow-ups): deaths or cases of lymphohematopoietic cancers (Boffetta et al. 1997, 1999; Gustavsson et al. 1992); cancers of the urinary bladder (Boffetta et al. 1997, 1999; Marsh et al. 2001a, Stone et al.
2004); melanoma (Boffetta et al. 1999, Gustavsson et al. 1992); and stomach cancers (Boffetta et al. 1997; Shannon et al. 2005; Gustavsson et al. 1992).

In population-based, case-control or registry studies of subjects with possible exposure to glass wool, statistically nonsignificant increases in pre- and postmenopausal breast cancer and ovarian cancer (Vasama-Neuvonen et al. 1999, Weiderpass et al. 1999) and in stomach, esophageal, rectal, gallbladder, and pancreatic cancers (Weiderpass et al. 2003) were observed among Finnish women. A marginally significant increase in rectal cancer (Dumas et al. 2000) and colon cancer (Goldberg et al. 2001) was observed among men in Montreal with “substantial” estimated exposure to glass wool. [Note that statistically nonsignificant increases in rectal cancer were also seen in the cohort study of Shannon et al. (2005), and in pancreatic cancer in the cohort study of Gustavsson et al. (1992).]

Finally, a marginally significant increase in non-Hodgkin’s lymphoma was observed by Hardell and Ericksson (1999).

**Studies in Experimental Animals**

Numerous studies of various types of commercial insulation glass wools, special-purpose glass fibers, and some experimental fibers have been conducted for carcinogenicity in experimental animals by inhalation, intraperitoneal (i.p.) injection, intrapleural injection, intratracheal instillation, and intrathoracic injection or implantation.

Although all inhalation studies conducted prior to the late 1980s were negative, the results were considered inconclusive because of various study limitations recognized by researchers in the field, including a failure in some studies to produce tumors in positive control groups exposed to asbestos fibers. A series of long-term inhalation studies were conducted in rats and hamsters in the late 1980s and early 1990s to address the limitations of the earlier studies. Two glass wool fibers (MMVF10 and MMVF11) and two special-purpose fibers (JM100/475 and 104E) were tested in separate studies.

Significantly increased incidences of lung carcinomas combined with adenomas occurred in male Wistar rats exposed to 104E microfibers but not to JM100/475 fibers; no significant increases in lung tumors or mesotheliomas were reported for male F344 rats exposed to MMVF10, or MMVF11. However, there were apparent positive trends for
both adenomas and combined tumors in male F344 rats exposed to MMVF10. Mononuclear-cell leukemia incidence was statistically significant for F344 rats exposed to Owens-Corning or JM100/475 glass fibers for 86 weeks. In the most recent inhalation study in male hamsters, a mesothelioma was observed in 1 of 83 animals exposed to JM100/475 glass fibers for 78 weeks. Although this result was not statistically significant, the authors considered it treatment related.

Significantly increased incidences of peritoneal tumors (primarily mesothelioma) were reported in almost all i.p. injection studies in rats using different types of fibers including insulation fibers such as MMVF10 and MMVF11 and special-purpose fibers such as JM475 (various diameters), M753, and E glass. However, no tumors were observed in some studies testing experimental fibers that have low biodurability. In most cases, tumor incidences were similar to those seen in the asbestos treatment groups. In addition, increased incidences of pleural sarcomas occurred in rats following intrathoracic implantation of some glass fibers (depending on the fiber dimensions) but not others. Increased incidences of neoplasms (mesothelioma, pleural sarcoma, and lung carcinoma) were observed in some intrapleural or intratracheal instillation studies in rats exposed to JM100 or JM104 microfibers and in intratracheal instillation studies in hamsters exposed to JM104 microfibers. No tumors were reported following intrapleural or intratracheal instillation of glass wool in mice, guinea-pigs, or rabbits.

A number of studies, including both intrathoracic implantation and i.p. injection of fibers, have been conducted with the intent of comparing fibers with different characteristics, such as differing fiber dimensions and biopersistence/durability. The earliest of these studies by Stanton and co-workers using intrathoracic implantation of glass fibers and other natural and synthetic fibers led the authors to conclude that fiber dimensions and durability were important in determining the tumorigenicity of the material. Later studies using i.p. injection reached similar conclusions in many cases, but some data suggest that the relationship might not be completely defined by those fiber characteristics.
Deposition, clearance, and retention

Fibers that are carried in the inhaled air to the tracheobronchial region are considered *inhalable* while those that reach the alveolar region are considered *respirable*. Fibers that are inhalable but non-respirable can deposit in the extrathoracic and tracheobronchial regions and can cause adverse effects. Deposition refers to the actual dose deposited in the lung and is influenced by the anatomy and physiology of the airway, respiratory rate, and physical properties of the fiber. Deposition occurs by impaction, sedimentation, interception, and diffusion. Peak deposition occurs in rodents and humans for fibers with aerodynamic diameters of 1 to 2 μm.

Clearance and retention of fibers are affected by chemical composition, size distribution, number of fibers deposited, and time since last exposure. Clearance mechanisms also depend on the region of deposition. Short fibers are readily phagocytized by alveolar macrophages and transported from the lower lung to the upper airways and cleared through the mucociliary escalator, or they can be cleared via lymphatics. Long fibers are not effectively cleared by phagocytosis, and can effectively kill the phagocyte, but depending on the fiber type, may be subject to dissolution and transverse breakage.

Particle overload (which has been observed in rats) occurs when the deposition rate of poorly-soluble, less toxic particles exceeds the normal clearance rate, and can result in adverse effects.

Dissolution, biodurability, and biopersistence of glass fibers

Dissolution occurs when water molecules attack the surface of the fiber and remove material. Biodurability describes the rate of removal through dissolution or disintegration; biopersistence includes biodurability plus physiological clearance and refers to the capacity of a fiber to persist and to conserve its chemical and physical features over time in the lung. Biodurability is expected to be similar in rats and humans, but biopersistence may be substantially different due to differences in the physiological clearance mechanisms. In general, biodurability of various fibers in the lung has been ranked as follows: glass fibers < refractory ceramic fibers < chrysotile asbestos < amphibole asbestos. Highly durable fibers, such as asbestos, are resistant to dissolution.
and transverse breakage. Although experimental dissolution rates for glass fibers show variability (up to a 30-fold range), they generally show some correlation with clearance rates of long fibers in short-term biopersistence studies. Certain components of SVFs are subject to leaching resulting in changes in composition over time. The literature indicates that the special-purpose fibers cited in this document tend to have greater biopersistence than the insulation glass wools. The fibers become weaker from fractures, peeling, and pitting and may break.

**Toxic effects**

Several studies have evaluated mortality from non-malignant respiratory disease or morbidity related to the respiratory system among workers exposed to glass wool. A significantly elevated SMR for non-malignant respiratory disease was found in the earlier updates, but not the most recent update of the large U.S. cohort study. Mixed findings have also been observed for adverse respiratory symptoms, pulmonary function, and lung abnormalities (detected on chest radiographs); workers in some studies were also exposed to asbestos.

Various types of glass wool fibers (MMVF10, MMVF11, 104E glass fibers, JM100/475 microfibers) caused adverse lung effects (such as inflammation and fibrosis) in rats exposed by inhalation (Bellmann et al. 2003, Bermudez et al. 2003, Cullen et al. 1997, Hesterberg et al. 1993, 2002). In hamsters, inhalation of MMVF10 fibers caused inflammatory effects, but not fibrosis (Bermudez et al. 2003, Hesterberg et al. 1993). In cytotoxicity studies, longer fibers induced greater toxicity in rat alveolar macrophages (Blake et al. 1998, Hart et al. 1994).

**Genetic and related effects**

Glass fibers were shown to induce production of reactive oxygen species in cell-free systems and cultured cells, to damage DNA, and to cause chromosomal aberrations, nuclear abnormalities, mutations, gene amplification in proto-oncogenes, and cell transformation in mammalian cells. However, glass wool fibers did not cause mutations in bacteria or cause sister chromatid exchange in mammalian cells, but only two types of fibers were tested in each of these assays. Glass wool fibers also induced DNA strand
breaks (measured by the comet assay) in macrophages and lung epithelial cells, and oxidative stress in rats, but did not induce mutations \textit{in vivo}. An increase in mutant frequencies was reported for benzo[a]pyrene and rock wool fibers instilled simultaneously in Big Blue rats.

Further, fiber persistence may also lead to inflammation-driven (indirect) genotoxicity, as reactive inflammatory cells release reactive oxygen species, growth factors, and cytokines. Fiber characteristics did not appear to be important in the production of reactive oxygen species, and studies assessing oxidative damage by different endpoints were positive for both special-purpose fibers and insulation glass wool fibers. Similarly, fibers of different lengths and diameters were able to cause DNA damage in mammalian cells. However, effects on chromosomes and nuclear abnormalities might be related to fiber characteristics; longer fibers appeared to be more potent in causing these genotoxic effects. Some studies suggested that thinner fibers were also more effective. Results from cell transformation studies also suggested that longer and thinner fibers produced higher transformation efficiency.

\textbf{Mechanisms of fiber carcinogenicity}

Several investigators have evaluated fiber characteristics (dimensions and durability or biopersistence) and tumorigenicity in studies in experimental animals. These studies (by i.p. injection and intrathoracic implantation) show that fiber dimensions and durability were important determinants of tumorigenicity. In intrathoracic implantation studies, pleural sarcomas were correlated with fiber dimensions; long, thin fibers were associated with the highest tumor incidence. Fibers with a high dissolution rate tended to have a low potency in the i.p. assay. A relationship between biopersistence in the lung and pathology was also observed in inhalation studies in rats. Clearance half-times of long fibers (> 20 \(\mu\)m) were approximately 400 to 800 days for two types of asbestos, 80 days for E glass, 50 days for JM100/475 glass, 15 days for MMVF10, and 9 days for MMVF11.

The major proposed mechanisms of fiber-induced carcinogenicity are related to the physical and chemical properties (such as size or dimensions, durability, surface reactivity, and chemical composition) of the fibers and to the inflammatory response that
results from the inhalation of fibers. Fiber size affects deposition and clearance, and biodurability and biospersion are related to biological effects. Fibers can directly interact with target cells (epithelial cells, mesothelial cells, fibroblasts) leading to an inflammatory response and/or genotoxicity. Fibers may induce genotoxic effects by interacting with the spindle apparatus of chromosomes, directly damaging DNA, or indirectly damaging DNA through chronic inflammation. Fibers may also induce epigenetic changes. Alveolar macrophages are activated in response to particulates or fibers deposited in the lung, resulting in increased release of reactive oxygen species, chemical mediators, and cytokines (such as TNF-α) and activation of signalling pathways. A sustained inflammatory reaction may result from incomplete phagocytosis and prolonged interaction of persistent fibers with the cell surface. Chronic imbalance between cytokines and growth factors may contribute to tissue injury, proliferation, and/or apoptosis, which may lead to fibrosis and tumors.

1 Introduction

Glass wool refers to fine glass fibers forming a mass resembling wool and most commonly used for insulation and filtration. Glass is an amorphous material produced by solidification from a molten state without crystallization and containing a glass former (e.g., silicon dioxide [SiO$_2$], boron trioxide [B$_2$O$_3$], phosphorus pentoxide [P$_2$O$_5$], or germanium dioxide [GeO$_2$]) that can be melted and quenched into a glassy state (IARC 2002). Silicon dioxide is the major glass former used for commercial applications because of its availability and low cost, but commercial glasses generally include additional oxides that modify the physical and chemical properties of the glass product, including viscosity, which is an important characteristic for fiberization. These modifiers include oxides of aluminum, titanium, zinc, magnesium, lithium, barium, calcium, sodium, and potassium.

There are two categories of glass wool based upon usage in commercial applications: insulation glass wool and special-purpose fibers. Insulation glass wools are used for applications such as thermal, electrical, and acoustical insulation and in weatherproofing, while the term “special-purpose glass fibers” is used to describe a category of fibers distinguished by their use in specialized products that include aircraft and aerospace insulation, battery separators, and high-efficiency filters.

Glass wool (respirable size) has been listed in the Report on Carcinogens since the Seventh Edition (1994) as reasonably anticipated to be a human carcinogen. It was nominated for delisting from the Report on Carcinogens by the North American Insulation Manufacturers Association based on the 2002 IARC reevaluation of glass wool. The 2002 IARC monograph evaluated Man-Made Vitreous Fibers, which included glass wool, as well as continuous glass filament, rock (stone) wool, slag wool, refractory ceramic fibers, and newly developed fibers. Glass wool was further divided into the categories of insulation glass wool and special-purpose fibers (see Sections 1.1.2 and 1.2). The 2002 IARC Working Group concluded that there was inadequate evidence in humans for the carcinogenicity of glass wool. They further concluded that there was limited evidence in experimental animals for the carcinogenicity of insulation glass wool.
and classified insulation glass wool as Group 3, not classifiable as to its carcinogenicity in humans. Special-purpose glass fibers such as E-glass and 475 fibers were classified as Group 2B, possibly carcinogenic to humans, based on sufficient evidence in experimental animals.

The following sections provide an overview of the various categories of synthetic vitreous fibers (SVFs) (Section 1.1), the chemical and physical characteristics of glass wools (Section 1.2), and methods for fiber classification (Section 1.3).

1.1 Synthetic vitreous fibers

SVFs are a large category that comprises glass wools, as well as other types of glass fibers not covered by this nomination, e.g., continuous glass filaments, and other types of "wools" such as rock wool, slag wool, and ceramic fibers. The general class of SVFs is defined in Section 1.1.1, and the categories of SVFs as defined by IARC (2002) are discussed in Section 1.1.2.

1.1.1 Definition of SVFs

SVFs are manufactured inorganic fibrous materials that contain aluminum or calcium silicates, and are made from a variety of materials, including rock, clay, slag, or glass (ATSDR 2004). Fibers are distinguished from other irregularly shaped particulate matter based on their tendency to form particles with a large aspect ratio (length to diameter ratio). Fibrous particulate matter can be either naturally occurring, like asbestos, or synthetic. SVFs differ from asbestos and other naturally occurring mineral fibers because they have an amorphous or glass-like rather than a crystalline structure. The absence of a crystalline structure can be used to aid in their identification. Historically SVFs have been referred to as man-made mineral fibers (MMMFs), or man-made vitreous fibers (MMVF), although the terms used in the United Kingdom have been defined as “machine-made” to preserve the acronyms and maintain gender neutrality. The exact nomenclature and taxonomy used to classify these materials have changed over time and are currently the focus of debate as reviewed by Moore et al. (2002).

Glass wool fibers were first introduced into commerce in the 1930s and are now among the world's most extensively used insulating materials. IARC (2002) described wool
(such as glass wool) as “a mass of tangled, discontinuous fibres of variable lengths and
diameters” and contrasted it with filaments, “which are continuous fibres (of
indeterminate length) with diameters having ranges that are more uniform and typically
thicker than those of wool.”

1.1.2 Categories of SVFs

SVFs and other mineral fibers have been classified according to origin (natural versus
manufactured), chemistry (organic versus inorganic), physical form and morphology
(e.g., filaments and wools), or commercial applications (e.g., insulation wools and
special-purpose fibers). IARC (2002) divided SVFs into the categories shown in Figure
1-1. However, there are a number of commercial and experimental products within each
category that vary in composition, dimensions, durability, and biological activity. The
categories identified by IARC are based on physical form and commercial applications,
but Moore et al. (2002) and other authors have proposed methods for grouping fibers
according to potential biological activity (Figure 1-2).
As illustrated in Figure 1-1, glass wool can be divided into two sub-categories, insulation wool and special-purpose fibers. Special-purpose fibers make up a small fraction of the glass wool market and are used, as the name implies, in specialized applications (see Section 2.1). Special-purpose fibers are more highly engineered than glass wool and typically contain oxides such as ZnO, ZrO₂, and BaO that improve the ability to fiberize the glass at diameters below 1 μm and increase durability, as reported in a public comment in response to FR 2004 (Carey 2004). Therefore, special-purpose fibers typically are smaller in diameter, more durable, and more biopersistent than the typical insulation glass wool. Biopersistence and toxicity will be discussed later in this review.

Although most published information about special-purpose fibers refers to 475 and E-glass, there are many other types. Although each manufacturer has its own product designations, special-purpose fibers share in common certain physical and chemical characteristics described in this section. In addition to 475 and E-glass, examples of other special-purpose fibers include UPF363, Evanite M and B (a version of 475 glass), and

---

1 Information provided in a public comment received from Tim Carey of Johns Manville, in response to a Federal Register notice of May 19, 2004 (FR 2004).
Lauscha A-, B- (also a version of 475 glass), and C-glass. Table 1-1 lists examples of insulation glass wools, and Table 1-2 lists examples of special-purpose glass fibers used in the studies reviewed in this document.

<sup>a</sup>WHO (1988) noted that these specifications were current at the time of that publication; however, specifications have changed over time.

<sup>b</sup>475 = general purpose borosilicate; E = electrical grade, alkali-free borosilicate [WHO definitions].

<sup>c</sup>[No explanation was reported by WHO for the overlap in range of diameters for codes JM100 and JM102.]

1.2 Chemical and physical properties

The chemical composition of glass wool products varies depending on the manufacturing requirement and end-use, but almost all contain silicon dioxide as the single largest oxide ingredient (IARC 2002). Silicon dioxide or one of a few other oxides is required in order to form glass, and these oxides are known as “glass formers.” The essential property of a glass former is that it can be melted and quenched into the glassy state. Other oxides are added as stabilizers and modifiers or fluxes. In addition, various lubricants, binders,
antistatic agents, extenders and stabilizers, and antimicrobial agents may be added to various products. Lubricants may be added to reduce dust generation. Binders, such as phenol-formaldehyde resins, melamine, or acrylic resins, may serve to hold the fibers together. The binder content for most insulation wool products is low but may reach 25% for some products.

Table 1-4 provides chemical composition data that were identified for various glass fibers discussed in this document.

l Roller et al. 1996.
m Experimental fibers (Lambré et al. 1998).
n Bellmann et al. 1987 footnote for CaO states “Include [sic] MgO.”
Important physical properties include fiber dimensions, density, and durability. Glass wool fiber diameters vary within a product but follow an approximately log-normal distribution. However, the fiber diameter is not an inherent property of the type of fiber but is controlled by the manufacturing process. All SVFs are manufactured to nominal diameters that vary based on the manufacturing process and the fibers’ intended use (ACGIH 2001). The nominal diameter is an estimate of the average fiber diameter of the product. ACGIH (2001) reported that insulation wool products typically have nominal diameters of 1 to 10 μm, although it was noted that most products have a nominal diameter within the 3 to 10 μm range. Special-purpose fibers have nominal diameters that range typically from 0.1 to 3 μm. Current glass wool production processes are not capable of producing fibers only at the nominal diameter, and as a result, the diameters of individual fibers in a glass wool product vary widely around the nominal diameter. IARC (2002) noted that a product with an average diameter of 5 μm will contain fiber diameters ranging from < 1 to > 20 μm. Unlike crystalline fibers, such as asbestos, glass fibers do not split lengthwise into fibers with smaller diameters. They can only break across the fiber resulting in shorter fibers with the same diameter.

The manufacturing process also affects fiber length. In glass wool insulation, most fibers are several centimeters long; however, fibers with lengths of less than 250 μm (considered by IARC as the upper limit of respirability) probably are present in all glass wool products (IARC 2002). Mean fiber lengths for JM475 are 1 to 1.5 mm, and for Evanite filter grade special-purpose fibers they are ≥ 4.5 mm as defined by a public comment in response to FR 2004 (Carey 2004). Fiber densities are not as variable as diameter and length and are typically 2.4 to 2.6 g/cm³ (IARC 2002).

1.3 Fiber classification
Fibers, classified by their physical dimensions, have been basically defined since the late 1950s as being greater than 5 μm long and having a length-to-width aspect ratio of at least 3:1 (i.e., the fiber is at least three times longer than its width) (Breysse et al. 1999, Walton 1982). Other more recent definitions have suggested that an aspect ratio of 5:1 will more readily discriminate fibrous from irregularly shaped particles. The World Health Organization (WHO) defines fibers as being greater than 5 μm long, thinner than
3 μm, and having an aspect ratio of > 3:1. The United States National Institute for Occupational Safety and Health (NIOSH) has two sets of fiber definitions, the so-called “A” and “B” rules (NIOSH 1994). Table 1-5 compares the NIOSH and WHO fiber definitions.

NS = not specified.

Depending on the production process, fibers can have relatively large or small diameters. The diameter of a fiber is an important property because very thin fibers can enter the respiratory tract and deposit deep in the lungs (see Section 2). Fibers with diameters less than 3 μm are usually considered able to penetrate into the lower respiratory tract of humans. These fibers are usually called “respirable,” although the term thoracic is more accurate. Baron has shown that the fraction with diameters less than 3 μm agrees well with the thoracic deposition fraction (Baron 1996). Since possible bronchogenic effects (i.e., lung cancer) are under consideration, a thoracic fraction is appropriate. This review will focus on the so-called “respirable” glass wool fibers since these are the fiber sizes that present the greatest inhalation risk.

Dose, dimension, and durability have been termed the three Ds, all of which are important in determining the carcinogenicity of fibers (see Section 5.3). See the Glossary and Section 5 for definitions of durability and the related terms biodurability, biopersistence, dissolution rate ($k_{dis}$), and Z-score. Several classification systems exist based on these characteristics; the following is a discussion of the European and German classification systems for labeling SVFs.

### 1.3.1 European classification system

In 1997, the European Union (EU) established criteria for labeling and classifying SVFs based on their potential human health hazard under the Dangerous Substances Directive.
Under this system, all SVFs are considered irritants and are classified for carcinogenicity according to the criteria in Table 1-6.

**Table 1-6. European carcinogenicity classification**

<table>
<thead>
<tr>
<th>Classification</th>
<th>Definition &amp; criteria</th>
</tr>
</thead>
<tbody>
<tr>
<td>(1) Carcinogen</td>
<td>Substances known to be carcinogenic to man. There is sufficient evidence to establish a causal association between human exposure to the substance and the development of cancer.</td>
</tr>
<tr>
<td>(2) Probable carcinogen</td>
<td>A substance that should be regarded as if it is carcinogenic to man. There is sufficient evidence to provide a strong presumption that human exposure to the substance may result in the development of cancer, generally on the basis of appropriate long-term animal studies or other relevant information. SVF Criteria: Diameter ≤ 6 μm; Solubility Index (KNB) ≤ 18%</td>
</tr>
<tr>
<td>(3) Possible carcinogen</td>
<td>A substance that is of concern as a possible human carcinogen, but available information is not adequate for a valid assessment. There is some evidence from appropriate animal studies, but this is insufficient to place the substance in Category 2. SVF Criteria: Diameter ≤ 6 μm; Solubility Index &gt; 18%.</td>
</tr>
<tr>
<td>(0) Not classified as a carcinogen</td>
<td>Exempt from carcinogenicity classification (but still considered an irritant). SVF Criteria: Diameter &gt; 6 μm</td>
</tr>
</tbody>
</table>

* Criteria used to classify insulation wools composed of fiber glass or rock/stone/slag wools that have not been evaluated in a carcinogenicity or biopersistence test.

* Nota R of Commission Directive 97/548/EEC, 12/5/97, states: “length-weighted geometric mean diameter less 2 standard errors greater than 6 μm.” This is roughly equivalent to a geometric mean diameter of 6 μm.

Based on this classification system, SVFs with diameters greater than 6 μm are not considered carcinogenic (because they are nonrespirable), but they are considered irritants (Hesterberg and Hart 2001). Untested SVFs with diameters ≤ 6 μm are categorized in Category 2 or 3 depending on the results of the Soluble Components Index (KNB). The KNB is equal to the sum of the percent composition of the more rapidly dissolving components (Na₂O + K₂O + CaO + MgO + BaO). This sum of alkali and alkaline earth oxides is also described by the term “Z-score,” and fibers with a Z-score less than or equal to 18% are considered to represent a greater potential hazard than those with a Z-score greater than 18% (Moore et al. 2002). However, Moore et al. (2002) noted that fibers are not customarily defined by their total alkali and alkaline earth oxides, and that it is not clear that such a “bright line” can divide the continuum of glass fibers into categories of risk or hazard. Nevertheless, Moore noted that the EC Directive would place glass microfibers (i.e., special-purpose fibers) in Category 2 (probable), and
standard insulation glass wools in Category 3 (possible). [However, many of the special-purpose fibers have Z-scores > 18%, e.g., JM104E = 28.5 and M753 = 24.8, and thus would be included in Category 3 along with insulation glass wools.] A Category 3 fiber can be exempted from carcinogenicity classification (but still be considered an irritant) if it passes one of the four tests described in Table 1-7. All of these tests are conducted in rats. In their final conclusions, Moore et al. reported that they did “not believe that there is scientific justification for the use of Z-scores as a basis for classifying substances as carcinogens.”

*WT$_{1/2}$ = weighted lung clearance half-time.

The weighted lung clearance half-time (WT$_{1/2}$) is calculated by weighting each clearance half-time (T$_{1/2}$) by multiplying it by the proportion of fibers in that pool ($a_1/\left[a_1 + a_2\right]$ or $a_2/\left[a_1 + a_2\right]$) and then summing the two weighted T$_{1/2}$ values and dividing by 2 (Hesterberg and Hart 2001).

#### 1.3.2 German classification system

Soon after the European classification system was enacted, Germany enacted its own criteria for classifying SVFs according to carcinogenicity (Hesterberg and Hart 2001). Germany considers every SVF to be carcinogenic, and very strict worker protection requirements are required unless the fibers pass one of the three tests outlined in Table 1-8. These include the carcinogenicity index (KI), biopersistence test, and intraperitoneal (i.p.) injection test. The KI is another solubility index that tries to predict fiber dissolution rate based on fiber composition. In the biopersistence test (intratracheal instillation), rats are instilled with 0.5 mg of fibers per day for 4 days, with a total dose of 2 mg. Lung burdens are evaluated for up to 3 months. The lung clearance half-time (T$_{1/2}$) for the fibers must be less than 40 days to pass this test. The intraperitoneal injection test is
conducted using the same protocol as that used by the European carcinogenicity classification (see Section 1.3.1) (Bernstein and Sintes 1999). In order to pass this test, the tumor incidence must not be significantly elevated above the level seen in controls (Hesterberg and Hart 2001).

1.4 Summary

Glass is an amorphous material produced by solidification from a molten state without crystallization and containing a glass former that can be melted and quenched into a glassy state. Silicon dioxide is the major glass former used for commercial applications. Glass wool refers to fine glass fibers forming a mass resembling wool and most commonly used for insulation and filtration. Glass wool fibers were first introduced into commerce in the 1930s and are now among the world's most extensively used insulating materials. Special-purpose fibers make up a small fraction of the SVF market and are used, as the name implies, in specialized applications.

Glass wool fiber diameters vary within a product but follow an approximately log-normal distribution. The fiber diameter is controlled by the manufacturing process. Fiber diameters vary based on the manufacturing process and the fibers’ intended use. The nominal diameter is an estimate of the average fiber diameter of the product. Insulation wool products typically have nominal diameters of 1 to 10 μm and special-purpose fibers have nominal diameters of 0.1 to 3 μm. The diameters of individual fibers in a glass wool product vary widely around the nominal diameter. Unlike crystalline fibers, such as asbestos, glass fibers do not split lengthwise into fibers with smaller diameters, but only break across the fiber resulting in shorter fibers with the same diameter.
SVFs and other mineral fibers have been classified according to origin (natural vs. manufactured), chemistry (organic vs. inorganic), physical form and morphology (e.g., filaments and wools), or commercial applications (e.g., insulation wools and special-purpose fibers).

Fibers, classified by their physical dimensions, have been basically defined since the late 1950s as being greater than 5 μm long and having a length-to-width (aspect) ratio of at least 3:1 (i.e., the fiber is at least three times longer than its width). WHO defines fibers as being greater than 5 μm long, thinner than 3 μm, and having an aspect ratio of > 3:1.

Fibers have also been examined based upon other characteristics, including biopersistence, retention and clearance rates, and biodurability. The European Union (EU) and Germany have established criteria for labeling and classifying SVFs based on their potential to be hazardous to human health.
2 Human Exposure

The vast majority of glass wool manufactured in the United States is used in home and building insulation products. A small percentage is used for a number of special applications; such as for aircraft and aerospace insulation, as battery separators, and in filtration products. Occupational exposure can occur in glass wool production facilities and other facilities, such as fiberglass insulating operations and pipe insulation installation. Limited information is available on environmental exposure and occurrence of glass fibers, but general population exposure can occur where they are used, e.g., as insulation materials, or from fibers in the air near manufacturing facilities.

This section provides information on the uses of glass fibers and glass-fiber products (Section 2.1); on the manufacturing process, production levels, and levels of imports and exports (Section 2.2); on occupational exposures (Section 2.3); on environmental occurrence and general population exposure (Section 2.4); on biological indices of exposure (Section 2.5); and on regulations and guidelines for glass fibers that are intended to reduce exposure (Section 2.6).

2.1 Uses for glass fibers

Glass fibers can generally be classified into two categories: low cost general-purpose fibers typically used for insulation applications and premium special-purpose fibers used in limited specialized applications (Wallenberger et al. 2001). Another class of glass fibers is the continuous glass filaments, also referred to as glass textile fiber (IARC 2002); however, these filaments are produced in nominal diameters ranging from 5 to 25 μm with very narrow variation around this mean value. Due to the larger diameter of these glass fibers, they are not considered respirable and therefore are not reviewed in this background document.

2.1.1 Glass wool for insulation

Glass wool has many commercially valuable physical properties, including low thermal conductivity and volumetric heat capacity, that enable glass wool materials to be effectively used for insulation purposes. As a result, the primary uses of glass wool are for thermal and sound insulation. The largest glass wool use is for home and building...
insulation purposes in the form of loose wool, batts (insulation in the form of a blanket, rather than a loose filling), blankets or rolls, or in the form of rigid boards for acoustic insulation. Glass wool is also used for industrial, equipment, and appliance insulation. A summary of the main insulation wool uses as defined by IARC is presented in Table 2-1.

### 2.1.2 Non-insulation uses (special-purpose fibers)

Special-purpose glass fibers are limited-production materials compared with insulation glass wool, but they are used for a variety of applications that either require a specialized glass formulation or particular diameter requirements. Typical products have nominal fiber diameters of less than 3 μm and frequently less than 1 μm with an average diameter ranging from 0.1 to 3 μm compared with the average of 1 to 10 μm for insulation glass wool fibers (ACGIH 2001). These specialty fibers are used in aircraft and aerospace insulation, as battery separators, and in filtration products. The largest market for special-
Purpose glass fibers is for battery separator media, with the primary component of such media being an acid-resistant borosilicate glass fiber. The purpose of the glass fiber media is to physically separate the positive and negative plates of the battery, while allowing the acid electrolyte to pass through the media (IARC 2002).

Another use of special-purpose glass fibers is in high-efficiency particulate air (HEPA) filters that are used in settings where high-efficiency filtration of air is required. Examples include use in hospitals, clean rooms of pharmaceutical laboratories, nanotechnology industries, microbiological laboratories, and nuclear power plants. These filters are used to increase the quality of indoor air, as these filters can remove sub-micron particulate matter as described by a public comment in response to FR 2004 (Carey 2004). See Table 2-2 for some examples of special-purpose glass fibers and their commercial uses.

### 2.2 Production, import, and export information

#### 2.2.1 Production methods

The major methods for fiber manufacture historically have been steam attenuation, the rotary or centrifugal process, and flame attenuation (Dement 1975). Only the latter two methods remain in use today. Glass for fiber manufacture is almost always based on silicon dioxide with varying amounts of other inorganic oxides, including oxides of alkaline earths, alkalis, aluminum, boron, iron, and zirconium (IARC 2002) (see also Table 1-4). In some cases, the additional oxides occur in the raw materials used to make the glass, while in others specific oxides are added in order to enhance the manufacturing process or the performance of the final product. The raw materials commonly used in the manufacture of insulation glass wool and special-purpose fibers are listed in Table 2-3.

Raw materials for a specific batch of glass fibers are first weighed and blended using automated processes before being added to the fiberglass furnace, where the materials are melted and homogenized at approximately 1,370°C (2,500°F) using either electricity or gas as the heat source (Wallenberger et al. 2001).

Rotary or centrifugal method

Steam blowing was initially used in the 1940s but was quickly replaced by the flame-attenuation process. Spinning processes were the next innovation to be introduced in the mid-1950s and were further enhanced with the addition of the rotary process, which remains the predominant method of manufacturing today (IARC 2002).
In the rotary process, fibers are produced as centrifugal force extrudes the molten material through small holes in the side of the spinning device (Burgess 1995). In the refiner section of the furnace, the temperature of the glass melt is lowered to about 1,260°C (2,300°F) (IARC 2002). A stream of molten glass from the fiberglass furnace flows along a heated forehearth lined with refractory material to a point directly above the fiber-forming station where it pours through single-orifice bushings into rotary centrifugal spinners (EIPPCB 2001). The molten glass is then extruded from the sidewall holes as small streams of glass to form the primary glass fibers through centrifugal action and aerodynamic drag forces. The primary fibers pass through a circular burner flame, whose hot gases attenuate the fibers to their final diameter and break the fibers into shorter lengths (IARC 2002). The resulting fibers, which have a range of lengths and diameters, form a veil of randomly interlaced fibers, which are sprayed with a phenolic (usually phenol-formaldehyde) resin binder and lubricant (usually mineral oil or paraffin oil) to improve the integrity, resilience, durability, and handling quality of the finished product. The lubricating oils are added to reduce dust and lint formation of the final product and reduce the amount of airborne fibers during their use. A gas-fired oven dries the product and cures the binder. The resin-coated fibers are formed into a mat of fibers. The resultant fibers typically range from 0.5 to 6 μm in diameter; however, the distribution of lengths is extremely broad (Moore et al. 2002).

As noted in Section 1, the nominal diameter is an estimate of the average fiber diameter of the wool product; however, within that product, the diameters of individual fibers vary widely around the nominal diameter, and all wool products will contain some percentage of respirable fibers (ACGIH 2001). Because smaller fibers become airborne more easily than larger fibers and because larger diameter fibers fall out of suspension in air faster than small diameter fibers, the distribution of airborne fiber diameters will differ from that of the product (ACGIH 2001, Krantz 1988); [i.e., the average diameter of airborne fibers will be smaller than the nominal diameter of the product]. In an assessment of occupational exposures to MMMF in Sweden, Krantz (1988) reported that median diameters of airborne fibers were in all cases much smaller, by almost one order of magnitude, than the nominal diameters of the products. ACGIH (2001) noted that in general, as nominal diameters decrease, exposure levels increase.
IARC (2002) reported that most fibers in insulation glass wool products have been found to be several centimeters in length, although fibers with lengths of less than 250 μm (which IARC reported as the upper limit for respirability) probably are present in all wool products. Fiber length contributes significantly to the ease with which a fiber becomes airborne, with shorter fibers of the same diameter becoming airborne more easily than longer fibers. As noted in Section 1, glass fibers do not break lengthwise, but rather break across the fiber resulting in shorter fibers with the same diameter.

Flame-attenuation method

A flame-attenuation process is used to produce very small diameter fibers, and this method is generally used to produce special-purpose fibers. The glass used to produce the fibers can be produced earlier and cooled into preforms, often as glass marbles (EIPPCB 2001). The marbles are added to a heated pot for the production of fibers in a process described as pot and marble.

The flame-attenuation method of producing fibers is a two-step procedure (IARC 2002). In the first step, the melt is drawn through the bushings of the furnace to produce strands of coarse fibers. The fibers are then remelted with a high-temperature gas flame, which is usually mounted at right angles to the primary fibers. The flame attenuates the coarse fibers into finer fibers, which are propelled by high-velocity gases through a forming tube. There, the fibers are sprayed with a binder and formed into mats, which can be further processed into a variety of special-purpose applications (IARC 2002). Special-purpose glass fibers are more highly engineered than glass wool products, and thus are significantly more expensive, according to a public comment from Johns Manville (Carey 2004).

U.S. production

Insulation products comprise the vast majority of synthetic vitreous fibers (SVFs) produced in the United States, and glass wool is the predominant SVF used for insulation products. IARC reported that in 1999, North American demand for glass wool insulation made up 54.8% of world demand in that category, while North American demand for rock or slag wool insulation made up only 7.6% of world demand for that category. In the year 2000, an estimated 3,388 million pounds (1.7 million tons) of fiberglass were used...
in building insulation (commercial and residential), with approximately 79.1% being produced as batts, blankets, or board, and the remaining 20.9% produced as blown or loose-fill insulation (Maxim et al. 2003). Furthermore, Maxim et al. presented an estimate that 80.9% of the fiberglass insulation sold was used for residential construction and 19.1% for commercial or industrial construction.

ATSDR (2004) reported 2002 Glass Manufacturing Industry Council (GMIC) data that indicated that 10 major manufacturers were operating about 40 plants within the United States, and the production volume of all glass fiber types, including glass wool, was estimated at about 3 million tons annually.

Special-purpose glass fibers make up a very small amount of the total SVFs produced in the United States, accounting for only about 1% of the total annual production (Carey 2004). In the United States, there are at least four companies that produce special-purpose glass fibers, with imports occurring in increasing amounts from China and other Asian countries. Special-purpose glass fibers products are not generally available to the general public. They usually are sold by the fiber manufacturer to commercial users in final products or alternatively to other manufacturers, where they are made into final products (Carey 2004).

Hesterberg and Hart (2001) reported that E glass was no longer produced as a microfiber in the United States and Europe but only as continuous filaments (most of which are too thick to be respirable). JM753 also is a discontinued product (Angus Crane, personal communication to Sanford Garner, SRA, International, February 11, 2005).

2.2.3 Import and export of glass fibers
The United States International Trade Commission (USITC) reports information on imports and exports only by cost. The combined value of imports of insulation products consisting of the five product categories labeled (1) mats, nonwoven, of glass fibers; (2) thin sheets (voiles), nonwoven, of glass fibers; (3) batts of nonwoven glass fibers; (4) pipe coverings of nonwoven glass fibers; and (5) other insulation products of nonwoven glass fibers.
fibers varied considerably from 2000 to 2008 with a maximum value of $356 million in 2006 and a minimum value of $189 million in 2001; the value for 2008 was $196 million (USITC 2009a). The value of exports for the product category insulation products of glass fibers increased steadily from $59 million in 2000 to $121 million in 2008 [note that the product categories differ for imports and exports] (USITC 2009b). No category for special-purpose fibers was identified for imports or exports.

2.3 Occupational exposures

Data from the latest U.S. Economic Census (USCB 2005) indicate that in 2002, there were 19,318 total workers (15,788 in manufacturing) employed within the North American Industrial Classification System (NAICS) code 327993, which “comprises establishments primarily engaged in manufacturing mineral wool and mineral wool (i.e., fiberglass) (sic) insulation products made of such siliceous materials as rock, slag, and glass or combinations thereof.” [Based on the proportions of glass wool to other mineral wools used in the production of insulation products in North America (see Section 2.2.2), it is likely that the majority of the workers are involved in the manufacture of glass fibers.] The number listed for 2002 was slightly lower than in 1997 (21,610 total employees with 17,791 in manufacturing). OSHA estimated that there were more than 225,000 workers in the United States exposed to synthetic mineral fibers in manufacturing and end-use applications. Synthetic mineral fibers were defined as “fibrous inorganic substances made primarily from rock, clay, slag, or glass” (Maxim et al. 2003). No other national level data were found to estimate the total number of people exposed occupationally; [however, significant U.S. occupational exposure can be inferred through review of a combined cohort of production workers (Marsh et al. 2001a) (see Section 3.2.1.1)]. This cohort consisted of workers employed during the period from 1945 to 1978 in 8 plants that produced glass wool or glass wool and filament. In a 1992 follow-up evaluation, the cohort had a total of 26,679 workers.

The remainder of this section provides information on occupational exposure to glass fibers during their manufacture (Section 2.3.1), and from non-manufacturing activities (i.e., during installation or removal) (Section 2.3.2). The data on occupational exposures are reported for specific product types as presented in the source documents, and fiber
manufacturing methods and diameters are reported when available. Because of the importance of the non-U.S. occupational epidemiology studies that are presented in Section 3, non-U.S. exposure data are presented in this section following the U.S. data.

2.3.1 Exposure during manufacturing

Initial studies of airborne exposure to glass fibers were conducted in the late 1960s. These studies included gravimetric analysis and reported exposures in terms of mg/m³. These early exposure studies (Corn et al. 1976, Corn and Sansone 1974, Esmen et al. 1978) demonstrated that similar mass-based exposures can result in highly variable fiber counts. This variability is determined by the fiber diameter distribution of the material. As a result, subsequent exposure assessments relied on fiber counts (fibers/cm³) using optical (phase-contrast) or electron microscopic methods of analysis. For the purposes of this report, only fiber count exposure estimates will be reported. Fiber counts may vary between different studies depending on how a countable fiber was defined and based on the sampling and analytical techniques employed.

[The development and evolution of sampling and analytical techniques combined with the adoption of different fiber definitions that have been used historically makes comparison of airborne fiber concentrations across time somewhat problematic. In addition, U.S. and European conventions are not exactly comparable. Because of widely varying fiber size distributions, there is no universally appropriate conversion factor between the various methods. This means that the reader should not draw fine distinctions in interpreting reported exposures. Differences in averaging times (often unspecified) also make comparison of fiber concentration estimates of exposure between studies difficult. In general, reported exposure concentrations in manufacturing environments generally represent 8-hour time-weighted averages (TWA) while reported exposure concentrations in non-manufacturing environments generally represent task-length averages (or TLA). During manufacturing operations, TWA levels that are based on sampling times of less than 8 hours are still representative of 8-hour TWA levels. Unless noted otherwise, levels presented for manufacturing operations are 8-hour TWAs.]
Production processes: glass fiber exposures and co-exposures

The air contaminants produced by the major production processes in glass fiber production facilities include the fibers themselves and other emissions associated with various processes (Smith et al. 2001). The exposure assessment by Smith et al. was conducted as part of the epidemiologic studies of Marsh et al. (2001a,b,c). Smith et al. also described the presence in the work areas of exposures other than the fibers themselves (Table 2-4) and identified co-exposures to substances that met the following criteria: (1) they are widely used, (2) there is a reasonable likelihood of exposure, (3) they have been used for more than 10 years, and (4) there must be a possible cancer risk, particularly lung cancer. Based on these criteria, the authors identified the following co-exposures in the SVF industry (listed in alphabetical order): aromatic hydrocarbons, arsenic, asbestos, asphalt, crystalline silica, epoxide compounds, formaldehyde, phenol (as a possible promoter), polycyclic aromatic hydrocarbons, radioactivity, styrene, and urea (as a possible promoter).

aThe authors noted that the list of operations and emissions was not exhaustive.
bThe nominal diameter of the bulk fiber is determined by measuring the length-weighted size distribution; the common sizes produced by each type are also listed, but other sizes might be made.
cAn airborne glass fiber was defined by the authors as < 5 μm in diameter with a length to width ratio > 3:1.

Glass fiber exposures in manufacturing facilities

One of the earliest studies of glass wool exposures was conducted in five manufacturing facilities (Johnson et al. 1969). Four of the five plants in this survey manufactured glass
wool insulation. The fifth plant produced continuous glass filaments for textile fabrics. Samples were collected for periods ranging from two to seven hours. A portion of the sampling medium was rendered transparent, and fibers with an aspect ratio of 3 or greater and a length greater than 5 μm were counted using 430x magnification. Fiber concentrations within fiber operations collected in the glass wool insulation plants without any size-selective inlet ranged from 0.0 to 1.01 fibers/cm$^3$.

Dement (1975) surveyed fiber exposures in four glass wool production facilities manufacturing large-diameter (> 1.0 μm) insulation products and six plants manufacturing small-diameter (< 1.0 μm) [special-purpose] glass fibers for use as filter paper and aircraft insulation. Analysis of the 167 samples collected across different products and fiber-forming methods as well as for scrap reclamation and the category “all other operations” from the four facilities manufacturing large-diameter insulation products showed mean fiber concentrations ranging from 0.04 to 0.2 fibers/cm$^3$ (sampling times not reported). Based on 123 samples from the six plants manufacturing small-diameter [special-purpose] glass fibers, the mean airborne fiber concentrations ranged from 1.0 to 21.9 fibers/cm$^3$ across bulk fiber handling and fabrication/finishing operations for three products (bulk fiber production, filter paper manufacturing, and aircraft insulation fabrication) (sampling time not provided).

Median airborne fiber diameters ranged from 1.1 to 4.3 μm and lengths ranged from 19 to 70 μm. Dement (1975) classified respirable fibers as being less than 3.5 μm in diameter and less than 50 μm in length. The percentage of fibers in the four large-diameter insulation glass wool manufacturing plants with diameter less than 3.5 μm ranged from 35% to 98% of the total fibers, while the percentage of fibers less than 50 μm in length ranged from approximately 40% to 91%. For the small-diameter [special-purpose] fiber production facilities, the percentage of fibers less than 3.5 μm and the percentage of fibers less than 50 μm were not presented; however, across bulk-fiber-handling and fabrication/finishing operations for the six plants the percentage of fibers with diameters of less than or equal to 3.8 μm ranged from 89% to 100%, while the percentage of fibers less than or equal to 48 μm in length ranged from 70% to 97%. Dement concluded that based on the sampling data from this study, fiber concentrations in small-diameter
[special-purpose] fiber operations are many orders of magnitude higher than concentrations seen in larger diameter [insulation-wool] fiber operations, and in addition, the smaller diameters and shorter lengths make the fibers more respirable.

The largest collection of U.S. glass wool manufacturing exposure data was gathered by Corn and Sansone (1974) and Esmen et al. (1979) in a series of studies in support of a large epidemiologic investigation (Enterline and Henderson 1975). Corn and Sansone reported the results of 115 air samples collected in three glass wool manufacturing facilities; however, one of the plants produced only fiberglass-reinforced plastics, and the data for this plant are not reported in Table 2-5. To avoid overload with particles, sampling filters were changed every 2 hours and, therefore, reported levels do not represent full-shift TWA concentrations. Phase-contrast optical microscopy was used, and fibers greater than 5 μm in length were reported (this is similar to NIOSH method 7400A counting rules). The percentage of respirable fibers less than 3.5 μm in diameter and greater than 5 μm in length was also reported. Across both plants, mean fiber concentrations (greater than 5 μm in length) ranged from 0.02 to 1.41 fibers/cm³. The range includes means for both personal and stationary sampling across different fiber manufacturing, fabrication, and non-manufacturing tasks. The highest fiber concentration was 3.16 fibers/cm³ measured in a filter-tube finishing operation. The percentage of fibers in the respirable size range was highly variable but generally ranged from 20% to 60%.

Esmen et al. (1979) reported on the exposures of U.S. production workers in 16 facilities that produced glass wool, glass filament, rock wool, and slag wool products. Seven of the plants studied produced glass wool (two of the seven facilities also produced continuous glass filament); for the plants that produced only loose glass fibers, the nominal diameters ranged from 3 to 10 μm. One facility produced glass fibers with nominal diameters ranging from 0.05 to 1.6 μm [fiber diameters that are generally associated with special-purpose glass fibers], and one facility received fibers with nominal diameters ranging from 7 to 10 μm from another facility and prepared the fibers for manufacturing [fabrication]. Samples were collected during 7- to 8-hour collection periods and fiber counting and sizing methods adhered to guidelines established by OSHA for asbestos [no
additional counting and sizing information was provided]. Across several plant operations (i.e., forming, production, manufacturing, maintenance, quality control, and shipping), the overall plant mean concentrations across the eight facilities manufacturing or fabricating the larger diameter fibers ranged from 0.0094 to 0.042 fibers/cm$^3$ for fibers greater than 5 $\mu$m in length. Mean exposure levels in the plant producing small-diameter [special-purpose] fibers ranged from 0.0097 to 1.56 fibers/cm$^3$ with an overall mean of 0.78 fibers/cm$^3$.

In another study, Esmen et al. (1982) evaluated airborne exposure levels of fine-diameter [special-purpose] fibers in two facilities that fabricated aircraft insulation products. Counting and sizing of fibers was performed by phase-contrast optical microscopy and electron microscopy, and sampling times were based on task-length rather than 8-hour work shifts. Mean airborne respirable fiber (i.e., diameters < 3 $\mu$m) concentrations ranged from 0.05 to 1.7 fibers/cm$^3$ across different jobs/tasks (e.g., sewer, cutter, cementer) for two production facilities. The highest single concentration observed was 3.8 fibers/cm$^3$.

A follow-up study of five of the nine glass fiber plants surveyed by Esmen et al. (1979) was reported in 1984 (Hammad and Esmen 1984). Roughly 200 samples were obtained and analyzed using the same methods described by Esmen et al. (1979). Four of the facilities produced large-diameter glass fibers (nominal diameters ranging from 1 to 15 $\mu$m), and one facility produced small-diameter [special-purpose] glass fibers (nominal diameters ranging from 0.05 to 1.6 $\mu$m). For the large-diameter fiber production facilities, across various areas of the production facilities, mean fiber concentrations ranged from 0.0047 to 2.22 fibers/cm$^3$. (The value of 2.22 fibers/cm$^3$ was from the quality control area of one of the facilities; the next highest mean value at this facility was 0.46 fibers/cm$^3$.) For the facility producing small-diameter [special-purpose] fibers, mean fiber concentrations ranged from 0.048 to 6.77 fibers/cm$^3$ across production areas.

Using historical exposure data from glass fiber production facilities, Smith et al. (2001) estimated airborne glass fiber exposure levels from the production of insulation glass wool and small-diameter [special-purpose] fibers for two time periods: before 1980 and from 1980 to 1990. Different methods had been used to collect and analyze the exposure
Plant-level mean concentrations for insulation glass wool production ranged from 0.045 to 0.262 fibers/cm³ and the simple [unweighted] mean of the plants combined was 0.15 fibers/cm³ for the period before 1980. For the period after 1980, plant means ranged from 0.026 to 0.278 fibers/cm³ with a simple [unweighted] mean for the plants combined of 0.091 fibers/cm³. For small-diameter [special-purpose] fibers, plant-level mean concentrations for the period before 1980 ranged from 0.027 to 1.94 fibers/cm³ with a simple [unweighted] mean for the plants combined of 0.662 fibers/cm³. Exposure levels measured after 1980 ranged from 0.025 to 1.86 fibers/cm³ with a simple [unweighted] mean of 0.745 fibers/cm³ for the plants combined.

In collaboration with the North American Insulation Manufacturers Association (NAIMA), Marchant et al. (2009) summarized exposure data collected or commissioned by NAIMA. As part of the Health and Safety Partnership Program (HSPP) (see Section 2.6.2), NAIMA developed an occupational exposure database for SVF. To populate the database, existing exposure data were collected from various sources, and NAIMA or its member companies also commissioned new exposure monitoring studies. Various sampling and analytical methods were used for the data that were collected; however, only fibers meeting the NIOSH 7400B rule were included in the results presented by Marchant et al. In addition, only personal sampling results for periods of at least 240 minutes were included in the results. Means of samples collected in glass wool manufacturing and fabrication environments (N = 2,304), ranged from 0.03 to 0.16 fibers/cm³. Although not specifically denoted as special-purpose glass fibers, data were also provided for several product categories generally associated with special-purpose fiber applications. For example, for aircraft insulation manufacturing, the mean respirable fiber concentration was 0.06 fibers/cm³ for primary manufacturing, 0.03 fibers/cm³ for secondary manufacturing, and 0.13 fibers/cm³ for fabrication. Filtration products had a mean concentration of 0.22 fibers/cm³ for primary manufacturing, 0.02 fibers/cm³ for secondary manufacturing, and 1.15 fibers/cm³ for fabrication.

Exposure levels similar to those reported in the U.S. studies have been reported in non-U.S. studies. In a large survey of occupational exposures to MMVF, Head and Wagg (1980) assessed respirable fiber levels in 25 plants and construction sites in the United
Kingdom, including 3 insulation glass wool manufacturing facilities and 4 facilities that manufactured glass fiber paper and filtration products using special-purpose fibers. Parallel sampling was used to estimate total airborne dust and fibers. Single gravimetric samples were taken for dust analyses, and, over the same time-period, multiple samples were taken for fiber-count analyses in order to avoid overload with particles. The authors noted that the results did not represent full-shift averages. Samples were analyzed using phase-contrast optical microscopy, and respirable fibers were defined as those with a diameter of less than 3 μm and length greater than 5 μm. Overall mean respirable fiber concentrations across the three insulation glass wool plants ranged from 0.12 to 0.31 fibers/cm$^3$, while individual samples ranged from 0.003 to 1.1 fibers/cm$^3$. For special-purpose fibers, overall mean concentrations ranged from 0.08 to 3.70 fibers/cm$^3$, while individual samples ranged from 0.02 to 18.83 fibers/cm$^3$. The maximum fiber count was found at a paper-slitting machine. The authors noted that higher dust levels were found at conversion processes (where fibers are converted to finished products) due to the greater degree of manipulation of the materials.

In support of a large European occupational epidemiologic study of MMVF, the Institute of Occupational Medicine, in Edinburgh, U.K., measured the concentrations of airborne MMVF fibers in 13 European production plants, including 4 glass wool plants. Fiber counts were made using phase-contrast optical microscopy, and fiber size was assessed using scanning electron microscopy. Respirable fibers were considered those with length $\geq$ 5 μm, diameter $<$ 3 μm, and aspect ratio $\geq$ 3. Sampling periods were generally 7 to 8 hours, but filters were changed more frequently if the researchers considered that high dust levels would result in a filter density that would make optical fiber counting difficult. The results of this analysis were initially reported by Ottery et al. (1984). However, around the time of that publication, it became apparent to the European scientific community that the phase-contrast optical microscope methods that were used to measure fiber levels did not always produce the same results when applied by different laboratories. This culminated in an effort in Europe to standardize the sampling and evaluation of man-made mineral fibers and to harmonize the performance of various national laboratories that were using those methods. Because of this effort, the sampling data from Ottery et al. were reanalyzed using a different counting method (WHO/EURO
phase-contrast optical microscope reference method) and determined to be too low by a factor of about 2.2. The results of the reanalysis were reported by Cherrie et al. (1986) and these results are presented in Table 2-5. The authors noted that the maximum mean concentration was associated with the manufacture of special fine fiber earplugs. [It is likely that these levels were associated with special-purpose fibers; however, Cherrie et al. did not specify categories for glass wool fibers, and the facility for which these levels were associated produced both insulation wools and “special fine fiber earplugs.”]

Krantz (1988) reported the results of an analysis of occupational exposure to SVF in nine Swedish factories that produced insulation wools (rock or glass wools) or special-purpose fiber products. Personal sampling was performed usually over two full shifts with sampling time varying between 2 and 8 hours depending on operation and fiber level. Fiber counting was performed using phase-contrast optical microscopy at a magnification of 500x. Respirable fibers were defined as having an aspect ratio $\geq 3$ and a diameter $\leq 3 \mu m$; fibers with lengths $< 5 \mu m$ were not counted. The results for the two categories of fibers are presented in Table 2-5. The authors noted that for both insulation wools and special-purpose fibers the maximum median diameter for airborne glass fibers was below 1 $\mu m$, and that when this value was compared with the nominal fiber diameter of the product, it was obvious that it was the fine (thin) fibers in the product that became airborne. It was also noted that, for the whole study, between 73% and 94% of the airborne fibrous dust was respirable.

Yeung and Rogers (1996) reported the results of a large study reviewing the national profile of occupational exposure to SVF, including glass wool, in Australia. SVF data consisting of 1,572 samples from 252 sampling activities was collected by standardized questionnaire from a number of different sources throughout Australia, including government agencies, occupational health and safety consultants, SVF manufacturers and end-users, and academia. All data were validated for technical integrity and it was also noted that 87% of the sampling results were analyzed in accredited laboratories. The authors reported that the nominal diameter of bulk glass wool typically ranged between 5 and 8 $\mu m$ and that between 10% and 20% of fibers in the product were less than 3 $\mu m$ in diameter. Based on 94 samples, the geometric mean fiber concentration was 0.03
fibers/cm\(^3\), and the range across all samples was from less than 0.01 fibers/cm\(^3\) to 0.2 fibers/cm\(^3\).

In 1990, an Australian standard of 0.5 fibers/cm\(^3\) was established for all forms of MMVF. Yeung and Rogers compared sampling data from before the establishment of the regulatory limit with data collected after its establishment and noted that no quantitative trend or difference in airborne exposure levels between the two time periods was apparent.

2.3.2 Non-manufacturing occupational exposures

Exposures can occur while installing, removing, fabricating, or otherwise working with glass wool outside the manufacturing environment. These applications are sometimes referred to as end-use, and workers engaged in these applications, therefore, can be referred to as end-users. Since glass wool is primarily used for insulation purposes, most of the end-use exposure data focuses on insulation activities. Exposures in these end-user applications are typically higher than in the fiber manufacturing environments.

Eight-hour TWA exposure estimates are not well suited to describe exposures for insulation installation and other end-use tasks because of the nature of these trades (Fowler et al. 1971). Typically, these workers are exposed during a working day to a series of peak exposures while they are handling the material. Fowler et al. described the scenario for end-users where one worker ordinarily cuts, applies, and finishes a single piece of insulation material and noted that this differs from exposures in a production plant where a worker likely performs a single task throughout the workday with less exposure fluctuation. Because of this, end-use exposures are typically measured for the period of active work (i.e., as task-length average concentrations) rather than for the full work shift (i.e., 8-hour TWA). As such, exposure levels between end-use operations and manufacturing operations often are not directly comparable.

As cited by Maxim et al. (2003), the United States Department of Labor (USDOL), Bureau of Labor Statistics (BLS) (2009), reported that approximately 53,000 workers were employed by insulation contractors in the year 2000. This number was projected to grow to 60,000 by 2010. In May 2007 the U.S. Bureau of Labor Statistics reported that nearly 31,000 workers were employed as “insulation workers” within the NAICS Code 238310 (Drywall and Insulation Contractors). Additionally, workers involved in other construction trades such as drywall installers, carpenters, and heating and cooling specialists also install insulation. Approximately 150,000 of these workers have periodic exposure to glass wool insulation materials (Maxim et al. 2003). Lees et al. (1993) cited OSHA estimates that in 1992, there were 185,000 full-time–equivalent construction workers employed in the U.S. residential insulation trades.
Residential homeowners engaged in home remodeling projects are potentially exposed to insulation materials through the removal and replacement of existing products. No data were identified regarding the number of individuals involved in these activities, although the majority of these projects involve the installation of batt and/or blanket insulation, rather than loose fill insulation (Maxim et al. 2002).

Fowler et al. (1971) sampled a variety of fiberglass insulating operations, including duct wrapping, wall and plenum insulation, pipe insulation and fan housing insulation. Task-length average (20 to 60 minutes) total breathing zone fiber concentrations ranged from 0.48 to 8.08 fibers/cm³ with a median of 1.26 fibers/cm³ and a mean of 1.8 fibers/cm³ based on phase-contrast optical microscopy. Fowler et al. estimated that about half of the airborne fibers generated during installation were less than 3.5 μm in diameter. Mean exposure levels to workers of other trades working close to the insulation operations were 0.1 fibers/cm³.

Worker breathing-zone exposure levels for insulation glass wool during the installation of commercial and residential insulation in buildings was evaluated by Esmen et al. (1982). Counting and sizing of fibers was performed by phase-contrast optical microscopy and electron microscopy, and sampling times were based on task-length rather than 8-hour work shifts. The average respirable fiber exposure of workers for all applications, except the blowing of thermal insulation into attics, ranged from 0.003 to 0.13 fibers/cm³. Average respirable glass wool exposure levels for various tasks during blowing attic insulation ranged from 0.31 to 1.8 fibers/cm³. The range of individual exposure levels for the blower (the task with the highest exposure levels) was 0.67 to 4.8 fibers/cm³.

Jacob et al. (1992) characterized the task-length (typically 1 to 2 hours) fiber concentrations during the installation of residential glass wool insulation in 13 cities throughout the United States. Sample collection and fiber counting methods followed NIOSH Method 7400 with some modifications that allowed for identification of fiber type (7400A method for total fibers and 7400B for respirable fibers). Jacob et al. reported results as a combination of counting fibers deposited on the filter and rinsed from the cowl. A cowl-rinsing procedure reported by Breysse et al. (1990) was used to evaluate...
the deposition of fibers on the inside of the collection cowl. The average fraction of fibers
on the cowl was reported to be 25% of the total fiber counts. Based on differential
counting, Jacob et al. reported total respirable fibers as well as respirable glass wool
fibers (fiber identity based on morphology and polarized light). Glass fibers were found
to account for between 40% and 70% of the respirable fibers. Mean respirable fiber
exposure to installers during the installation of batt insulation was 0.059 fibers/cm³ with a
95% confidence interval of 0.049 to 0.073 fibers/cm³. Mean respirable-fiber exposures
during blowing wool insulation ranged from 0.12 to 0.91 fibers/cm³ across products and
tasks, with the installers having the highest mean exposures.

Lees et al. (1993) conducted a comprehensive residential insulation installation exposure
survey in the early 1990s. Workers were monitored during insulation operations in 107
houses in 11 different states, and results were presented as task-length averages. Similar
to Jacob et al. (1992), fiber counts included fibers deposited on the inside of the
conducting cowl. Lees et al. (1993) reported respirable fiber (NIOSH 7400B rules)
concentrations during installation of glass wool batt insulation in homes ranging from
0.02 to 0.42 fibers/cm³, with a mean of 0.14 fibers/cm³. The installation of loose
fiberglass insulation that had a binder resulted in mean exposures of 0.55 fibers/cm³ for
the installer and 0.18 fibers/cm³ for the feeder. The highest exposures were noted for
installation of loose insulation without binder. For installers, exposure levels ranged from
1.32 to 18.4 fibers/cm³, with a mean of 7.67 fibers/cm³, while for feeders, levels ranged
from 0.06 to 9.36 fibers/cm³, with a mean of 1.74 fibers/cm³.

More recently, Marchant et al. (2009) reported an overall mean SVF exposure level
during glass wool installation operations of 0.39 fibers/cm³ and a mean level of 0.26 for
retrofit/removal operations based on data from the NAIMA database on occupational
exposures to SVF (see previous section on manufacturing exposures). In a task-exposure
analysis, the mean batt insulation installation exposure level was 0.11 fibers/cm³, while
the mean loose-fill insulation installation exposure level was 0.51 fibers/cm³. Fiber
sampling and counting were conducted using NIOSH 7400B rules, and a minimum
sampling time of 240 minutes was required for inclusion in the database.
In addition to residential and building insulation, insulation glass wool is fabricated for and used in a variety of other commercial products. Using NIOSH 7400A and B techniques, Jacob et al. (1993) evaluated glass wool exposures in 11 different end-user manufacturing environments, including the fabrication and assembly of metal building and manufactured housing insulation, pipe insulation, small appliance manufacturing, air handling ducts, and water heaters. The mean concentration of respirable fibers (NIOSH 7400B fibers) ranged from 0.006 to 0.087 fibers/cm$^3$. These counts included fibers rinsed from the cowl.

Data on exposures during glass wool removal are limited. Jacob et al. (1993) assessed exposures during pipe and ceiling board removal. The arithmetic mean total fiber exposure was 0.29 fibers/cm$^3$ with a 95% confidence interval of 0.2 to 0.41 fibers/cm$^3$.

Breysse et al. (2001) reported end-user glass wool exposures in a variety of commercial applications. Applications sampled included duct board, duct liner, duct wrap fabrication and installation, and pipe insulation installation. Samples were collected using NIOSH Method 7400 (both A and B methods were applied but only the 7400B results were reported). A task-based sampling strategy was employed; therefore, exposure levels reflect task-length average concentrations. Fiber samples were analyzed using phase-contrast microscopy, and concentrations were reported according to NIOSH 7400B counting rules and included cowl fibers. The addition of cowl fibers increased concentrations by 35% to 47%. Mean end-user fiber concentrations ranged from 0.03 to 0.68 fibers/cm$^3$ across products and tasks. The highest fiber concentrations, from 0.17 to 2.13 fibers/cm$^3$, were found during duct wrap insulation installation.

Exposure levels similar to those reported in the U.S. studies have been reported in non-U.S. studies (Head and Wagg 1980, Perrault et al. 1992, Yeung and Rogers 1996).

Head and Wagg (1980) studied airborne concentrations of respirable insulation glass wool fibers in three manufacturing plants and two construction sites in the United Kingdom, and reported slightly higher levels among workers installing domestic glass wool insulation than for production workers. The maximum mean level for installation of
fiberglass insulation blankets in a domestic loft was 1.02 fibers/cm³ with a maximum individual level of 1.76 fiber/cm³.

In the early 1990s an occupational exposure survey of MMVF insulation products was conducted at several industrial construction sites in Montreal, Canada where workers were installing or removing insulation (Perrault et al. 1992). Area sampling was performed with sampling times ranging from 0.5 to 4 hours for the whole study (which included analyses of other fibers and locations). Respirable fibers (defined by the authors as having a diameter of < 3 µm, a length of > 5 µm and an aspect ratio > 3:1) were counted using phase-contrast optical microscopy based on WHO methodology. For glass wool, two sites were investigated: one site where refractory fibers and glass wool products were being installed and another site where only glass wool insulation was being installed. A geometric mean of 0.01 fibers/cm³ was reported for the site where only glass wool insulation was being installed.

As discussed earlier, Yeung and Rogers (1996) reported the results of a large study to review the national profile of occupational exposure to MMVF in Australia. MMVF exposure data, including data from installation and removal activities, were collected by standardized questionnaire from a number of different sources throughout Australia. For non-manufacturing exposures, slightly higher levels were reported for glass wool installation compared with removal (maximum geometric means of 0.12 fibers/cm³ versus 0.04 fibers/cm³ and maximum individual samples of 0.8 fibers/cm³ versus 0.2 fibers/cm³). Levels associated with glass wool removal were similar to levels associated with production, which had a geometric mean concentration of 0.03 fibers/cm³ and a range of less than 0.01 to 0.2 fibers/cm³.

2.4 Environmental occurrence and general population exposure in the United States

No information was identified on environmental occurrence and exposure to specific glass fiber products; therefore, most of the data presented in this section are from occurrence and exposure to SVFs as a group.

SVFs do not occur naturally in the environment, but they may be released into the environment during production, installation, use, removal, and disposal. Additionally, SVFs and glass fibers were found in air and dust samples following the terrorist attacks on the World Trade Center in September, 2001. [It also is likely that elevated levels could result from building implosions or structure fires.] Like other inorganic substances, SVFs do not undergo typical transformations in the environment, such as photolysis and biodegradation. As described in Section 1, SVFs are reasonably soluble under acidic or alkaline conditions, dissolving about 2 to 4 times quicker than crystalline fibers such as asbestos. The transport and partitioning of SVFs are largely governed by fiber size, with large fibers removed from air and water by gravitational settling at a rate dependent upon their size. Small fibers may remain suspended for long periods of time.

The primary route of SVF release into the environment is through the air. No published data were identified on quantities of SVFs released into the environment in the United States, or on contamination of soil, water, or food by SVFs. There are limited data on general population non-occupational exposures to SVFs. [Non-occupational exposures might occur during do-it-yourself home remodeling activities due to release of glass wool fibers from insulation and building materials.]

Jacob et al. (1992) measured airborne glass wool concentrations before and after insulation installation. Post-installation mean respirable fiber concentrations were low, ranging from 0.002 fibers/cm³ for batt installation to 0.001 fibers/cm³ for blowing wool operations. Post-installation concentrations were not significantly different from pre-installation concentrations.

2.4.1 Indoor and ambient levels

In order to assess the fiber release from air ducts lined with fiberglass, Balzer et al. (1971) measured fiber levels in 13 buildings. Results suggested that there was no increase
in fiber concentration due to air passing through ducts lined with fiberglass. Additionally, Balzer et al. found that the glass fiber concentration outside of the buildings averaged 0.0002 fibers/cm³.

Miller et al. (1995) analyzed the fiber concentrations in living spaces of 14 homes both prior to installation of insulation and again the evening following installation. Total fibers were measured at levels ranging from < 0.001 to 0.009 fibers/cm³ before installation, and from 0.03 to 0.012 fibers/cm³ one day post-installation using phase-contrast microscopy and NIOSH 7400B counting rules. The mean living-space fiber concentrations were not significantly elevated after installation. Similar results were obtained when using scanning electron microscopy to count only SVFs. These results suggest airborne fiber concentrations diminish rapidly following installation.

In order to evaluate concern that the erosion of SVFs from insulation materials may contribute to fiber levels in the indoor environment, Carter et al. (1999) collected 205 area samples in 51 residential and commercial buildings. Twenty-one air samples were collected simultaneously outdoors at 19 buildings. All samples were analyzed by phase-contrast microscopy following the NIOSH 7400B counting rules. The mean value for all respirable indoor fibers was 0.008 fibers/cm³ with a median value of 0.007 fibers/cm³ and a maximum value of 0.029 fibers/cm³. Ninety-seven percent (97%) of the respirable fibers identified by scanning electron microscopy with energy-dispersive X-ray microanalysis (SEM-EDX) were determined to be organic. MMVF were detected in only two samples. The median of the outdoor samples collected at 19 different locations was < 0.001 fibers/cm³, and individual samples ranged from < 0.001 to 0.009 fibers/cm³.

Switala et al. (1994) assessed the concentration of respirable glass fibers near a large fiberglass wool manufacturing facility in an urban area, and also in a rural area, both in Ohio. Airborne glass fiber concentrations based on phase-contrast microscopy and NIOSH 7400B rules ranged from < 1.0 × 10⁻⁵ to 1.4 × 10⁻⁴ fibers/cm³. These levels were similar to the measured levels in ambient air from a rural site located 10 miles away from the plant. The concentration of glass fiber concentrations at the rural location ranged from
< 1.0 \times 10^{-5} to 1.5 \times 10^{-4} \text{ fibers/cm}^3, during the same sampling period. Glass fibers accounted for < 1\% of the total respirable fibers measured at these sites.

2.4.2 Other possible sources of exposure

The general public could be exposed to glass fibers from building implosions, structure fires, natural disasters, or terrorist attacks. Although no data were identified for airborne glass concentrations for such events, Lioy et al. (2002) suggested that high levels of airborne glass fibers resulted from the collapse of the World Trade Center based on samples of settled dust following the terrorist attacks on the World Trade Center in New York City on September 11, 2001. Lioy et al. reported the results of dust samples that were taken on September 16 and 17 from three undisturbed locations within a mile of the World Trade Center site. All three samples consisted of 40\% glass fibers (mass percentage), with the remaining mass consisting of varying amounts of nonfiber material (cement/carbon), cellulose, and chrysotile asbestos. Landrigan et al. (2004) suggested that compounds and materials present in the plume from the World Trade Center event would be similar to those found in plumes from building fires or building implosions. Exposure from the World Trade Center event was primarily from inhalation or ingestion of dust directly after the event or due to resuspension of dust during clean-up activities following the event (Landrigan et al. 2004, Lioy et al. 2002). Additional indoor exposure to residents may have also occurred from resuspended residual dust remaining in the residence or from ventilation systems not properly cleaned.

Studies reporting general population exposures to airborne glass fibers in ambient air are summarized in Table 2-7.

2.5 Biological indices of exposure

There are no traditional biological indices of exposure for SVFs, as these are not compounds that metabolize or break down in the body in the usual sense. Assessment of biological exposure to SVFs has been attempted through the measurement of fiber retention in human lung tissue (IARC 2002). In a study of autopsies of glass, rock, and slag wool workers in the United States, analytical transmission electron microscopy was used to determine retention of fibers in the lung 12 years after the end of exposure. No significant difference was observed between SVFs in the lungs of 112 production workers (101 glass wool and 11 rock or slag wool workers) or controls (112 consecutive autopsies from the same hospital) in the study. The authors concluded that either the SVFs disappeared from the lungs in less than 12 years, the workers did not inhale enough SVFs to result in a difference when compared with the controls 12 years after the end of the exposure, or the fixative fluids used for the lungs could have altered some retained fibers (IARC 2002).

In a study investigating a possible biomonitoring method for SVF exposure, Paananen et al. (2004) performed nasal lavage on workers from 2 factories and measured concentrations of MMVF by electron microscopy. Cytokines (IL-6, IL-8, TNF-alpha, and IFN-gamma) were also assayed, and inflammatory cells (lymphocytes, eosinophils, neutrophils, and macrophages) were counted microscopically. In nasal lavage samples, the mean concentration of MMVF (length > 1.5 \( \mu m \)) was 3,260 fibers/cm\(^3\) in factory 1, 11,680 fibers/cm\(^3\) in factory 2, and below 55 fibers/cm\(^3\) in the control group. The group-specific mean concentration of MMVF in nasal lavage samples correlated with production rates and airborne fiber levels in both plants. No significant differences in the biological response (inflammatory cells, cytokines) were found between the exposed groups and the control group. The authors concluded that nasal lavage could be used as a biomonitoring method in the assessment of MMVF exposure.

2.6 Regulations and guidelines

2.6.1 Regulations

U.S. Environmental Protection Agency (EPA)
Clean Air Act

National Emission Standards for Hazardous Air Pollutants (NESHAP): Fine mineral fiber emissions from facilities manufacturing or processing glass (of average diameter 1 micrometer (μm) or less) is listed as a Hazardous Air Pollutant (HAP)

New Source Performance Standards (NSPS): Manufacturers of wool fiberglass are subject to provisions of NSPS for the control of particulates as prescribed in 40 CFR 60.292 and 293.

Occupational Safety and Health Administration (OSHA)

Permissible Exposure Limit (PEL) = 15 mg/m³ (total); 5 mg/m³ (respirable) (based on regulation for "particulates not otherwise regulated")

Guidelines
American Conference of Governmental Industrial Hygienists (ACGIH)

Threshold Limit Value - Time-Weighted Average Limit (TLV-TWA) = 1 fiber/cm³ (respirable fibers)

National Institute for Occupational Safety and Health (NIOSH)

Recommended Exposure Limit (REL) = 3 fibers/cm³ (TWA) (fibers with diameter ≤ 3.5 μm & length ≥ 10 μm); 5 mg/m³ (TWA) (total) (listing is for "fibrous glass dust")

Occupational Safety and Health Administration (OSHA)

Health and Safety Partnership Program (HSPP) for manufacturers:
Maximum concentration of 1 WHO fiber/cc (cm³), 8-hour TWA for respirable SVF (WHO fiber is a fiber with diameter < 3 μm, length ≥ 5 μm and length to diameter ratio ≥ 3:1)

Summary

The vast majority of SVF produced and used in the United States consists of glass wool used for home and building insulation. Small amounts of glass fibers are produced for special applications such as use in battery separator media, high-efficiency filters, and aircraft insulation. Glass wool is produced by heating the glass to high temperatures,
extruding the molten glass to form small streams of glass fibers, and using centrifugal
force to attenuate the streams of glass into glass fibers. Finer fibers are formed by flame
attenuation. Most general purpose insulation glass wools have nominal diameters ranging
from 1 to 10 μm, while special-purpose fibers generally range from 0.1 to 3 μm;
however, product bulk samples may have fibers with diameters that are several times
greater or smaller than the nominal diameters. ACGIH noted that because of this
variation, all wool fiber products contain respirable fibers. The physical properties of
fibers affect their likelihood of becoming airborne, with smaller fibers more likely to
become airborne. Because of this, the average diameter and length may be smaller, and
the percentage of respirable fibers higher, for airborne fibers compared with the bulk
product.

Occupational exposure may occur in manufacturing facilities as well as for end-users,
such as during installation, removal, fabrication, or otherwise working with glass wool
outside the manufacturing environment (end-use). OSHA has estimated that more than
225,000 workers in the United States are exposed to synthetic mineral fibers in
manufacturing and end-use applications. General population exposure may occur from
exposure to SVFs from insulation and building materials or from fibers in the air near
manufacturing facilities or areas near building fires or implosions. Exposure may also
occur during do-it-yourself home remodeling activities.

No traditional biological indices of exposure exist for SVFs, although the measurement
of fibers in human lung tissue has been attempted as a means to assess exposure to SVFs.
In addition, a recent study investigated the use of nasal lavage as a biomonitoring method
for SVFs.

Fine mineral fiber emissions are regulated by the EPA, respirable fibers ("particulates not
otherwise regulated") are regulated by OSHA; ACGIH, NIOSH, and OSHA have set
guidelines for fibers in the air in the workplace.
3 Human Cancer Studies

This section reviews cohort and case-control studies that evaluated exposure to glass wool and cancer risk. Most of the cohort studies have been mortality studies; few incidence studies have been conducted. The largest studies were conducted with workers involved in the manufacture of synthetic vitreous fibers (SVF). These include (1) combined cohort mortality studies of U.S. workers conducted by the University of Pittsburgh, which included a total of nearly 26,700 workers potentially exposed to glass wool at the last follow-up (Marsh et al. 2001a,b,c, Stone et al. 2004), together with nested case-control studies of this cohort (Chiazze et al. 1992, 1993, Enterline et al. 1987, Marsh et al. 2001a, Stone et al. 2001, Youk et al. 2001), (2) a European cohort mortality study comprising a total of 6,936 glass wool-exposed workers with at least one year of employment at the last follow-up (Boffetta et al. 1997), an incidence study of 2,611 workers from this cohort (Boffetta et al. 1999), and a nested case-control study of part of this cohort (Gardner et al. 1988), (3) a smaller Canadian cohort studied by Shannon et al. (2005, 1984, 1987), and (4) a smaller hospital-based French cohort studied by Moulin et al. (1986). Other cohort studies have been conducted with workers exposed to glass wool during use, mainly through employment in insulation work in the construction industry.

Section 3.1 describes cohort and case-control studies of manufacturing workers who were exposed mostly to glass wool, rather than to mixed fibers including rock or slag wool, glass filament, or special fibers. Section 3.2 describes findings for workers exposed mostly to mixed glass wool and glass filament. Section 3.3 briefly reviews cohort studies and a series of mainly population-based, case-control studies of potential mixed SVF exposure.

3.1 Glass wool exposure: cohort and case-control studies

Data from the groups in these studies that were exposed mostly to glass wool are reported in Table 3-4 and discussed below.
3.1.1 U.S. cohort

A number of U.S. plants (Table 3-1) manufacturing one or more SVFs have been studied by various investigators from the 1980s onwards, both as separate cohorts and, under the direction of the University of Pittsburgh, as a combined cohort. Parts of this cohort were previously studied and followed up by Enterline and colleagues (Bayliss et al. 1976, Enterline and Henderson 1975, Enterline and Marsh 1980, 1984, Enterline et al. 1983, Enterline et al. 1987, Marsh et al. 1990, Morgan et al. 1981), including nested case-control studies of respiratory cancers by Enterline et al. (1987), and Chiazze et al. (1992, 1993, see below).

The cohort (Table 3-4), including production and maintenance workers from eight plants in seven states that produced glass wool or glass wool and filament, comprising white male workers only, was followed up initially until 1977 and then 1982 (Enterline and Marsh 1984, Enterline et al. 1983, Enterline et al. 1987), and subsequently to 1985 (Marsh et al. 1990). The cohort was then expanded to include nonwhite and women workers and followed until 1992 (Marsh et al. 2001a,b,c, Stone et al. 2004). The most recent follow-up also included a second nested case-control study, a more detailed characterization of work histories and exposures, and an examination of the effect of smoking and other co-exposures. No statistically significant increase in respiratory cancer mortality was observed among glass wool-exposed workers either in the cohort SMR analysis or in the nested case-control study before or after controlling for smoking in the 1982 follow-up (Enterline et al. 1987). In the 1985 follow-up (Marsh et al. 1990), 340 deaths from respiratory cancer were observed among a total of 11,380 workers (SMR = 1.12 [95% CI = 1.00 to 1.24, according to IARC (2002)]); a trend towards an increase in risk with increasing time since first employment but not with duration of employment was observed.

U.S. cohort study: 1992 update (Marsh et al. 2001a)

In the 1992 follow-up, five of the plants produced mostly glass wool with a small amount of continuous glass filament production, and four plants (two of which were combined as Plant 15) produced a mixture of glass wool and continuous filament. Four of the eight
1 plants also made small diameter (< 1.5 μm) glass or quartz microfibers for special applications as well as larger glass wool fibers and/or filament (Table 3-4).

Source of data: Marsh et al. 2001a.

aSpecial-application glass or quartz microfibers (< 1.5 μm) were also made at this plant.
In this follow-up, female workers and male workers employed between 1963 and 1978 were included to make a total of 32,110 workers, of whom 26,679 were exposed to glass wool or glass wool and filament. Female workers made up 12.5% of the entire cohort (including glass wool, wool and filament, and filament workers) and represented 9.5% of the person-years of employment. In this follow-up, approximately half the cohort had > 5 years of employment. Most of the male workers were engaged in production. Short-term workers (< 1 year or, in two plants, < 6 months) were excluded. Approximately half of the cohort had > 30 years from first employment to the last ascertainment of vital status, 80% of the cohort > 20 years, and nearly all workers had > 10 years. Death certificates were obtained for 98.2% of deaths in the first follow-up and 98.8% in the second.

Standardized mortality ratios (SMRs) were calculated for white males and females from both local (county) rates and U.S. population rates. The cohort study had 80% statistical power to detect a 10% or greater excess risk of respiratory cancer, although the power was less for the female workers when analyzed separately.

Detailed exposure matrices were constructed from a combination of historical technological data and industrial hygiene data, collected from 1970 to 1990, to estimate plant-, job title-, and department-specific exposures and individual worker job histories. The air contaminants produced by the major production processes in glass fiber production facilities include the fibers themselves and other emissions associated with various processes (Quinn et al. 2001, Smith et al. 2001) (see Table 2-5). Smith and coworkers used airborne fiber data contained in manufacturer databases to assign respirable fiber exposures to workers in the cohort study. Estimated fiberglass exposures to small-diameter fibers measured before 1980 ranged from 0.027 to 1.94 fibers/cm³ with a mean of 0.662 fibers/cm³. Estimated exposure levels measured after 1980 were very similar, ranging from 0.025 to 1.86 fibers/cm³ with a mean of 0.745 fibers/cm³.

For the nested case-control study and internal analyses of female workers (discussed below), mean, median, and cumulative exposures to respirable fibers (Rfib) (defined as fibers with diameter ≤3 μm, length > 5 μm, aspect ratio > 3:1) and a range of other compounds were estimated from plant start-up to the end of 1987 (or closure if before this date) (Quinn et al. 2001, Smith et al. 2001, Stone et al. 1996). The median average
exposure to Rfib in the five glass wool plants ranged from 0.039 to 0.167 fibers/cm³, and the median cumulative exposure ranged from 1.839 to 6.382 fibers/cm³-months. In the three glass wool + filament plants, the median average exposure ranged from 0.018 to 0.040 fibers/cm³ and the median cumulative exposure from 0.892 to 1.833 fibers/cm³-months. No distinction was made between respirable fibers from glass wool and from filament. It is important to note, however, that respirable fiber concentrations in filament operations were often up to three orders of magnitude lower than glass wool fibers and frequently below or at the limit of detection. Thus the estimated Rfib levels essentially reflect glass wool exposure. Smith et al. (2001) also identified co-exposures to substances that met the following criteria: (1) they were widely used, (2) there was a reasonable likelihood of exposure, (3) they had been used for more than 10 years, and (4) there must have been a possible cancer risk, particularly lung cancer. Based on these criteria, the authors identified the following co-exposures in the SVF industry: aromatic hydrocarbons, arsenic, asbestos, asphalt, crystalline silica, epoxide compounds, formaldehyde, phenol (as a possible promoter), polycyclic aromatic hydrocarbons, radioactivity, styrene, and urea (as a possible promoter).

With respect to respiratory cancers, Marsh et al. reported statistical results for combined respiratory system cancers (larynx, trachea, bronchus, and lung; ICD 160–163), and for other cancers. A total of 838 deaths from lung cancer was reported for the entire cohort, together with 29 deaths from cancer of the larynx and 7 other respiratory system cancers. Among the combined (male and female) cohort, a slight excess of respiratory cancer was observed among combined short- and long-term workers in mostly glass wool (SMR = 1.18, 95% CI = 1.04 to 1.34, \( P < 0.05 \), 243 deaths) but not in glass wool + filament (SMR = 1.02, 95% CI = 0.94 to 1.12, n.s., 490 deaths) or filament-only plants (SMR = 1.04, 95% CI = 0.87 to 1.22, n.s., 141 deaths). A small, but statistically significant excess of respiratory cancers was observed among all workers (exposed to glass wool and/or filament) with 1 to 5 years employment (SMR = 1.12, 95% CI = 1.01 to 1.24, \( P < 0.05 \), 378 deaths). No excess of respiratory cancers was observed among long-term (> 5 years employment) workers for either mostly glass wool (SMR = 1.06, 95% CI = 0.90 to 1.26, n.s., 138 deaths), glass wool + filament (SMR = 1.03, 95% CI = 0.91 to 1.16, n.s., 277 deaths), or filament-only plants (SMR = 0.96, 95% CI = 0.76 to 1.19, n.s., 81 deaths)
(Table 3-2). According to calculations made by IARC (2002), the SMR for respiratory cancer for all eight plants was 1.06, 95% CI = 0.99 to 1.14, 733 deaths) using county rates for comparison (U.S. rates were slightly lower). For the four plants making special fibers, the SMR calculated by IARC (2002) was 1.06, 95% CI = 0.97 to 1.15, 490 deaths). Among all workers in the 10 fiberglass plants in this study (including those making filament only, which comprised approximately 17% of the total cohort), a slight trend towards increasing respiratory cancer mortality with time since first employment and calendar time was observed but not with duration of employment. Workers in the entire cohort hired between 1950 and 1959 had slightly higher rates for respiratory cancers than those hired before or after that period [data not shown]. No consistent relationship with age at hire was observed among the whole cohort [data not shown].

Source: adapted from data in Marsh et al. 2001a. 32,110 male and female workers with > 1 year employment (except for one glass wool and one glass wool + filament plant where workers with > 6 months employment were included) (1945 to 1978) followed up to 1992 with 98.8% ascertainment of cause of death.

a Special application fibers (< 1.5 μm diameter) also made.
bIncludes some filament operations.
cCompared with local county rates. The use of local county mortality rates to calculate SMRs resulted in slightly lower estimated risks compared with national rates.
dIn the whole cohort, including filament workers, there were 15,404 short-term workers (< 5 years employment) and 16,706 long-term workers (≥ 5 years employment).
eSeparate facilities or buildings used for making either wool or filament.
With respect to other cancers, an analysis of mortality due to mesothelioma among the entire 10-plant cohort was conducted (Marsh et al. 2001b), but it was complicated by the lack of consistent diagnostic identification by the International Classification of Diseases (ICD) codes, particularly in older versions, according to the authors. Using different classification schemes to identify “possible” malignant mesothelioma deaths, 10 such cases were initially identified via death certificates in the entire cohort (16 plants, including 6 other plants with rock/slag wool production). Eight of ten possible deaths had potential asbestos exposure, according to the authors. Pathology reports for five of these deaths revealed that two were not mesothelioma and three were doubtful. No excess of mesothelioma was found in the glass wool cohort using a broad definition of mesothelioma spanning several ICD revisions or a more strict definition that focused on pleural mesothelioma. [However, SMR analyses may not be appropriate for evaluating mesotheliomas (see Section 3.5.2).]

No other cancers were found in statistically significant excess; nonsignificant excesses of buccal cavity and pharynx cancers (SMR = 1.11, 95% CI = 0.85 to 1.42, 63 deaths) and bladder and other urinary organs cancers (SMR = 1.07, 95% CI = 0.82 to 1.37, 64 deaths, county comparisons) were observed among the entire glass wool and filament cohort (10 plants) (Marsh et al. 2001a). The SMR for all 2,243 cancer deaths combined was 0.94 (95% CI = 0.90 to 0.98; county comparison) in the total fiber-exposed cohort, [which suggests the possibility of a healthy-worker effect].

Smoking is the major potential confounder for respiratory system cancers. An early attempt to adjust for the effect of smoking on respiratory cancer mortality for the male Newark, Ohio workers in the U.S. cohort was conducted by Chiazze et al. (1995) based on smoking data obtained from interviews with proxies or survivors with a 13% sample of the original Newark cohort (used in a subsequent case-control analysis; see below). The estimated smoking prevalence thus obtained was compared with expected smoking rates for white males obtained from several National Health Interview Surveys. According to this method, some 82% of the cohort were estimated to have ever smoked compared with an expected 73%; when SMRs were adjusted for smoking, they decreased (in the Newark cohort followed to 1982) from 119.6 to 107.8 (range 105.4 to 110.2 for
minimum and maximum smoking estimates). A somewhat higher prevalence of ever smokers was observed among male fiberglass workers compared with the 1980 U.S. population. (Some 76% had ever smoked and most had started before the age of 20.) Rates were also higher than among local populations. A slightly lower than expected rate of ever smoking was observed among the sample of female smokers (41.8% vs. 44.5% in the U.S. population). No relationship between smoking and level of glass wool exposure was observed. Adjustment for estimated smoking reduced all respiratory cancer SMRs to non-significance (Marsh et al. 2001c), and the authors estimated that approximately 7% of the observed excess of respiratory cancers in males could be attributable to smoking. (Note that the effect of smoking on respiratory cancer risk was also examined in a nested case-control study of this cohort, described below, together with the effects of other potential exposures, such as formaldehyde. No attempt to adjust for formaldehyde or other exposures was made in the external analysis of mortality in this cohort, however.)

Stone et al. (2004) conducted a more detailed mortality study of the 266 cancer deaths, including 53 deaths from respiratory cancers, observed among the 4,008 women in the 1992 follow-up. The women were employed from 1945 to 1978 (the period of 1940 to 1978 was used for one plant) with at least one year of employment (6 months was used as the minimum for two plants). Less than 2% were lost to follow-up. Only 633 (15.8%) of the women worked in the five glass wool plants, and the majority of these worked in packing, transport, or inspection rather than production. Of the remaining women, 1,765 (44.0%) worked in the wool and filament plants and 1,610 (40.2%) in filament plants. The median average level and median cumulative level of exposure to respirable fibers in glass wool plants was 0.059 fibers/cm³ and 2.951 fibers/cm³-months, respectively, and 0.008 fibers/cm³ and 0.318 fibers/cm³-months, respectively, in the plants making a combination of glass wool and filament. Filament exposures were very low, with an average median of 0.001 fibers/cm³ and cumulative exposure of 0.079 fibers/cm³-month. These are somewhat lower exposures than those experienced by the male cohort. A large number of the female workers had minimal exposure (close to the limits of detection) and less than five years of employment. SMRs were presented for the whole SVF cohort only (including filament-only workers).
With respect to respiratory cancers, excluding the larynx, the observed SMR was 0.99 (95% CI = 0.74 to 1.29, 52 deaths) compared with national rates and 1.02 (95% CI = 0.76 to 1.34) compared with county rates (Stone et al. 2004). One death from cancer of the larynx was observed (SMR = 0.98, 95% CI = 0.02 to 5.48, county comparison). No other excess cancer deaths were observed. In an internal analysis, respiratory cancers among women who were potentially exposed to mostly glass wool were compared with women potentially exposed to filament only. Only the 3,563 women who were alive and at risk at 44 years of age (the age at death of the youngest respiratory cancer case) were included. All respiratory cancer mortality (ICD 160–163) was significantly elevated among mostly glass wool-exposed workers in a univariate analysis (relative risk [RR] = 3.24, 95% CI = 1.27 to 8.28, 6 deaths). In a multivariate model including average and cumulative exposure and time since first employment, the estimated RR increased to 3.69 (95% CI = 1.38 to 9.87) when glass wool-exposed women were compared with filament only-exposed women. The risk of respiratory cancer was significantly associated with duration of employment (Wald $P$ value = 0.020): women with between five and nine years employment had a statistically significant elevated relative risk of 2.30 (95% CI = 1.24 to 4.27, 16 deaths) on univariate analysis compared with workers with less than 5 years employment, but not with 10 to 19 years (RR = 0.82, 95% CI = 0.34 to 1.98, 6 deaths), or 20 or more years of employment (RR = 0.67, 95% CI = 0.23 to 1.92, 4 deaths). [Note that the numbers of cases in the latter group were small.] Time since first employment was associated with an increased risk of respiratory cancers (Wald $P$ value = 0.037), particularly for workers with > 30 years since first employment relative to those with < 20 years since first employment. Women hired between 1950 and 1970 had higher rates of respiratory cancer than those hired before 1950 or after 1970 (Wald $P$ value = 0.042). Neither the average level nor cumulative level of Rfib exposure was related to respiratory cancer mortality in the entire cohort. Multivariate analyses confirmed the patterns seen in the univariate analysis. No statistically significant effects of other exposures were observed in this cohort; cumulative exposure to formaldehyde was examined in both univariate and multivariate analyses but was not significantly associated with glass wool exposure or respiratory cancers.
With respect to other cancers among the entire female cohort (Stone et al. 2004), a nonsignificantly elevated risk of cancer of the bladder and other urinary organs was observed in the entire cohort (SMR = 1.62, 95% CI = 0.70 to 3.20, 8 deaths, local comparison), but no excess mortality for other cancer sites was observed. Deaths from several specific cancers (breast, and lymphatic and hematopoietic cancers) occurred significantly less often than in the comparison populations. The SMR for all causes of death was 0.77 (95% CI = 0.72 to 0.82, 930 deaths, county comparison) in this cohort, [which suggests the possibility of a healthy-worker effect as in the male cohort].

Case-control studies

Enterline et al. (1987) conducted a nested case-control study of workers who had died from respiratory cancers between 1950 and 1982 from the first follow-up of the U.S. cohort from 1977 to 1982. The case-control study included all 333 cases or deaths from respiratory cancers occurring from 1950 to 1982 among workers exposed to glass wool and continuous filament. A random sample of 529 workers without malignant respiratory cancer or nonmalignant respiratory disease, 43 or more years of age and stratified by age, year of birth, and plant were selected as controls, representing about 4% of the cohort. Smoking data were obtained from interviews with surviving cases and controls or proxies. All cases and controls used in the analyses had data either on ever-smoking status (242 cases and 387 controls) and/or duration and time since starting smoking (211 cases and 374 controls). In maximum likelihood backward stepwise logistic regression models, smoking was, as expected, significantly related to respiratory cancers (estimate of log odds ratio = 2.59 in step 1 of a model with year of birth, age, smoking and cumulative glass wool exposure plus an interaction term, using 242 cases and 387 referents). Time-weighted cumulative exposure to glass wool was not significantly associated with respiratory cancer risk before (log odds ratio estimate = –0.0224 in step 1 of the above model) or after controlling for different measures of smoking, nor was there evidence of an interaction effect between smoking and cumulative exposure to glass wool among these cases (the interaction term in the above model for ever smoking was 0.0146, \( P = 0.7024 \); in addition, there was no interaction effect between years of smoking and exposure to glass wool). [Note that only 27% of the cases and controls were ever smokers, which may decrease the power to detect an interaction effect.] Among 34-
44-year-old referents (representing 5% of the referents) and 65+ year olds (representing 24% of the referents) a somewhat greater percentage was estimated to have ever smoked than in the U.S. white male population (34 to 44 year olds: 75% for referents vs. 71.2% for U.S. white male population; 65+ year olds: 73.4% for referents vs. 66.7% for U.S. white male population). Among the 45 to 64 year olds, representing 71% of the referents, the proportion of ever smokers was similar to that of the U.S. population (79.2% vs. 78.4%, respectively).

Chiazze et al. (1992, 1993) conducted a nested case-control study of the Newark, Ohio cohort (Plant 9), employed for one year or more from 1940 to 1962 and followed until 1982. Exposure and work histories were reconstructed from employment, plant process, and industrial hygiene records. In addition to glass wool and filament, exposures were estimated for asbestos, talc, formaldehyde, respirable silica, and asphalt. In an initial analysis of 162 cases of lung cancer and 363 controls, unadjusted odds ratios (ORs) for cumulative respirable glass wool exposure (using workers with < 100 fibers/cm³-days exposure as a reference) were 1.43 (95% CI = 0.90 to 2.72, 37 cases) for 100 to 299.9 fibers/cm³-days and 0.95 (95% CI = 0.56 to 1.61, 27 cases) for ≥300 fibers/cm³-days (Chiazze et al. 1993). Only year of hire before 1945 and employment duration of less than five years were significantly associated with an increase in lung cancer in the unadjusted analysis. [The authors did not conduct an analysis by time since first exposure, and did not indicate a possible reason for the increase in lung cancer among workers hired prior to 1945. In a separate analysis of lung cancer among workers exposed to fine fibers, made in the 1940s until 1950, no association with lung cancer was observed, although the number of exposed workers was small (10 cases and 24 controls). Demographic and smoking data were obtained by interview, mainly with proxy respondents, for approximately 87% of cases and 79% of controls. Among subjects for whom interview data were available were 152 deaths from respiratory cancers, including 144 lung cancer deaths, which were matched with 276 respiratory cancer and 260 lung cancer controls, all from within the plant. In a conditional logistic regression model, which also simultaneously adjusted for smoking, education, age at first hire, year of hire, asbestos, formaldehyde, silica, talc, and asphalt, odds ratios for lung cancer were significantly associated only with smoking (6+ months vs. less than 6 months) and age at
first hire, and nonsignificantly elevated with year of hire before 1945 (Chiazze et al. 1993). In this model, nonsignificant odds ratios of 1.72 (95% CI = 0.77 to 3.87) for cumulative exposure of 100 to 299.99 fibers/cm\(^3\)-days and 0.58 (95% CI = 0.20 to 1.71) for cumulative exposure of ≥ 300 fibers/cm\(^3\)-days were observed in comparison with lung cancers among workers with exposure of < 100 fibers/cm\(^3\)-days. Ever smoking (6 months or more) yielded an adjusted odds ratio of 26.17 (95% CI = 3.32 to 206.5) for lung cancer. [No actual industrial hygiene records existed for the period of employment of the cohort, and a number of changes in industrial process took place over the years, according to the authors, who relied on a historical reconstruction of exposures to characterize workers’ exposure profiles (Chiazze et al. 1993). Smoking and other demographic data were obtained from proxies, and 14% of respiratory cancer cases and 22% of their controls who did not have interview data were excluded. A large majority of the cohort smoked (57% to 96%, depending on the decade of birth, for occasional + regular smokers), and nearly all the lung cancer cases occurred among smokers.]

A nested case-control study was also conducted with male workers who had died of respiratory cancers between 1970 and 1992, from the later (1992) follow-up of the entire cohort (Marsh et al. 2001a, Stone et al. 2001, Youk et al. 2001). Approximately 40% of the workers had < 5 years employment. Adjustment for smoking was possible for 631 cases and 570 randomly selected age-matched controls at risk during the 1970 to 1992 time period and who were alive at the time the age-matched case died. Data on smoking was obtained by interviews with proxies of the cases and either proxies of the respondents or the respondents themselves. Subjects were classified as ever or never smokers: 609 cases were ever smokers and 22 cases were never smokers. In the unadjusted analysis, Rfib exposure was associated with a nonsignificantly elevated risk of respiratory cancers (RR = 1.79, 95% CI = 0.77 to 4.14, \(P = 0.17\), 622 exposed, 9 unexposed cases). After adjustment for ever smoking, the relative risk was slightly decreased (RR = 1.37, 95% CI = 0.55 to 3.42, \(P = 0.50\)). For respiratory cancers among workers in the five mostly glass wool plants, the unadjusted relative risk of respiratory cancers (compared with 92 cases among workers in filament-only plants) was 1.12 (95% CI = 0.77 to 1.62, 183 cases); this risk decreased slightly after adjustment for ever smoking (RR = 1.06, 95% CI = 0.71 to 1.60). For workers exposed to both glass wool
and filament, the adjusted relative risk was 1.01 (95% CI = 0.69 to 1.47, 356 cases). No
association with duration of employment or time since first employment was observed in
either unadjusted or adjusted analyses. [Note that race was a significant risk factor for
respiratory cancers but was not included in further analyses because most of the excess
risk was associated with unknown race.]

Marsh et al. (2001a) also evaluated several measures of exposure to respirable fibers
(average, cumulative, and duration) and respiratory cancer risk. Relative risks were
calculated for deciles of each exposure measure. Non-baseline levels of average intensity
of exposure to respirable fibers (Rfib-AIE) were associated with relative risks ranging
from 1.23 to 2.47 for individual deciles of exposure in the unadjusted model; several of
the exposure decile-specific RRs for average intensity of exposure were statistically
significant in the models after controlling for smoking or for smoking and plant.
Statistically significant heterogeneity was observed in the unadjusted RRs ($P = 0.02$), but
the heterogeneity was not statistically significant after controlling for ever smoking ($P =
0.07$) or plant and ever smoking ($P = 0.19$). A test for exposure-response trend was not
statistically significant, however. No association was observed between respiratory
cancer risk and cumulative exposure to respirable fibers ($P > 0.30$) or duration of
exposure ($P > 0.21$). Neither of the trend tests for cumulative exposure or duration of
exposure was statistically significant.

The association between average intensity of exposure to respirable fibers and respiratory
cancers was reanalyzed by different models in two later publications (Stone et al. 2001,
Youk et al. 2001). Youk et al. performed analyses using weighted exposure estimates.
These included time lags (where exposure is discounted for a specified period before the
start of the observation time) and unlagged or lagged time windows (so that only
exposures occurring within certain time frames are counted). Adjusting for smoking, risk
estimates for deciles of exposure measures for both average intensity and cumulative
exposure to respirable fibers were lower in the weighted models compared with the
unweighted models; no relationship between increasing average or cumulative exposure
to respirable fibers and respiratory cancer was observed.
Stone et al. (2001) performed analyses that allowed the modeling of collinearity, effect
modification, and potential confounding by co-exposures, including quantitative
estimates of formaldehyde and silica exposure and qualitative estimates of other
exposures, as well as the effects of smoking and demographic variables. No association
was observed between average intensity, cumulative exposure, or duration of exposure to
respirable fibers and respiratory cancers in numerous polynomial models that included
quantitative measures of exposure to respirable fibers, formaldehyde, and silica as
continuous variables in the same model.

Ever smoking accounted for some of the heterogeneity in risk among the different plants
according to the authors, suggesting a possible correlation between smoking and
exposure to fiber type. Stone et al. (2001) reported that nonsmokers had somewhat lower
average intensity of exposure and cumulative exposure to respirable fibers than smokers.
However, there was no evidence of an interaction effect between smoking and average
respirable fiber exposure ($P = 0.60$) (Stone et al. 2001).

As noted, a number of other potential exposures (arsenic, asbestos, asphalt, epoxy,
formaldehyde, polycyclic aromatic hydrocarbons, phenolics, silica, styrene, and urea)
were examined in association with respiratory cancer risk in the case-control study,
although with the exception of formaldehyde and silica, only qualitative (exposed or non-
exposed) estimates of exposure were available. Using dichotomous variables for each of
the co-exposures and adjusting for ever smoking, Marsh et al. (2001a) reported a
statistically significant positive association for formaldehyde and a significant inverse
association for epoxy exposure. In a further analysis using estimates of glass fiber,
formaldehyde, and crystalline silica exposure as continuous rather than dichotomous
variables (Stone et al. 2001), higher levels of formaldehyde exposure were significantly
associated with respiratory cancer risk before and after adjustment for smoking. A trend
towards increasing risk with the higher silica-exposed group was also observed.
Misclassification of exposure to at least some of the co-exposures was considered likely,
in part due to the short duration of employment of approximately 40% of the workers in
the case-control study (Stone et al. 2001).
Strengths and limitations

[Strengths of the study include (1) the representation of close to one million person-years at risk in the combined male and female U.S. cohort (Marsh et al. 2001a), which had 80% statistical power to detect a 10% or greater excess risk of respiratory cancer, although the female cohort study of Stone et al. (2004) had considerably less power, (2) almost complete ascertainment of vital status, and (3) adequate length of follow-up for most expected latency periods. Most of the male workers were engaged in production, and reconstruction of exposures was detailed and based in part on industrial hygiene samples. The major limitations include qualitative rather than quantitative assessments of levels of several potentially confounding co-exposures and limited smoking data, which were obtained mainly from proxies and which did not permit detailed analyses by level or duration of smoking. In addition, approximately 40% of the cohort was short-term workers (less than five-years employment) and had higher rates of respiratory cancers, but analyses of cancers among these workers by demographics, smoking, and occupational co-exposures were not analyzed separately.

3.1.2 European cohort

IARC has conducted cancer mortality and incidence studies of SVF-exposed male and female production workers in 13 SVF plants across 7 European countries since 1976 (Boffetta et al. 1992, 1997, 1999 Gardner et al. 1986, 1988, Saracci et al. 1984, Simonato et al. 1986). The 8,335 workers, representing 201,105 person-years at risk, were exposed to glass wool from five factories, one in each of five countries, and were included in a cohort mortality follow-up by Boffetta et al. (1997) (Table 3-3). The U.K. plant, which constituted the largest subcohort and 70% of expected deaths, also produced some continuous filament and other specialty fibers of varying diameters (Gardner et al. 1988, Gardner et al. 1986). In addition, a cancer incidence study was conducted with workers in three of the five countries (excluding the United Kingdom and Italy, which did not have national cancer registries) by Simonato et al. (1986). The latter cohort was also followed up in an incidence study by Boffetta et al. (1999).]

Cherrie et al. (1986) conducted exposure measurements for four of the glass fiber plants included in the European cohort and reported a range for respirable concentrations of fibers from 0.01 to 1.00 fibers/cm³, with the highest concentrations being associated with the manufacture of special fine fiber earplugs. The mean concentrations in main production ranged from 0.01 to 0.05 fibers/cm³ and in secondary production from 0.02 to 1.00 fibers/cm³, and are closely comparable with the ranges seen in main and secondary production in the U.S. manufacturing plants. With respect to individual plants, the ranges for average concentrations of respirable fibers across all job categories were 0.01 to 1.00 fibers/cm³ (Sweden), 0.01 to 0.05 fibers/cm³ (Finland), 0.01 to 0.07 fibers/cm³ (Norway), and 0.01 to 0.16 fibers/cm³ (United Kingdom). The plant in Italy produced glass wool from 1946 to 1960 only, and no contemporary measurements of glass wool were available.

Individual cohorts

Parts of the European cohort have been studied by individual investigators in the component countries. In an early study of part of the Norwegian cohort (Andersen and Langmark 1986), one plant producing glass wool was included, but constituted only 23% (N = 546) of their total cohort, the remainder being exposed to rock wool. Cancer mortality and incidence were reported mainly for both exposed groups combined. A slight excess of all cancer deaths was observed. A statistically significant excess cancer incidence of the buccal cavity and pharynx (SIR = 1.68, 7 cases), and nonsignificantly elevated risks of cancers of the intestine (SIR = 1.24, 17 cases), trachea, bronchus, or lung (SIR = 1.39, 20 cases), and bladder (SIR = 1.20, 8 cases) were reported in the whole
cohort [CIs were not specified]. Workers with > 1 year of employment and > 20 years
since first exposure had a two-fold increase in the risk of lung cancer (SIR = 2.06, 9 cases
). Among the glass wool workers, lung cancer incidence was reported separately and was
lower than expected (2 cases among those with > 1 year of employment, SIR = 0.69; SIR
= 0.63 for the 2 cases among all glass wool workers).

Bertazzi et al. (1986) conducted an early study of cancer mortality in a manufacturing
plant in Italy, which became part of the European cohort. This plant produced mostly
glass wool for about 15 years, until 1960, and then only continuous filament. No asbestos
use was reported. Male workers (N = 1,098) with greater than one year of employment
hired up to 10 years prior to the end of follow-up were included, and 98.9% were
successfully followed up for the period from 1944 to 1983. A slight excess of total cancer
deaths was observed compared with national referents; a statistically nonsignificant
increase in laryngeal cancer was observed (SMR = 1.88, 95% CI = 0.52 to 4.88, 4 deaths,
compared with regional comparison rates). This increase occurred mainly among workers
hired prior to 1960 before age 25 and who had at least 15 years since first employment
and the greatest cumulative exposure. No significant increases in lung or other cancers
were observed (SMR = 0.96, 95% CI = 0.50 to 1.68, 12 lung cancer deaths, compared
with regional rates).

In an earlier mortality and incidence study of the Swedish cohort (Plato et al. 1995b),
male and female glass wool manufacturing workers were included (N = 1970). Mortality
was followed from 1952 to 1990 and cancer incidence from 1958 to 1989. No smoking
data were available in this study. No excess of mortality from all cancers combined was
observed when compared with either regional or national rates (SMR = 1.00, 95% CI =
0.82 to 1.22, 102 deaths, regional comparison). No excess of lung cancers was observed
(SMR = 0.97, 95% CI = 0.57 to 1.69, 14 deaths, regional comparison), except for a
nonsignificant excess among workers with 30 or more years since first employment
(SMR = 1.43, 95% CI = 0.74 to 3.05, 8 deaths, regional comparison). No significant
excesses of other cancers occurred. A similar pattern was observed with lung cancer
incidence (SIR = 0.93, 95% CI = 0.54 to 1.48, 17 cases, regional comparison).
In an earlier mortality study of the U.K. glass wool and filament manufacturing workers (Gardner et al. 1986), 4,766 male and female workers at a glass wool manufacturing plant were followed from 1946 until 1984. Some asbestos exposure also occurred in this cohort. A slight but nonsignificant excess of lung cancers was observed among males (SMR = 1.24, 95% CI = 0.98 to 1.59, 69 deaths) but not females (SMR = 0.96, 95% CI = 0.60 to 3.09, 7 deaths) when local comparison rates were used. A significant excess of stomach cancer occurred among women workers (SMR = 1.53, 95% CI = 1.02 to 6.04, 6 deaths, local rates).

The Finnish cohort of glass wool manufacturing workers was studied by Teppo and Kojonen (1986). Some asbestos exposure in addition to glass wool exposure occurred in the plant. Among 616 male and 325 female workers, employed from 1953 to 1977 and followed for an average of 12.1 years to 1981, a slight but nonsignificant excess of all cancers combined was observed among female workers (SMR = 1.16, CI not specified, 12 deaths), and a deficit among male workers (SMR = 0.74, CI not specified, 11 deaths). A slight decrease in lung cancer deaths was observed. A similar pattern was observed for cancer incidence among both sexes combined, with no observed excess of lung cancer (SIR = 0.61, 95% CI = 0.17 to 1.56, 4 cases). Only bone cancer was significantly increased (SIR = 10.26, 95% CI = 1.24 to 37.05, 2 cases). [The study was limited by small numbers of exposed subjects and short follow-up time.]

Combined cohort studies

The combined cohort, consisting of the glass wool cohorts from five countries described above, was followed up for mortality until 1990 or 1992, depending on the subcohort (Boffetta et al. 1997), and for incidence until 1995 (Boffetta et al. 1999). A nested case-control study was also conducted. Loss to follow-up was between approximately 2% and 10%. Exposure was considered in three technological phases (early, intermediate, and late) representing the highest to lowest relative exposure periods (Boffetta et al. 1997).

Mortality study. With respect to respiratory cancers, an excess of lung cancer deaths (SMR = 1.27, 95% CI = 1.07 to 1.50, 140 deaths) was observed among 6,936 glass wool workers with at least one year of employment and representing 167,675 person-years at risk (Boffetta et al. 1997). [It should also be noted that in the total cohort, including
workers exposed to glass wool, rock and slag wool, or filament, the SMR for lung cancer was slightly higher among short-term workers with less than one year of employment (SMR = 1.48, 95% CI = 1.18 to 1.83, 83 deaths) than longer term workers; analyses for short-term workers exposed only to glass wool were not presented, however.] Adjustment of SMRs for local factors reduced the SMR to 1.12 (95% CI = 0.95 to 1.31). Seventy-eight percent (78%) of the observed lung cancer deaths occurred in the U.K. cohort, in which the SMR was significantly elevated (SMR [national rates] = 1.37, 95% CI = 1.13 to 1.65, 109 deaths). None of the other four glass wool plants had statistically significant excess of lung cancers, [although the number of deaths was low and confidence intervals were wide]. Analysis by technological phase did not suggest a consistent trend in lung cancer mortality; SMRs for workers with greater than one year of employment were 1.07 (95% CI = 0.64 to 1.67, 19 deaths) for the early phase, 1.40 (95% CI = 1.14 to 1.70, 100 deaths) for the intermediate phase, and 1.02 (95% CI = 0.63 to 1.56, 21 deaths) for the late phase (see Table 3-4). No trend with duration of employment was observed: SMRs were 1.11 (95% CI = 0.82 to 1.46, 50 deaths) for 1 to 4 years; 1.18 (95% CI = 0.80 to 1.68, 301 deaths) for 5 to 9 years; 1.68 (95% CI = 1.23 to 2.25, 451 deaths) for 10 to 19 years; and 1.17 (95% CI = 0.66 to 1.93: 15 deaths) for 20+ years. No increase in lung cancer risk with time since first employment was observed: SMRs were 1.6 (18 deaths) for 0 to 9 years, 0.89 (5 deaths) for 10 to 19 years, 1.30 (9 deaths) for 20 to 29 years, and 1.65 (13 deaths) for 30 or more years [95% CIs not specified]. With respect to other cancers, a significant increase in all cancer deaths combined was observed among glass wool workers (SMR = 1.11, 95% CI = 1.01 to 1.22, 460 deaths). Some, mostly statistically nonsignificant, increases in specific cancers were observed. Buccal cavity and pharyngeal cancer (SMR = 1.47, 95% CI = 0.71 to 2.71, 10 deaths) showed a slight excess in glass wool workers, as did bone cancer (SMR = 2.66. 95% CI = 0.86 to 6.21, 5 deaths), bladder cancer (SMR = 1.13, 95% CI = 0.62 to 1.89, 14 deaths), lymphatic and hematopoietic cancers (SMR = 1.42, 95% CI = 0.94 to 2.07, 27 deaths) and cancers of ill-defined and unspecified sites (SMR = 1.69, 95% CI = 1.13 to 2.42, 29 deaths). One death from mesothelioma among the glass wool cohort was reported.

Incidence study. In the cancer incidence study, 2,611 glass wool workers with greater than one year of employment, representing 68,523 person-years at risk, were studied
(Boffetta et al. 1999). Loss to follow-up was approximately 6% for the whole cohort. A nonsignificant excess risk of lung cancer was observed (SIR = 1.28, 95% CI = 0.91 to 1.74, 40 cases). A slight trend towards an increase in the relative risk for lung cancer was observed with increasing time since first employment (RR = 2.3, 95% CI = 0.6 to 9.2, 15 deaths, for > 30 years vs. RR = 1.9, 95% CI = 0.8 to 4.8, 15 deaths, for 20 to 29 years, compared with a referent of 1 to 19 years since first employment), in contrast to the combined mortality study and findings for the U.K. and Italian cohorts. No relationship between relative risk and duration of employment was observed, using a 15-year lag and adjusting for age, gender, country, time since first employment, and technological phase: RRs were 0.8 (95% CI = 0.3 to 2.0, 8 cases) for 5 to 9 years, 0.8 (95% CI = 0.3 to 2.4, 4 cases) for 10 to 19 years, and 0.7 (95% CI = 0.08 to 5.3, 1 case) for 20 or more years, compared with a referent of 1 to 4 years of employment. Similarly, no relationship between lung cancer risk and technological phase was observed, adjusting for age, gender, country, and time since first employment: the RR for early vs. late phase (referent) was 0.6 (95% CI = 0.2 to 1.5, 20 cases); no cases were observed in the intermediate phase (Table 3-4). As in the mortality study, a statistically nonsignificant increase in the SIR for combined oral cavity, pharynx, and larynx cancers was observed (SIR = 1.41, 95% CI = 0.80 to 2.28, 16 cases). SIRs in excess of 1.00 were also observed for stomach cancer (SIR = 1.05, 95% CI = 0.67 to 1.57, 24 cases), breast cancer (SIR = 1.08, 95% CI = 0.72 to 1.55, 29 cases), bladder cancer (SIR = 1.39, 95% CI = 0.88 to 2.08, 23 cases), skin melanoma (SIR = 1.13, 95% CI = 0.54 to 2.08, 10 cases), leukemia (SIR = 1.25, 95% CI = 0.54 to 2.46, 8 cases), and other, not otherwise defined sites (SIR = 1.01, 95% CI = 0.78 to 1.29, 65 cases), but none was statistically significant. The observed incidence of all cancers combined was slightly lower than the expected rate (SIR = 0.99, 95% CI = 0.89 to 1.11, 324 cases).

Strengths and limitations. [Strengths of the study include the large size of the cohort, almost complete ascertainment of vital status, and adequate length of follow-up to observe long latency cancers such as lung cancer. The major limitations were the imprecision of exposure classification within the plants, the absence of work history information for the early years of the study (pre-1977), and the confinement of the exposure assessment to the assignment of technological phases within plants. No direct
exposure measurements were used in either the SMR or SIR analyses. In addition, no information on potentially confounding exposures, including smoking or other co-exposures, was available.

**Case-control study**

A nested case-control study of lung cancers was conducted on 3,548 male and 1,186 female workers at the U.K. glass wool plant, which also produced superfine fibers (1 to 3 μm and 2 to 5 μm diameter) for part of the time (Gardner et al. 1988). Up to eight sex- and age-matched controls from the workforce with greater than one year of employment who were alive at the time of death of the case were randomly selected. Based on information about manufacturing processes and job title or category, potential exposure to different types of SVF and asbestos was assigned to cases and controls. No direct measurements of glass fiber levels were available, except for those taken during a survey conducted in 1977 (as part of the cohort study). No data on smoking and other exposures were available. Seventy-three (73) deaths from lung cancer (66 males and 7 females) and 506 controls were included in the final analysis. The relative risk for lung cancer for all respirable superfine and other glass wool fibers (defined as diameter ≤ 3 μm, length > 5 μm, and aspect ratio > 3:1) was 1.2 (95% CI = 0.7 to 2.0, 33 exposed deaths). (For glass wool separately, the relative risk for lung cancer was 1.1 (95% CI = 0.7 to 1.9, 31 deaths) and for superfine fibers separately it was 1.3 (95% CI = 0.3 to 5.8, 2 deaths.) Within individual categories of glass wool fiber types, no statistically significant increases in lung cancer risk were observed. No relationship between duration of exposure, time since first exposure or job category and lung cancer was observed, except for a statistically significant relative risk (RR = 2.0) for 17 lung cancer deaths observed among workers exposed to glass wool and/or superfine fibers with 10 to 19 years since first exposure (CI not stated). No significant association between lung cancer and asbestos was observed, and addition of asbestos exposure to the regression models did not alter the relative risk estimates for glass wool. [The power of the study was not stated, but the numbers of deaths among the different categories of fibers were small; too few workers were exposed to superfine fibers, in particular, for conclusions to be drawn, according to the authors. In addition, only 48% of the original cohort had five or more years of employment. It is not
clear whether the length of time since first exposure (not stated) was adequate to detect long-latency cancers for a number of the workers.]

3.1.3 Canadian cohort

This cohort mortality study included 2,557 male workers employed in glass wool manufacture for at least 90 days from 1955 to 1977. The first follow-up study was conducted in 1984 (Shannon et al. 1984, 1987) and the second study extended the follow-up from 1984 to the end of 1997 and included data on cancer incidence from 1969 to 1997 (Shannon et al. 2005). Findings from the latest follow-up are discussed below.

The cohort consisted of 2,576 men employed for at least 90 days from 1955 to 1977 in three groups followed to 1997: those who worked only in the manufacturing plant, those who worked only in the office, and those who worked in both (“mixed exposure”) (Shannon et al. 1984, 1987, 2005). No direct measurements of exposure were available prior to 1978; samples taken subsequently suggested average levels below 0.1 fibers/cm³ and peaks generally less than 0.2 fibers/cm³. Average concentrations between 1977 and 1990 were approximately 0.03 fibers/cm³ (Shannon et al. 2005). [It is not clear what proportion of these fibers was in the respirable range.] Ascertainment of vital status was complete for 97% of the cohort, but only 502 workers were followed beyond 20 years after first exposure, 13 of whom were office workers [with little opportunity for exposure]. No smoking data were available.

A total of 94 deaths from all cancers combined was observed among the manufacturing plant workers (SMR = 1.15, 95% CI = 0.93 to 1.40); 12 among office workers (SMR = 1.13, 95% CI = 0.59 to 1.98) and 6 among workers with mixed (plant and office) exposure (SMR = 0.47, 95% CI = 0.17 to 1.03) (Shannon et al. 2005). All subsequent analyses were of plant-only workers.

With respect to respiratory cancers, a significant excess of lung cancer was observed among plant-only workers (SMR = 1.63, 95% CI = 1.18 to 2.21, \( P < 0.05 \), 42 deaths). Among plant-only workers with > 20 years of employment, the SMR for lung cancer was 1.89 (95% CI = 1.10 to 3.03, \( P < 0.05 \), 17 deaths) and for plant-only workers with > 20 years of employment and > 40 years since date of first exposure, the SMR for lung cancer
was 2.82 (95% CI = 1.13 to 5.82, $P < 0.05$, 7 deaths). For plant-only workers employed prior to 1960, lung cancer mortality was also significantly elevated (SMR = 1.72, [CI not stated], $P < 0.05$, 31 deaths). No other trends with duration of employment or date since first exposure were statistically significant. When only lung cancer deaths since the end of the first follow-up among plant-only workers were considered, the SMR was 1.42, 95% CI = 0.90 to 2.13; 23 deaths).

In the cancer incidence part of the study, comparing rates with cancer registry data for Ontario (available only from 1969), 50 cases of lung cancer were observed among plant-only workers from 1969 to 1996, yielding a significant SIR of 1.60 (95% CI = 1.19 to 2.11, $P < 0.05$). Fifty-four (54) cases of lung cancer were observed among all workers combined (SIR = 1.34, 95% CI = 1.01 to 1.75, $P < 0.05$). SIRs in excess of 1.00 were also observed for kidney, rectal, and stomach cancer, but none was significant. No significant trends with duration of employment or date since first exposure were observed, although, as in the case of lung cancer mortality, the highest SIR occurred among the group with the longest duration of employment according to the authors [SIRs not reported]. While comparison with province-based cancer mortality and incidence data were considered less than ideal, the authors noted that local (county) rates were too unstable to permit comparison.

The authors concluded that, notwithstanding the lack of direct exposure data and lack of smoking data, there was a suggestion of a modest effect of glass wool on lung cancer rates in both the mortality and morbidity data. The authors also considered that the lack of an increase in mortality or morbidity from known non-cancer, smoking-related diseases such as cardiovascular and respiratory disease suggested that smoking among exposed workers was not excessive.

With respect to other cancers in the extended mortality study, no significantly elevated cancers were observed among plant workers, although kidney cancer rates were somewhat higher than expected (SMR = 1.46, 95% CI = 0.30 to 4.27, 3 deaths). In the cancer incidence study, a statistically significant excess of kidney cancer was observed in the whole cohort (SIR = 1.92, 95% CI = 1.05 to 3.21, $P < 0.05$, 14 cases) but did not
reach significance among the plant-only workers (SIR = 1.92, 95% CI = 0.96 to 3.43, 11 cases). The authors concluded that glass wool is unlikely to be a causal factor in kidney cancer, in part because no other cohort study has observed such an effect. They suggested that silica might be a factor, since it is associated with renal disease, although as noted, no direct measurements of silica or other agents were available for this cohort. [It should also be noted that the overall all-cause SMR in this cohort was low (0.88), suggesting a healthy-worker effect.]

3.1.4 French cohort

A small cohort incidence study, initiated as a result of an observed “excess” of cancers of the pharynx, larynx, and buccal cavity by an industrial physician, was conducted on male workers in a single glass wool plant in France (Moulin et al. 1986). All 1,374 male workers employed between 1975 and 1984 with a minimum of one year of employment were studied. Follow-up was conducted up to the time of study (1984), so that the maximum length of follow-up was approximately 10 years. Approximately 12,800 person-years at risk were available for analysis, of which slightly more than half were among potentially exposed production workers. Men lost to follow-up (N = 101) were considered to be still living and contributed 465 person-years to exposure. Twenty-five percent (25%) of the entire cohort was followed for more than 20 years since first hire, and the average duration of employment was 16 years. Cancers were identified from company insurance records, and regional cancer rates were used for comparison. The mean diameter of fibers in the plant was 6.4 μm, with 30% < 3 μm and 10% < 1 μm. The average concentration of respirable fibers was < 0.2 fibers/cm³. Smoking data were collected for 966 men still working at the factory in 1983 and estimated for the remainder of the cohort. Forty-one cases of cancer were reported over the total of 10 years of follow-up. Five cases of lung cancer were observed in the whole cohort (SIR = 0.74, 95% CI = 0.24 to 1.72). Referent cancer rates used for the estimation of standardized incidence ratios were calculated based on the average of three regional cancer registries in France, weighted by population size. (Although none of the referent population rates included the region in which the plant was located, mortality rates for the plant region were similar to those for the regions in which incidence data were available, according to the authors.)
Among potentially exposed production workers, there were four cases of lung cancer, too few to permit an adequate examination of a trend by duration of employment (Table 3-4). An increase in cancers of the upper respiratory tract or upper gastrointestinal tract combined (ICD 8th Revision codes 141–149 and 161) was observed, which included cancer of the larynx, buccal cavity, and pharynx (SIR = 2.18, 95% CI = 1.31 to 3.41, 19 cases in the entire cohort) and 17 among potentially exposed production workers). Among the production workers with > 10 years duration of employment, a significant increase in the risk of these latter cancers was observed (Table 3-4). No other SIRs for specific cancers were reported by the authors, but the SIR for all other cancers combined (excluding lung, upper respiratory and digestive tract cancers) was lower than expected (SIR = 0.77, 95% CI = 0.45 to 1.24, 17 cases), [suggesting the possibility of a healthy-worker effect]. Smoking was not taken into account in the statistical analyses, but the authors noted that the smoking prevalence among the current employees was similar to population values, with approximately 75% ever-smokers; slightly fewer heavy current smokers than expected were observed.

[The principal limitations of the study include the small numbers of potentially exposed production workers and short follow-up time (10 years), yielding only 12,800 person-years of risk, only approximately half of which occurred among production workers. In addition, it is not clear whether the reliance on company insurance records to identify cancer incidence cases might have resulted in the misclassification or omission of certain cases.]

| Marsh et al. 2001a              | Nested case-control study of respiratory cancer (lung and larynx) | Exposure Assessment  
Same as Marsh et al. above  
Job location-weighted exposures were determined for a given time period, plant, department, and job title, and were used to determine quantitative exposure to respirable fibers (Rfib)  
Other agents – quantitative exposure estimated for formaldehyde (FOR); qualitative estimation for other agents  
Summary exposure measures:  
Rfib duration (Rfib-dur)  
Rfib cumulative (Rfib-cum)  
Rfib average intensity exposure (Rfib-AIE) | Adjusted RR (95% CI); no. of deaths for respiratory cancers  
Rfib 1.37 (0.55–3.42); 622  
Fiber production group  
F: 1.0 (Ref); 92  
GW: 1.06 (0.71–1.60); 183  
GW+F: 1.01 (0.69–1.47); 356  
P\text{trend}  
Duration of employment \( P > 0.05 \)  
Time since first employment \( P > 0.05 \)  
Rfib summary exposure measures (Marsh et al. 2001a)  
P for Global Test for heterogeneity  
Smoking:  
Unadjusted  
Adjusted  
Rfib-dur \( P > 0.21 \) \( P > 0.21 \)  
Rfib-cum \( P > 0.30 \) \( P > 0.30 \)  
Rfib-AIE \( P = 0.02 \) \( P = 0.07 \)  
(Rfib-AIE, \( P = 0.19 \) when adjusted for smoking and plant). Some statistically significant RR for specific deciles of AIE exposure found in the two adjusted models, none of the test for trends were significant  
Rfib summary exposure measures: time weighted (Youk et al. 2001) or polynomial models (Stone et al. 2001)  
No association with Rfib-AIE | Confounding  
Smoking and race were significantly associated with respiratory cancer risk  
Smoking information obtained from interviews with proxies and survivors  
98% of workers exposed to Rfib, 91% to FOR, and 77% to phenolics; other exposures included urea, silica, and asbestos  
Formaldehyde exposure significantly related to respiratory cancer before and after adjustment for smoking, no association with exposure to other substances  
Small numbers prevented evaluation of effect modification by smoking |

</table>
| Gardner et al. 1988 UK        | Nested case-control study of lung cancer mortality  
Cohort: U.K. plant was part of the Boffetta cohort  
3,548 men, 1,186 women  
Employed > 1 year  
Employed: 1946–78  
Follow-up: 1948–84  
Cases: 73 (66 men, 7 women) non-office workers who died from lung cancer  
 Controls: 506 workers randomly chosen and matched by age, gender, and alive at the death of corresponding case (up to 8 controls for each case)  
RR calculated by conditional logistic regression for matched case-control sets | Exposure Assessment  
Factory records (job titles, dates, and clock numbers, type of fiber produced) used to code job descriptions. Workers categorized by fiber type and occupational groups  
Superfine (specialty) fibers (1–3 or 2–5 μm diameter) and glass wool fibres produced by flame attenuation process (superfine only), Owens blowing process and rotary TEL (derived from Laboratoire Experimental Thermique) process, both of which resulted in respirable fibers (diameter < 3 μm, length > 5 μm and aspect ratio > 3:1) | RR (95% CI): cases/controls for lung cancer  
Fiber type  
all respirable fibers 1.2 (0.7–2.0); 33  
all glasswool 1.1 (0.7–1.9); 31  
all superfine fibers 1.3 (0.3–5.8); 2  
Higher RR for glass wool produced by Owens (1.4) than TEL process (0.9)  
Occupational category  
No significant associations observed for most general categories, but lung cancer significantly elevated for granulating/blowing wool workers, maintenance engineer workers, boilermen, and warehouse workers  
Employment duration and time since first exposure  
No significant associations |  
Confounding  
Workers also exposed to asbestos OR = 1.5 (0.8–2.5, 24 deaths); controlling for asbestos did not alter results for glass wool or superfine fibers  
No data on smoking available  
Other limitations  
Small number of exposed cases in the subgroup analyses |
| Shannon et al. 2005 Ontario, Canada | Retrospective mortality and incidence study  
2,557 male glass wool manufacturing workers; extended follow-up of Shannon et al. cohort  
Mortality  
Employed: > 90 days | Exposure Assessment  
Work histories and information on production  
Historical exposures estimated to be < 1 f/cm³  
Workers divided into 3 groups:  
production plant only (~50%) office-only  | Mortality study among plant workers  
SMR (95% CI); no. of deaths (Ontario comparison)  
all causes 0.93 (0.83–1.05); 299  
all cancers 1.15 (0.93–1.40); 94  
Cancers with elevated SMRs  
kidney cancer 1.46 (0.30–4.27); 3 |  
Confounding  
Potential exposure to formaldehyde, phenol, carbon monoxide, solvents, asphalt fumes, total dust, crystalline silica; most exposures were less than current threshold levels |

LH – lymphohematopoietic.

aAnalyses are for exposed production workers.
3.2 Mixed glass wool and continuous filament

3.2.1 U.S. cohort

Taking the data for those workers who had estimated exposure to both glass wool and continuous filament (N = 15,718) (Marsh et al. 2001a), similar SMRs were observed for respiratory cancer mortality among workers with mixed (glass wool + filament) exposure (SMR = 1.02, 95% CI = 0.94 to 1.12, 490 deaths, all workers, and SMR = 1.03, 95% CI = 0.91 to 1.16, 277 deaths, workers with 5 or more years of employment) and among workers in the three plants that produced only continuous filament (SMRs = 1.04, 95% CI = 0.87 to 1.22, 141 deaths, all workers, and SMR = 0.96, 95% CI = 0.76 to 1.19, 81 deaths, workers with 5 or more years of employment). Similarly, in the nested case-control study, the relative risk of respiratory cancer among workers with mixed glass wool and filament exposure is 1.01 (95% CI = 0.69 to 1.47, 356 cases, adjusted for smoking) when filament-exposed workers are used as the referent. (Note that the RR for glass wool-exposed workers is 1.06, 95% CI = 0.71 to 1.60, adjusted for smoking). [Note that filament exposure in the three plants producing both types of fiber appears to be very low, suggesting that, as IARC (2002) pointed out, “mixed exposure” workers can be considered to be exposed mainly to glass wool.]

In the case-control study conducted by Chiazze et al. (1992, 1993) of 166 lung cancer deaths among workers from one of the plants in the U.S. cohort (described above), that produced both glass wool and continuous glass filament, a decrease in lung cancer risk with cumulative exposure to respirable fibers of both types combined was observed.

3.2.2 European cohort

It appears that the five glass wool plants included in the European cohort produced mostly glass wool. In the case of the plant in the United Kingdom, continuous filament and other special superfine fibers were also produced (Gardner et al. 1986), and it is also possible that some workers from the other plants in the combined cohort also had exposure to filament (or other SVF). Among the U.K. workers, no analyses by fiber type were conducted in the mortality study; as noted above, an overall excess of lung cancer deaths was observed when national but not regional comparison rates were used. [In the subsequent nested case-control study of lung cancer among the U.K. workers (Gardner et al. 1986), the relative risk of respiratory cancer among workers with mixed glass wool and filament exposure is 1.01 (95% CI = 0.69 to 1.47, 356 cases, adjusted for smoking) when filament-exposed workers are used as the referent. (Note that the RR for glass wool-exposed workers is 1.06, 95% CI = 0.71 to 1.60, adjusted for smoking). [Note that filament exposure in the three plants producing both types of fiber appears to be very low, suggesting that, as IARC (2002) pointed out, “mixed exposure” workers can be considered to be exposed mainly to glass wool.]

In the case-control study conducted by Chiazze et al. (1992, 1993) of 166 lung cancer deaths among workers from one of the plants in the U.S. cohort (described above), that produced both glass wool and continuous glass filament, a decrease in lung cancer risk with cumulative exposure to respirable fibers of both types combined was observed.
al. 1988) only one case was observed in association with exposure to continuous filament only, and it is not possible to evaluate the risk of lung cancer associated with mixed glass wool and filament exposure. The relative risk for lung cancer among workers exposed to superfine fibers (2 cases) is higher than for glass wool but not significant (Table 3-4).

3.3 Mixed SVF exposure (not otherwise specified)
There are several other studies of workers and/or populations that might have been exposed to SVF including glass wool, but, with the exception of the case-control studies by Siemiatycki (1991), Dumas et al. (2000), and Baccarelli et al. (2006), in which the authors attempted to distinguish cases with estimated glass wool exposure from those with other SVF exposure, exposure was mixed and/or no data were available to categorize exposure by fiber type. The principal studies are reviewed briefly here. These studies are described in Tables 3-5 and 3-6.

3.3.1 Cohort studies
In a cohort mortality and incidence study of 135,035 male construction workers exposed to SVF in Sweden (Engholm et al. 1987), all but 11 of whom were followed up until 1982, no excesses of all cancer mortality (SMR = 0.84, 95% CI = 0.81 to 0.88, 2,153 deaths) or incidence (SIR = 0.94, 95% CI = 0.91 to 0.97, 3,810 cases) or lung cancer mortality (SMR = 0.86, 95% CI = 0.79 to 0.95, 444 deaths) or incidence (SIR = 0.91, 95% CI = 0.83 to 1.00, 440 cases) were observed. An excess of pleural cancer cases (SIR = 2.13, 95% CI = 1.35 to 3.20, 23 cases) was observed, however. The authors concluded that considerable exposure to asbestos might also have occurred among these cases, based on the observed incidence of pleural mesotheliomas, which they considered to be closely correlated with asbestos exposure, even though in 21 of these cases, the workers answered “no” to asbestos exposure on an exposure questionnaire. In a nested case-control study of this cohort, in which industrial hygienists estimated average exposures, the relative risk for lung cancer was not statistically significantly elevated among workers estimated to have low-medium or high SVF exposure but no asbestos exposure, after adjustment for smoking and population density (RR = 2.12, 95% CI = 0.99 to 4.54), nor among those with both medium to high SVF and asbestos exposure (RR = 1.21, 95% CI
= 0.60 to 2.47, adjusting for asbestos exposure), but the RR was significantly elevated among those with substantial exposure only to asbestos (Table 3-5).

Cancer mortality and incidence were investigated in a cohort of 2,807 male workers, 1,068 of whom were classified as potentially exposed to SVF and 397 with unknown exposure, who were employed in 11 plants in the Swedish prefabricated wooden house industry (Gustavsson et al. 1992, Plato et al. 1995a, 1997). Men employed for a minimum of one year from the start of SVF use [year not identified in papers] to 1971 were followed from 1968 to 1985. It was not possible to distinguish glass wool from rock wool exposure since both sources of insulation material were used at different periods. The other principal exposure was wood dust. The numbers of deaths from both combined cancers and specific cancers, including lung cancer (SMR = 0.68, 95% CI = 0.37 to 1.13, 14 deaths), were lower than expected rates. Stomach cancer was statistically significantly increased (SMR = 1.59, 95% CI = 1.00 to 2.41, 22 deaths), and several cancer sites showed elevated but not statistically significant increases in SMRs (pancreas, liver, lymphomas, and all lymphohematopoietic cancers). No relationship between the estimated level of exposure, duration of employment or time since first employment was observed. The incidence study yielded similar results, with a statistically significant excess for stomach cancer (SIR = 1.78, 95% CI = 1.15 to 2.63, 25 cases) (Table 3-6), and elevated but not statistically significant increases in SIRs for pancreas, liver, all lymphohematopoietic cancers, nasal, melanoma, and other skin cancers.

LH = lymphohematopoietic cancer.
3.3.2 Other case-control and cancer registry studies

Several population-based or hospital-based, case-control studies have examined SVF and cancer outcomes. With the exception of the studies by Siemiatycki (1991), Dumas et al. (2000), and Baccarelli et al. (2006), none of these studies attempted to distinguish glass wool exposure from other SVF exposure. Most of the studies were on respiratory cancer, and are described in Table 3-6.

Respiratory cancer

Among 176 cases of lung cancer studied in a population-based, case-control study by Kjuus et al. (1986), no association between SVF and lung cancer was observed after adjustment for smoking (OR = 1.0, 95% CI = 0.4 to 2.5, 13 exposed cases).

Siemiatycki (1991) conducted a population-based, case-control study from 1979 to 1986 in which the associations between 11 cancer sites and occupational exposures were examined among men in Montreal. Cases were compared with both other cancer controls and population controls. The OR for potential exposure to “glass wool” (based on converting job histories to probable exposure by industrial hygienists and chemists) and lung cancer was 1.2, 95% CI = 0.5 to 2.5, 11 exposed cases, compared with population controls), after controlling for age, smoking, demographic variables, and other exposures. [Note that odds ratios based on population controls were very similar to those based on other cancer controls.] A subsequent report of this study was described by Pintos et al. (2008), together with a second case-control study of lung cancer among males and females 35 to 75 years of age exposed to either SVF (not otherwise classified) or asbestos. This study was conducted between 1996 and 2001 among the same population of Montreal as the earlier study. Data on smoking and demographic variables were obtained by interviews with survivors or, in some cases, proxies. Pintos et al. (2008) designated exposures as SVF (not otherwise classified). In their report of the first study, “nonsubstantial” exposure to SVF among men was associated with an odds ratio for lung cancer of 1.03 (95% CI = 0.67 to 1.58, 62 cases), but a decrease in risk for “substantial” exposure was also observed (OR = 0.63, 95% CI = 0.23 to 1.43, 13 cases). In the second study, again reporting for males only, the OR for nonsubstantial exposure was 1.16 (95% CI = 0.74 to 1.81, 67 cases), and for substantial exposure, the OR = 1.48, (95% CI = 0.52
to 4.21, 11 cases). In the pooled analysis, the ORs for nonsubstantial and substantial exposure were 1.10 (95% CI = 0.81 to 1.49, 129 cases) and 0.86 (95% CI = 0.45 to 1.63, 24 cases), respectively. All odds ratios were adjusted for smoking, asbestos, and demographic variables. According to the authors, no interaction between smoking and potential SVF exposure was observed, but the number of never smokers in this population was small.

Martin et al. (2000) also conducted a small nested case-control study of lung cancer among a cohort of French male utility workers and reported a decrease in risk among 33 cases (as determined from a company-specific, job-exposure matrix) who were potentially exposed to SVF compared with 8 controls (OR = 0.73, 95% CI = 0.32 to 1.7, adjusted for socioeconomic status and asbestos exposure).

Bruske-Hohlfeld et al. (2000) and Pohlabeln et al. (2000) analyzed pooled data from two case-control studies of lung cancer incidence among male workers in a variety of occupations in Germany. Exposure to SVF occurred mainly outside the production industry and among construction workers in this cohort, and was estimated on the basis of job descriptions obtained from a questionnaire administered to participants. Potential exposure to SVF had occurred for 304 cases and 170 controls as insulation mat installers and for 55 cases and 52 controls as electrical insulation fitters. For SVF exposure (not otherwise classified) among insulation installers, a statistically significant increase in lung cancer risk was observed; the odds ratio for all workers after adjustment for smoking and asbestos exposure was 1.48 (95% CI = 1.17 to 1.88, 304 cases). Among electrical fitters, the OR was 1.00 (95% CI = 0.63 to 1.58, 55 cases). Among all workers with > 20 years of SVF exposure, a risk of 1.69 (95% CI = 1.01 to 2.81, 61 cases, adjusted for asbestos and smoking) was observed; those with > 30 years of exposure had a risk of 2.03 (95% CI = 1.04 to 3.95, 47 cases, both adjusted for asbestos and smoking). Among insulation installers who reported using glass or mineral wool only and who did not report asbestos exposure, the odds ratio was not statistically significant (1.56, 95% CI = 0.92 to 2.65, 51 cases, adjusted for smoking).
A hospital-based, case-control mortality study of lung cancer among Russian workers exposed to glass wool and/or other SVF was conducted by Baccarelli et al. (2006) using autopsy data. Job-specific exposure data were obtained from monitoring data collected by industrial hygiene centers. The 474 male and 66 female lung cancer deaths were matched with 582 controls on age, gender, region, and year of death. Controls with smoking-related diseases were excluded. After adjusting for age, smoking, and location, the OR for 10 male cases of glass wool exposure was 1.77 (95% CI = 0.57 to 5.51). For 14 male cases exposed to other SVF (excluding glass wool but including slag wool and ceramic fibers) the OR was 3.34 (95% CI = 1.18 to 9.45). After additional adjustment for asbestos exposure (found among four subjects with lung cancer), the OR among male workers exposed only to glass wool was 1.56 (95% CI = 0.49 to 5.02, number of deaths not specified); for other SVF, excluding glass wool, the OR was 3.25 (95% CI = 1.16 to 9.11, number of deaths not specified). There were only two cases of SVF exposure among women, and no excess risk was observed. Analysis of the data by exposure duration and level and cumulative exposure for workers exposed either to glass wool alone or to all SVF did not reveal any significant trends, although the OR for average intensity of exposure among workers exposed to more than 75% of the maximum allowable concentration (MAC) of glass wool (reported by the authors as 2 mg/cm\(^3\)) was higher (OR = 3.61, 95% CI = 0.64 to 20.4) than for workers exposed to less than 75% of the MAC (OR = 0.83, 95% CI = 0.16 to 4.18; both ORs adjusted for smoking, age, and region).

A multi-center case-control incidence study of lung cancer among workers exposed for at least one year to asbestos and/or mixed SVF was conducted by Carel et al. (2007) among newly diagnosed workers in Central and Eastern Europe and the United Kingdom. The 2,205 male cases were frequency matched with 2,305 controls. Exposure and potential confounders were determined by in-person interviews with the subjects. Forty-nine percent (49%) of the 115 SVF-exposed cases were exposed to glass wool alone, and a further 27% to glass wool and mineral fibers. Data were presented only for mixed SVF exposure, however. After adjustment for age, smoking, regional center, asbestos, and other exposures, the OR for SVF exposure was not significant (OR = 1.23, 95% CI =
0.88 to 1.7, 115 cases). No significant trends with exposure duration, level, or cumulative exposure were observed, and no differences were noted by country of residence.

Marchand et al. (2000) conducted a hospital-based, case-control study of cancer incidence of the larynx and hypopharynx in association with SVF and/or asbestos exposure. The analysis included 296 cases of laryngeal cancer and 201 cases of hypopharyngeal cancer that were matched with 295 hospital-based controls who had other types of cancer. For those ever exposed to “mineral wool” (which could include both glass wool and rock/slag wool), nonsignificant excesses of laryngeal cancer (OR = 1.33, 95% CI = 0.91 to 1.95, 130 cases) and hypopharyngeal cancer (OR = 1.55, 95% CI = 0.99 to 2.41, 99 cases) were observed after adjustment for age, smoking, and alcohol consumption. (Statistically significant increases in laryngeal cancer [OR = 1.51, 95% CI = 1.03 to 2.22, number of cases not specified] and hypopharyngeal cancer [OR = 1.65, 95% CI = 1.05 to 2.58, number of cases not specified] were observed among the mineral wool group [adjusted for smoking, age and alcohol consumption] if a 15-year latency period was used in the exposure calculation.) After adjustment for the effect of asbestos, to which most of the subjects were also exposed, the odds ratios for ever exposure to mineral wool were slightly reduced (OR for laryngeal cancer = 1.23, 95% CI = 0.79 to 1.91, 130 cases; OR for epilarynx = 1.61, 95% CI = 0.85 to 3.04, 51 cases; OR for hypopharynx = 1.51, 95% CI = 0.90 to 2.52, 99 cases). No other types of fibers were associated with ORs exceeding 1.00, with the exception of laryngeal cancer in association with microfiber exposure [OR adjusted for smoking, age, and alcohol = 1.28, 95% CI = 0.51 to 3.22, 16 cases].

Other cancers
In a case-control incidence study, Rodelsperger et al. (2001) investigated mesotheliomas among 137 German men recruited from clinics in Hamburg and compared their occupations, 125 of which were determined by interview, with those of 125 age-, sex-, year of birth- and residence-matched controls randomly selected from population registries and also interviewed using a structured questionnaire. [Note that the response rate among controls was only 63%.] Cases of mesothelioma were confirmed by a panel of pathologists. Detailed self-reported job histories were used to categorize workers
according to exposure to SVF (not otherwise classified) and asbestos, and to quantitatively estimate average levels of fiber exposure, according to three levels of exposure, and cumulative exposure. Conditional logistic regression was used to calculate odds ratios separately for job categories and industries. The risk of mesothelioma among ever SVF-exposed cases was $\text{OR} = 6.12$ (95% CI = 2.90 to 12.93, $P < 0.05$, 55 cases), adjusted for age and region of residence, and $3.08$ (95% CI = 1.17 to 8.07, $P < 0.05$), after additional adjustment for asbestos exposure. Two cases of mesothelioma were not exposed to asbestos.

A case-control study of the Montreal population (see Siemiatycki 1991), using controls with cancers other than lung, rectal, or other digestive system cancers, examined the association between rectal cancer and a range of occupational exposures (Dumas et al. 2000). Exposures were assigned for cases and controls by industrial hygienists based on interview data for lifetime occupations. Fourteen cases with “any” estimated exposure to glass wool had an OR (adjusted for age, education, respondent status, alcohol, and smoking) of 0.9 (95% CI = 0.5 to 1.6); eight cases with “substantial” estimated exposure to glass wool had an unadjusted OR of 4.3 (95% CI = 1.7 to 11.3) compared with controls with other cancers (except lung and other intestinal cancers). None of the analyses adjusted for other exposures, however.

Goldberg et al. (2001) also examined the association between 497 cases of colon cancer and a range of occupational exposures in the same male population, using a combined referent group consisting of 1,514 age-matched controls with other cancers plus a second group of 533 population-based controls; ORs of 1.9 (95% CI = 0.4 to 1.6, 15 cases) and 2.0 (95% CI = 0.8 to 5.4, 6 cases), adjusted for age, smoking, and exposure to “selected noncollinear” occupational agents and to nonoccupational risk factors, were observed in association with “nonsubstantial” and “substantial” glass wool exposure, respectively. [Note that it is not clear whether the analysis included adjustment for asbestos and other specific exposures, however.]

Vasama-Neuvonen et al. (1999) and Weiderpass et al. (1999, 2003) conducted cancer registry-based studies of 5,072 cases of ovarian cancer (Vasama-Neuvonen et al. 1999),
23,638 cases of breast cancer (Weiderpass et al. 1999), and 7,935 cases of gastrointestinal cancer (Weiderpass et al. 2003) (diagnosed between 1971 and 1995) in association with occupational exposures among the entire female Finnish working population. A statistically nonsignificant association with SVF (not otherwise classified) (SIR = 1.3, 95% CI = 0.9 to 1.8, number of cases not specified) was observed for ovarian cancer, after controlling for various demographic and childbirth variables, when occupations with 20% or more people with estimated exposure were compared with those with less than 20% exposed. Among the breast cancer cases, a significant trend towards increasing incidence with higher estimated exposure levels to SVF was observed; medium to high exposure was associated with a significant increase in incidence (SIR = 1.32, 95% CI = 1.05 to 1.66, number of cases not specified), and low exposure with an SIR of 1.01 (95% CI = 0.90 to 1.12). However, the excess cancers occurred among building workers who were estimated by the authors to have also had asbestos exposure, which was independently associated with a similar level of risk in this cohort. Relative risks were calculated for women with gastrointestinal cancer designated as having either no, low, or medium/high exposure to occupational agents, including SVF. A statistically significant elevation in risk of stomach cancer was observed among women designated as having low exposure to SVF (RR = 1.23, 95% CI = 1.01 to 1.49, number of cases not specified) (Weiderpass et al. 2003). The same relative risk was observed in women with medium to high potential exposure but was not significant. Compared with nonexposed women, the trend was significant (P = 0.03).

In a small population-based, case-control study in Sweden of 404 cases of non-Hodgkin’s lymphoma (NHL) conducted by Hardell and Eriksson (1999), a significantly increased risk of NHL was associated with potential exposure to glass wool as ascertained by questionnaire in a univariate analysis (OR = 1.5, 95% CI = 1.0 to 2.3, 63 cases and 76 controls). [Note that some cases and controls were deceased, and proxies were used for questionnaires.] No trend with increasing exposure was noted. [No other variables were considered, however.]

<sup>a</sup>OR = odds ratio; RR = risk ratio; SIR = standardized incidence ratio.
3.4 Other reviews

Epidemiological studies of glass wool and other SVF exposure were reviewed by IARC (1988, 2002). IARC (1988) classified glass wool, rock wool, and slag wool as possibly carcinogenic to humans (Group 2B). The 2001 IARC working group (IARC 2002) evaluated the cohort and case-control studies of glass wool manufacturing workers and studies of mixed SVF exposure among construction workers and other users that are included in the present background document (with the exception of the more recent update of the U.S. cohort by Stone et al. (2004), the most recent update of the Canadian cohort by Shannon et al. (2005) and the case-control studies of mixed SVF exposure by Baccarelli et al. (2006), Carel et al. (2007) and Pintos et al. (2008). Based primarily on evidence from the U.S. and European cohort and nested case-control studies, IARC (2002) concluded that the epidemiological evidence for the carcinogenicity of glass wool was “inadequate” and thus did not permit a conclusion regarding the presence or absence of a causal association.

In addition, WHO reviewed the data for glass wool and other SVFs in 2000 (WHO 2000). They pointed to the difficulty of distinguishing the effects of SVFs from smoking and other co-exposures on lung cancer rates, and concluded that the epidemiological data available to that date suggested no excesses of lung cancers among production workers exposed to glass wool or glass microfibers and no increases in incidence of mesothelioma among production workers. (WHO did conclude, however, that at least part of the excess cancers observed among rock/slag wool-exposed workers was attributable to exposure to those fibers.) WHO did not evaluate upper respiratory tract cancers or other cancer sites.

Several other reviews of the carcinogenicity of glass wool in humans have been published, including those by Infante et al. (1994), Lee et al. (1995), Wilson et al. (1999), and Hesterberg and Hart (2001). In addition, de Vuyst et al. (1995) and Steenland and Stayner (1997) have reviewed earlier studies of lung cancer among a number of cohort and case-control studies of glass wool-exposed populations.

3.5 Summary by tumor site

This section summarizes the findings by cancer sites. [Note that, in a number of the cohort studies, the principal cancer sites of interest have been lung cancer and upper
respiratory tract cancers, due mainly to the structural similarity between glass wool, other
mineral fibers, and asbestos; because less emphasis has been placed on other cancer sites,
ot not all sites are reported on in individual studies, and detailed analyses such as exposure-
response relationships were not evaluated.]

3.5.1 Lung cancer
The two largest combined cohort mortality studies in the United States and Europe
(Boffetta et al. 1997, Marsh et al. 2001a), at their latest follow-ups, reported SMRs for
respiratory cancer of 1.18 (95% CI = 1.04 to 1.34; lung + larynx) (Boffetta et al.) and
1.27 (95% CI = 1.07 to 1.50, lung only) (Marsh et al.) (males and females combined).
Separate subcohort mortality studies of the U.S. and European cohorts and the incidence
studies generally reported small elevations of respiratory cancer risk similar to those
observed in the later combined follow-up studies. Shannon et al. (2005) reported an SMR
of 1.63 (95% CI = 1.18 to 2.21) and an SIR of 1.60 (95% CI = 1.19 to 2.11) for lung
cancer in their second follow-up of a Canadian cohort of glass wool manufacturing
workers, but no smoking data were available. Moulin et al. (1986) reported a decreased
incidence of respiratory cancer among glass wool manufacturing workers in France (SIR
= 0.74, 95% CI = 0.24 to 1.72) based on 5 cases and a short follow-up period.
A modest trend of increasing risk of lung cancer among workers with longer time since
first employment (> 30 years) was noted in the U.S. cohort by Marsh et al. (2001a) and
among workers with > 30 years since first hire in the European cohort (Boffetta et al.
1997). With respect to duration of exposure, the U.S. workers with < 5 years of
employment had higher SMRs for respiratory cancer than longer-term workers, although
there was no consistent trend towards an increase in respiratory cancer with increasing
duration of employment (Marsh et al. 2001a). A statistically significant increase in lung
cancers was seen among relatively short-term workers (5 to 9 years of employment)
using workers with < 5 years of employment as the referent group, but not among longer-
term workers, [although the smaller numbers of long-term workers limited the power to
detect an effect if present]. In the European mortality cohort, workers with < 1 year of
employment had slightly higher rates of lung cancer than those with > 1 year of
employment (these workers were excluded from further analysis). There was an increase
in lung cancer risk with duration of employment among workers with 10 to 19 years of employment in the mortality study (Boffetta et al. 1997), but no trend with duration of employment was observed in the incidence study (Boffetta et al. 1999).

In the nested case-control studies of U.S. glass wool manufacturing workers (Chiazze et al. 1992, Chiazze et al. 1993, Marsh et al. 2001a, Stone et al. 2001, Youk et al. 2001) no significant associations between duration of employment, time since first hire, average intensity of exposure and cumulative exposure to glass wool and lung cancer were observed using various measures of estimated exposure to respirable fibers and controlling for smoking and some co-exposures. However, in the unadjusted analysis, significant heterogeneity was observed with average intensity of exposure and respiratory cancer (Marsh et al. 2001a). Similarly, an earlier nested case-control study of U.K. workers (Gardner et al. 1988) found no increase in lung cancer risk in association with glass wool exposure, with the exception of a 2-fold increase in risk among workers with 10 to 19 years since first hire, who might also have had exposure to superfine fibers. Lung cancers were significantly elevated in certain specific job categories, however, including those employed in granulating wool, warehouse workers with unspecified jobs, electrical maintenance workers, and boilermen maintenance workers, although the numbers of cases in these categories were small.

There are comparatively few women workers in SVF manufacturing, and few have been studied. It is noteworthy that, in the detailed follow-up study of women workers in the U.S. cohort (Stone et al. 2004), women workers were estimated to have lower average exposures to glass wool than male workers, and no overall increase in respiratory cancers was observed in comparison with national or local rates. However, a statistically significant three-fold increase in respiratory cancer was observed when an internal comparison of glass wool vs. filament-exposed workers was conducted (although only six deaths were observed).

Siemiatycki 1991) have investigated lung cancer, mainly in association with unclassified or mixed SVF. Statistically nonsignificant excesses of lung cancer were observed by Siemiatycki (1991) in association with glass wool (OR = 1.20, 95% CI = 0.5 to 2.5, 11 cases), and by Baccarelli et al. (2006) in association with glass wool (OR = 1.77, 95% CI = 0.57 to 5.51, 10 cases). In the case of mixed SVF exposure, Kjuus et al. (1986) found no association with lung cancer in an early study (OR = 1.0, 95% CI = 0.4 to 2.5, 13 cases). Carel et al. (2007) observed a small increase in lung cancer in association with mixed SVF exposure (OR = 1.23, 95% CI = 0.88 to 1.71, 115 cases), and Pintos et al. (2008) observed a marginal increase in lung cancer among a population estimated to have “nonsubstantial” exposure to mixed SVF (OR = 1.10, 95% CI = 0.81 to 1.49, 129 cases) but not among a smaller group with “substantial” exposure (OR = 0.86, 95% CI = 0.45 to 1.63, 24 cases). However, (Brüske-Hohlfeld et al. 2000, Pohlabeln et al. 2000) observed a statistically significant increase in lung cancer among all workers ever potentially exposed to SVF vs. never exposed (OR = 1.48, 95% CI = 1.17 to 1.88, 304 cases, adjusted for smoking and asbestos) and which was mainly confined to workers with 20 to 30 years and 30 or more years of employment.

Berrigan (2002) conducted a meta-analysis of SMRs for respiratory cancers in 10 case-control and 10 cohort mortality studies of SVF exposure, including a combined analysis of five cohorts exposed to glass wool (Boffetta et al. 1997, 140 deaths; Enterline and Henderson 1975, 5 deaths; Marsh et al. 2001a, 243 deaths; Morgan et al. 1981, 39 deaths; Shannon et al. 1987, 19 deaths), representing a total of 446 observed deaths from respiratory cancers (vs. 370.1 expected). Aggregate estimates of risk were calculated using standard methods for fixed effects; individual SMRs were weighted by the inverse of the variance estimate. National rates were used to calculate SMRs with the exception of the data from Marsh et al. (2001a). The author noted that the use of local rates tended to yield lower SMR estimates than national rates in seven of the cohort studies included in the meta-analysis. The case-control studies of glass wool-exposed workers included Enterline et al. (1987), Engholm et al. (1987), Gardner et al. (1988), Chiazze et al. (1992, 1993), Bruske-Hohlfeld et al. (2000), and Marsh et al. (2001a). Aggregate estimates of risk for case-control studies were not calculated due to heterogeneity of results and the use of different exposure levels. The combined SMR for all five cohorts was 1.23 (95%
CI = 1.10 to 1.38), compared with SMRs of 1.08 (0.93 to 1.26) for glass filament and 1.32 (1.15 to 1.52) for rock wool. [Note: some laryngeal cancers were included in this analysis].

3.5.2 Mesothelioma

Data for mesotheliomas reported among glass wool-exposed populations are summarized in Table 3-7. Marsh et al. (2001b) observed 10 possible deaths (7 among glass wool or glass wool + filament workers) from mesothelioma based on death certificates, at least three of which were found to be doubtful based on pathology reports. A deficit of mesothelioma was observed among glass wool-exposed workers relative to expected rates, using different coding schemes, according to the authors. Boffetta et al. (1997) observed only one death from mesothelioma among glass wool-exposed workers, but the authors did not calculate expected rates for this cancer. In a smaller cohort study, Engholm et al. (1987) reported a significant excess of pleural mesothelioma among male construction workers (SIR = 2.13, 95% CI = 1.35 to 3.20, 23 cases). A number of these cases were associated with occupations with potential exposure to asbestos (e.g., plumbers), according to the authors, although self-reported asbestos exposure was considered to be unreliable in this cohort. It also is not clear to what extent exposure to SVF might have occurred among these cases. An earlier case-control study by Rodelsperger et al. (2001) reported a three-fold increase in risk of mesothelioma after adjustment for asbestos and other potential confounders, but the authors acknowledged the possibility of residual confounding by asbestos in this analysis.

[Mesothelioma is strongly linked to asbestos, and extremely rare without asbestos exposure. Unlike lung cancer, there is just one major established cause. The largest study in the United States showed that 88% of pleural mesothelioma in adult men was attributable to asbestos (Spirtas et al. 1994). The consequence of this is that the “expected” numbers from the general population are largely due to asbestos exposure and cannot be used as a comparison with observed mesotheliomas among glass wool workers not exposed to asbestos. Therefore the SMR for glass wool workers not known to be exposed to asbestos is underestimated.]
A second concern with evaluating mesothelioma is that while there is a need to assess the medical evidence that deaths labeled on death certificates as being due to mesothelioma actually had mesothelioma, there is also a parallel need to review deaths from other causes as well. Selikoff et al. (1992) reviewed medical records for all deaths in the U.S. insulator cohort, and the overall effect was to increase the numbers of mesothelioma identified in the study. In the Marsh et al. cohort study, medical evidence was obtained only for deaths classified on death certificates as due to mesothelioma, with a reduction in the number of known cases.}
Table 3-7. Mesothelioma among glass wool-exposed populations.

3.5.3 Upper gastrointestinal and upper respiratory cancers (other than lung)

Marsh et al. (2001a) reported that the SMRs for laryngeal cancer among all the workers in the entire glass fiber cohort (including filament-exposed workers) was 1.04 (95% CI = 0.70 to 1.5, 29 deaths). A nonsignificant decrease in SMR observed for “other” respiratory cancer was 0.80 (95% CI = 0.32 to 1.66, 7 deaths). Adjusting for smoking reduced the risk for laryngeal cancer as well as for lung cancer. Boffetta et al. (1999, 1997) reported statistically nonsignificant excesses of cancer of the larynx among glass wool-exposed workers, and nonsignificant excesses of cancers of the upper gastrointestinal tract (esophagus, buccal cavity, oral cavity, and/or pharynx) also have been reported in both of these cohorts. Moulin et al. (1986) also reported a significant excess of “upper respiratory and alimentary tract” cancers (SMR = 2.18, 95% CI = 1.31 to 3.41), but specific cancer sites were not reported. Marchand et al. (2000) reported excesses of laryngeal (OR = 1.33, 95% CI = 0.91 to 1.95, 130 cases) and hypopharyngeal cancer (OR = 1.55, 95% CI = 0.99 to 2.41, 99 cases; all adjusted for age, smoking, and alcohol) associated with exposure to “mineral wools” (consisting of rock/slag wool and glass wool) in a case-control study. Increases in risk also were reported for buccal cavity and pharynx (SMR = 1.11, 95% CI = 0.85 to 1.42, 63 deaths, among combined glass wool and filament-exposed workers) by Marsh et al. (2001a), and among glass wool-exposed workers by Boffetta et al. (1997) (SMR = 1.47, 95% CI = 0.71 to 2.71, 10 deaths), and Boffetta et al. (1999) (SIR = 1.31, 95% CI = 0.65 to 2.34, 11 cases). [Given the low expected rates for these cancers, the power to detect significant increases in mortality or incidence of these cancer sites and to adjust for potential confounders is limited even in large cohort studies.]

3.5.4 Other cancer sites

[Note that not all cohort studies reported data for each cancer site. In this summary, findings for subcohorts or earlier follow-ups of the multi-site U.S. and European, and Canadian cohorts have not been included separately.]

Among glass wool-manufacturing workers, a number of elevated risks (SMRs or SIRs above 1.0) for deaths or cases in other cancer sites have been reported; these sites included: bladder (SIR = 1.39, 95% CI = 0.88 to 2.08, 23 cases, Boffetta et al. 1999;
Among other SVF-exposed workers, statistically significantly increased risks in stomach cancer mortality and incidence (SMR = 1.59, 95% CI = 1.00 to 2.41, 22 deaths; SIR = 1.78, 1.15 to 2.63, 25 cases) were observed among male workers in the Swedish prefabricated wooden house industry (Gustavsson et al. 1992). In addition, statistically nonsignificant increases were observed in this study for cancers of the liver (SMR = 1.67, 95% CI = 0.45 to 4.28, 4 deaths, and SIR = 1.45, 95% CI = 0.62 to 2.86, 8 cases); pancreas (SMR = 1.34, 95% CI = 0.71 to 2.29, 13 deaths, and SIR = 1.43, 95% CI = 0.71 to 2.56, 11 cases); prostate (SMR = 1.01, 95% CI = 0.63 to 1.55, 21 deaths); genitourinary system (SMR = 1.01, 95% CI = 0.48 to 1.86, 10 deaths); lymphoma (SMR = 1.63, 95% CI = 0.70 to 3.22, 8 deaths); and all lymphohematopoietic cancers (SMR = 1.05, 95% CI = 0.58 to 1.72, 15 deaths, and SIR = 1.35, 95% CI = 0.85 to 2.02, 23 cases); nasal cancer (SIR = 2.00, 95% CI = 0.03 to 11.13, 1 case); melanoma (SIR = 1.28, 95% CI = 2.64, 7 cases); and other skin (SIR = 1.23, 95% CI = 0.85 to 2.02, 8 cases).

In addition, in population-based, case-control or registry-based studies of subjects with possible exposure to glass wool or mixed SVF, increases in premenopausal and postmenopausal breast cancer risk were observed (SIR = 1.15, 95% CI = 0.74 to 1.79 and...
SIR = 1.30, 95% CI = 1.02 to 1.64, respectively, for occupations in which at least 20% of women were potentially exposed to SVF) were observed by Weiderpass et al. (1999). A marginal increase in ovarian cancer (SIR = 1.3, 95% CI = 0.9 to 1.8) also was observed in association with occupations in which at least 20% of women were potentially exposed to SVF (Vasama-Neuvonen et al. 1999). Several studies have reported some increases in cancers of the gastrointestinal tract in association with potential SVF exposure. In a study of gastrointestinal cancers and occupation among Finnish women by Weiderpass et al. (2003), increases in cancers of the stomach (RR = 1.23, 95% CI = 1.01 to 1.49, low exposure, and RR = 1.23, 95% CI = 0.85 to 1.77, medium/high exposure), esophagus (RR = 1.29, 95% CI = 0.83 to 2.00, low exposure, and RR = 1.61, 95% CI = 0.80 to 3.25, medium/high exposure); rectum (RR = 1.06, 95% CI = 0.83 to 1.35, low exposure only); gallbladder (RR = 1.03, 95% CI = 0.55 to 1.95, medium/high exposure); and pancreas (RR = 1.34, 95% CI = 0.89 to 2.03, medium/high exposure) were observed. A statistically significant increase in rectal cancer also was observed among 8 male cases with “substantial” estimated exposure to glass wool (OR = 4.3, 95% CI = 1.7 to 11.3) in a hypothesis-generating study by Dumas et al. (2000), and an increase in colon cancer (OR = 2.0, 95% CI = 0.8 to 5.4, 6 cases with “substantial” estimated exposure) was observed by Goldberg et al. (2001). Finally, a marginally significant increase in non-Hodgkin’s lymphoma (OR = 1.5, 95% CI = 1.0 to 2.3, 63 cases) was observed in a case-control study, primarily focused on pesticide exposures, by Hardell and Ericksson (1999).

3.6 [Methodological issues]  
Several methodological considerations are important in interpreting the epidemiology studies.

3.6.1 Statistical power of the studies  
The most informative studies are the U.S. and European cohort and nested case-control studies of glass wool production workers. The principal methodological strengths of these cohort and case-control studies are, first, that adequate numbers of workers have been followed over a sufficient period of time to detect cancers with both shorter and longer

---

3 The title of this section is bracketed to indicate the presence of opinion throughout this section rather than bracketing specific statements.
latencies, and they yield a large number of person-years at risk and thus sufficient power
to detect modest increases in cancer mortality for all but very rare cancers. Second,
ascertainment of vital status was close to complete, with little evidence of systematic bias
in follow-up. There also were sufficient cancer outcomes to permit some exposure-
response relationships to be examined and some confounding variables to be taken into
account in internal comparisons and/or case-control analyses. In addition, the U.S. cohort
was expanded to include women and non-white subjects. Other cohort and case-control
studies are smaller and have relatively low statistical power to detect effects. It should
also be noted that average glass wool exposures are one-tenth or less of the exposure
levels for asbestos in the cohorts studied for asbestos (see, for example, Armstrong et al.

3.6.2 Ascertainment of vital status and diagnoses
Mortality and incidence studies rely on complete and accurate ascertainment of vital
status or cancer incidence and accurate diagnoses. Follow-up for the larger cohort studies
was almost complete and unlikely to be biased in terms of exposure status within the
cohorts. Reliance on reported underlying cause of death from death certificates is known
to result in some misdiagnoses and incomplete information, but is likely to be
nondifferential and thus would bias findings towards the null. Cancer diagnoses obtained
in incidence studies from medical records or cancer registries may be more accurate and
complete than death certificate data, although some misdiagnoses and information errors
occur. The potential impact of misdiagnosis or misclassification of cancer endpoints is
clearly more pronounced for rarer cancers where only a few cases are expected, such as
cancer of the larynx or pharynx, than for more common cancers such as lung cancer, or
where the possibility of misdiagnosis without additional (e.g., histopathological)
confirmation is greater, such as with mesotheliomas.

3.6.3 Appropriateness of comparison populations and control groups
In the standardized mortality studies of Marsh et al. (2001a) and Boffetta et al. (1997),
both national and regional or local comparison expected rates of lung cancer were used to
calculate SMRs. In both studies, slightly higher SMRs were obtained when national
rather than local (county) comparison rates were used or adjusted for. (Depending on the
mobility and other characteristics of the exposed population, local populations are likely to be more representative of the exposed population, assuming that expected cancer rates are calculated from large enough populations to be robust.)

In the U.S. and French cohorts, SMRs for all cancers combined were slightly lower than expected (in Marsh et al. 2001a, for example, all-cause cancer mortality was 0.94 (95% CI = 0.90 to 0.98, county comparison) and in the French cohort of Moulin et al. (1986) the cancer incidence rate for cancers other than respiratory and upper gastrointestinal tract was 0.77 (95% CI = 0.45 to 1.24), suggesting the possibility of a healthy-worker effect. However, in the European combined cohort (Boffetta et al. 1997) the SMR for all cancers among the glass wool workers was slightly elevated (1.11, 95% CI = 1.01 to 1.22), although the SIR was not (0.99, 95% CI = 0.89 to 1.11). In the second follow-up of the Canadian cohort (Shannon et al. 1987) the SMR for all cancers was also elevated among plant workers (SMR = 1.15, 95% CI = 0.93 to 1.40), although all-cause SMR among plant workers was slightly decreased compared with expected rates (SMR = 0.93).

3.6.4 Determination of exposure-response relationships

Due to a lack of actual exposure measurements across time and in each job category in most of the cohort studies, the construction of job-exposure matrices was based primarily on limited monitoring data and/or knowledge of industrial processes and industrial hygiene practices, changes in these practices over several decades in some cohorts, and job descriptions. In addition, the biopersistence of glass wool fibers (see Section 5) might obscure delineation of meaningful relationships between, on one hand, duration of exposure, or changes in levels of exposure over time, and cancer risk. In addition, the exclusion of short-term workers with either < 1 year or < 6 months of employment, as was done in a number of cohort studies, means that the effect of very short-term exposures was not examined.

Adequate follow-up time, especially for cancers of longer latency, such as lung cancer (which might have an average latency of 20 or more years) is also necessary in order to be able to adequately examine exposure-response relationships for such cancers. In the most recent follow-ups of both the U.S. and European cohorts, relatively large numbers of workers had more than 15 to 30 or more years since first exposure. In several other
cohort studies, however, the time since first exposure, at least for parts of the cohorts, might have been insufficient to detect an effect if present.

It is possible that referent occupational groups or populations might also have been exposed to glass wool. The possibility of misclassification of exposure among “exposed” and “unexposed” groups, or cases and controls, can significantly impact the ability to detect modest effects of exposure if present, and would generally tend to bias findings towards the null. In the case of the Stone et al. (2004) cohort study, for example, internal controls that were exposed to glass filament were used in one comparison, and might possibly have been also exposed to glass wool. In the nested case-control studies, potentially exposed reference groups might have been used for some comparisons (e.g., in Marsh et al. 2001a). In plants where workers could have had several jobs or where their jobs did not involve fixed processes or locations within the plant (e.g., maintenance workers, truck drivers, packers, cleaners, etc.) it might be more difficult to characterize exposure than for fixed process jobs. Exposure might also depend on the extent to which airborne exposure to fibers was controlled and contained. According to exposure reconstruction studies carried out by Marsh, Boffetta, and others, the use of resin binders, improved ventilation, and other control measures from, in most cases, the mid 60s to 70s resulted in lower estimated exposures to production workers in later years, and presumably less ambient contamination in the vicinity of the production areas. However, characterization of early exposures was limited by a lack of documented exposure-monitoring data in these and other cohort and case-control studies.

3.6.5 Potentially confounding exposures

For lung cancer, the most significant confounding exposure is smoking. Boffetta et al. (1997), citing a model of lung cancer and smoking proposed by Axelson (1978), estimated that a 20% difference in the proportion of smokers could result in a 30% increase in lung cancer among SVF-exposed workers compared with unexposed referents. Smoking data for workers in the European, French, and Canadian cohorts were not available. In the case of the French cohort, an estimate of smoking prevalence was based on information obtained from 966 workers still employed at the factory; the authors concluded that smoking was similar to that in the general population and reported
no association with the SIR for lung cancer. Attempts to estimate the extent of smoking
and its relationship to observed lung cancer rates in the U.S. case-control studies were
based on interviews with samples of survivors or proxy respondents. The estimated
proportion of smokers in this study (Buchanich et al. 2001, Marsh et al. 2001a,c, Stone et
al. 2001) was somewhat higher than that of the general population, although the
proportion of smokers in the female cohort appears to be slightly lower. Marsh et al.
(2001c) estimated that approximately 7% of the observed increase in respiratory cancers
in the entire cohort could be attributable to smoking, and adjusting for this reduced the
SMRs for respiratory cancers to nonsignificance. In the case-control study of this cohort
(Marsh et al. 2001a, Stone et al. 2001), ever smoking accounted for a 13-fold increase in
risk of lung cancer compared with never smoking; adjustment for ever smoking slightly
lowered the risk for lung cancer attributable to glass wool from RR = 1.12 (95% CI =
0.77 to 1.62) to 1.06 (95% CI = 0.71 to 1.60). Residual confounding could obscure a
relationship between glass wool and lung cancer, however. Note, however, that in an
earlier case-control study of part of the U.S. cohort (Chiazze et al. 1992, 1993), adjusting
for smoking and other variables did not appear to decrease the risk of lung cancer
associated with moderate levels of respirable fiber exposure, although the risk for higher
levels was slightly attenuated.

In a number of cohort and case-control studies, including the U.S. cohort, some workers
were exposed not only to glass wool but also to glass (continuous) filament, rock wool or
other SVF. In the case of continuous filament, the external (SMR) analysis of the U.S.
cohort (Marsh et al. 2001a) indicated that filament-only workers had a lower risk than
glass wool-only workers, but a slightly higher risk than that observed among mixed glass
wool + filament workers. In the nested case-control study of this cohort, a lower risk was
observed among workers exposed to filament than to either glass wool alone or glass
wool + filament (see Table 3-2). IARC considered the workers in the wool and filament
plants in the U.S. cohort to be largely exposed to glass wool (IARC 2002). Exposure to
glass filament in other studies also appears to yield a nonsignificant risk of respiratory
cancers; the meta-analysis by Berrigan et al. (2002) estimated that the overall respiratory
cancer risk from filament exposure is low (RR = 1.08, 95% CI = 0.93 to 1.26), whereas
for rock wool, the estimated risk is higher than for glass wool (RR = 1.32, 95% CI = 1.15
to 1.52), although smoking or other confounding exposures might account for some or all of the increase in risk. Exposure to superfine fibers might also be associated with an increase in the risk of respiratory cancer, as suggested, for example, by data from Gardner et al. (1988). For mixed glass wool and other SVF exposures, especially if they included rock or slag wool, or superfine fibers, it is not possible to distinguish the contribution of one or other type of fiber to the risk of lung cancer.

Other potentially confounding exposures in the glass wool manufacturing industries include asbestos, asphalt, resins, formaldehyde (used in glass wool binders), polyaromatic hydrocarbons, phenolics, silica, styrene, and urea, according to Marsh et al. (2001a). Of these, formaldehyde was the most prevalent exposure in the U.S. study and was independently associated with a significant increase in risk of lung cancer (RR = 1.61, 95% CI = 1.02 to 2.57, adjusted for smoking), although formaldehyde has not clearly been associated with lung cancer in other studies. Asbestos is a potential concern both in manufacturing and in construction and other industries that use glass wool, particularly where asbestos might have been used in the past. As noted above, mesothelioma has rarely been observed in the absence of asbestos exposure. Construction workers and fiber installation workers could also be exposed to asbestos during, for example, remediation work on older buildings. In the U.S. cohort, however, no evidence of a confounding effect of asbestos was observed in the nested case-control study (Marsh et al. 2001a). Of the 10 possible cases of mesothelioma observed in the whole cohort, most appeared to be associated with asbestos, according to the authors (Marsh et al. 2001b). In the Boffetta et al. study (1997), 4 deaths from mesothelioma occurred in the last follow-up of the entire cohort, but only one among glass wool workers, and at least three were related to asbestos exposure, according to the authors. Silica exposure is also a possible concern for respiratory cancers, but in the U.S. cohort, no relationship was observed, nor were any other potentially confounding exposures significantly associated with respiratory cancers.

3.7 Summary

A number of epidemiological studies have evaluated the relationship between glass wool exposure and cancer in humans. The studies fall into three main groups: (1) cohort and case-control studies of workers in SVF manufacture, (2) cohort and case-control studies
of workers exposed in glass wool applications (e.g., insulators and construction workers),
and (3) population-based, case-control studies.

Studies within the SVF manufacturing industry have attempted to distinguish between
exposure to different types of SVF, and the large cohort and nested case-control studies
of workers exposed in plants predominantly engaged in glass wool manufacture are the
most informative. [The principal limitations of the glass wool cohort and case-control
studies of manufacturing workers include potential misclassification of exposure,
particularly for past exposures for which few monitoring data are available, inadequate
length of follow-up in some studies for cancers of longer latency, potential confounding
by smoking or co-exposure to other chemicals, and possible misdiagnosis or inadequate
ascertainment of some cancer outcomes, such as mesothelioma. Studies of workers in
SVF applications (two cohort studies and three case-control studies of respiratory cancer)
and the population-based, case-control studies or cancer registry studies (cancers of the
respiratory and/or gastrointestinal tract, non-Hodgkin’s lymphoma, breast, colon, ovary
and rectum) have generally been unable to distinguish between types of fibers and are
consequently less informative, although intermittent exposures might be higher than
observed among manufacturing workers (IARC 2002). In addition, these studies
generally had small numbers of potentially glass wool-exposed subjects and shorter
follow-up times than studies of manufacturing workers, and thus, limited statistical power
to detect long-term effects.]

Cancer mortality or incidence has been studied in four cohorts of manufacturing workers:
(1) a combined cohort of male and female U.S. SVF manufacturing workers including
five plants making mostly glass wool and three making glass wool and filament (Marsh et
al. 2001a, Stone et al. 2004), (2) a combined cohort of male and female manufacturing
workers in five European glass wool plants (Boffetta et al. 1997, 1999), (3) a cohort of
male manufacturing workers in Canada (Shannon et al. 2005), and (4) a cohort of male
manufacturing workers in France (Moulin et al. 1986). [The cohorts of manufacturing
workers in the United States and Europe are the largest studies and have adequate follow-
up to detect cancers with longer latencies (220,700 person-years of exposure in the U.S.
cohort and approximately 201,000 person-years of exposure in the European cohort).]
both cohorts, several earlier studies of subcohorts have been conducted, together with two
nested case-control studies of respiratory cancer in the U.S. cohort (Marsh et al. 2001a,
Chiazze et al. 1992, 1993) and one of lung cancer from part of the European cohort
(Gardner et al. 1988).

Reconstruction of glass wool exposures indicated that measurable exposure to respirable
glass wool fibers occurred among production workers, and that exposure was higher in
the earlier periods of operations. However, as IARC (2002) noted, the concentrations of
fibers to which production workers were exposed were generally low.

The potential effect of glass wool exposure on lung and upper respiratory tract cancers
has been studied most extensively, due to the structural similarity between glass wool,
other SVFs, and asbestos. Findings for respiratory cancers and other tumor sites of
interest are discussed below.

Respiratory cancers

Statistically significant increases in respiratory cancer mortality were observed among
glass wool-exposed workers in unadjusted analyses in the United States (SMR = 1.18,
95% CI = 1.04 to 1.34, \( P < 0.05 \), lung + larynx, compared with local rates) (Marsh et al.
2001a), European (SMR = 1.27, 95% CI = 1.07 to 1.50, \( P \)-value not given, lung only,
compared with national rates) (Boffetta et al. 1997), and Canadian cohorts (SMR = 1.63,
95% CI = 1.18 to 2.21, \( P < 0.05 \), lung only, compared with regional rates) (Shannon et al.
2005). Among female workers in the U.S. cohort, no increase in respiratory cancer
(trachea, bronchus, and lung) was observed in the whole cohort compared with national
or local mortality rates, but in an internal analysis of glass wool-only vs. filament-only–
exposed workers, a three-fold increase in these cancers was observed (RR = 3.24, 95% CI
= 1.27 to 8.28, Wald \( P \)-value = 0.014) (Stone et al. 2004). Excesses of lung cancer
incidence were observed among the European workers (SIR = 1.28, 95% CI = 0.91 to
1.74, compared with national rates, \( P \)-value not given) (Boffetta et al. 1999) and
Canadian workers (SIR =1.60, 95% CI = 1.19 to 2.11, \( P < 0.05 \), compared with regional
rates) (Shannon et al. 2005), but not among French workers (SIR = 0.74, 95% CI = 0.24
to 1.72, compared with regional rates) (Moulin et al. 1986).
Attempts were made to control for the effects of smoking and other potentially confounding exposures, including asbestos, formaldehyde, and silica, in the nested case-control study of the U.S. cohort. Adjusting for ever/never smoking (using data obtained from a sample of proxies) reduced the risk of lung cancer mortality among U.S. glass wool workers exposed to respirable fibers (mostly from glass wool) from RR = 1.79 (95% CI = 0.77 to 4.14, $P = 0.17$) to RR = 1.37 (95% CI = 0.55 to 3.42, $P = 0.50$). (Formaldehyde exposure was also independently associated with lung cancer in this cohort, but models for glass wool and lung cancer adjusting for both formaldehyde and smoking were not presented.) [The European, Canadian, and French studies had few data on potentially confounding exposures.]

Several studies evaluated exposure-response relationships for respiratory cancers. In the U.S. cohort and case-control studies, no clear exposure-response relationships with duration of exposure or cumulative exposure were observed. An association between average intensity of exposure was observed in an unadjusted model but not in models adjusted for smoking or other confounders or in weighted-exposure models (Marsh et al. 2001a, Stone et al. 2001, Youk et al. 2001). There was a modest trend towards increased risk with longer time since first hire in the U.S. but not the European cohort. Similarly, in the nested case-control studies of lung cancer among the U.K. subgroup of the European cohorts, no clear exposure-response relationships with lung cancer were observed, with the exception of a statistically significant increase among glass wool and/or superfine fiber-exposed workers after 10 to 19 years since first hire in the case-control study of the U.K. subcohort by Gardner et al. (1988) (RR = 2.0, confidence intervals not given, 17 cases). In the Canadian cohort, there was some evidence of a trend towards increased risk with longer duration of employment, time since first hire, and year of hire (Shannon et al. 2005).

Statistically significant increases in lung cancer risk were found among insulation installers in Germany (OR = 1.48, 95% CI = 1.17 to 1.88, 304 cases) and among combined insulation installers and electrical insulation fitters with either 20 or more years (OR = 1.69, 95% CI = 1.01 to 2.81, 61 cases) or 30 or more years (OR = 2.03, 95% CI = 1.04 to 3.95, 47 cases) of potential exposure (Bruske-Hohlfeld et al. 2000). However, no
increases in lung cancer risk were found in other studies of construction and application workers or in the population-based, case-control studies of lung cancer. [In general, glass wool exposure cannot be distinguished from other SVF exposure in these studies, and few attempts to adjust for smoking and other confounders were conducted.]

Mesothelioma

Only one death from mesothelioma was observed among glass wool-exposed workers in the European cohort (Boffetta et al. 1997). Marsh et al. (2001b) observed seven possible deaths from malignant mesothelioma among the glass wool- or glass wool + filament-exposed workers, but a review of pathology reports or medical records, which were available for only three of these cases, showed that at least two of them were possible misdiagnoses. An earlier case-control study by Rödelsperger et al. (2001) reported a three-fold increase in risk of mesothelioma among mixed SVF-exposed individuals after adjustment for asbestos and other potential confounders (OR = 3.08, 95% CI = 1.17 to 8.07, \( P < 0.05 \), 55 cases), and a two-fold increase in pleural mesothelioma incidence (SIR = 2.13, 95% CI = 1.35 to 3.20, 23 cases) was observed among a cohort of construction workers by Engholm et al. (1987), but confounding by asbestos might have occurred in these studies.

Upper respiratory and upper gastrointestinal cancers

Marsh et al. (2001a) did not report these cancers separately for the glass wool-exposed workers, but no increases in these cancers were observed in the combined (glass wool- and filament-exposed) cohort (SMR for larynx = 1.01, 95% CI = 0.68 to 1.45, 29 deaths; SMR for buccal cavity and pharynx = 1.11, 95% CI = 0.85 to 1.42, 63 deaths). In the European cohort, a small increase in buccal cavity + pharyngeal mortality and incidence (SMR = 1.47, 95% CI = 0.71 to 2.71, 10 deaths; SIR = 1.31, 95% CI = 0.65 to 2.34, 11 cases), and in laryngeal mortality and incidence (SMR = 1.08, 95% CI = 0.29 to 2.75, 4 deaths, and SIR = 1.68, 95% CI = 0.55 to 3.93, 5 cases), was observed among glass wool-exposed workers (Boffetta et al. 1997, 1999). Moulin et al. (1986) reported a statistically significant excess of “upper respiratory and alimentary tract” cancers in the French cohort (SIR = 2.18, 95% CI = 1.31 to 3.41, 19 cases, including one unexposed production worker and one maintenance worker). In a hospital-based, case-control study, Marchand
et al. (2000) reported small increases in both laryngeal cancers (OR = 1.33, 95% CI = 0.91 to 1.95, 133 cases) and hypopharyngeal cancers (OR = 1.55, 95% CI = 0.99 to 2.41, 99 cases; each analysis adjusted for smoking, age, and alcohol intake) among men ever exposed to “mineral wools.” When a 15-year latency period was used, the risks of laryngeal and hypopharyngeal cancer increased (OR = 1.5, 95% CI = 1.03 to 2.22, and 1.65, 95% CI = 1.05 to 2.58, respectively, cases not specified). No significant interaction with asbestos exposure was observed, but few subjects were exposed to mineral wools and not to asbestos.

Other cancer sites
No statistically significant excesses of other tumors have been reported in the largest cohort mortality or incidence studies of production workers or construction workers. [Note that some studies did not report data for all cancer sites.] A number of elevated risks (SMRs or SIRs above 1.0) have been reported for a number of sites in single studies, but only for the following cancer sites in more than one cohort study (excluding earlier studies of subcohorts or earlier follow-ups): deaths or cases of lymphohematopoietic cancers (Boffetta et al. 1997, 1999; Gustavsson et al. 1992); cancers of the urinary bladder (Boffetta et al. 1997, 1999; Marsh et al. 2001a, Stone et al. 2004); melanoma (Boffetta et al. 1999, Gustavsson et al. 1992); and stomach cancers (Boffetta et al. 1997; Shannon et al. 2005; Gustavsson et al. 1992).

In population-based, case-control or registry studies of subjects with possible exposure to glass wool, statistically nonsignificant increases in pre- and postmenopausal breast cancer and ovarian cancer (Vasama-Neuvonen et al. 1999, Weiderpass et al. 1999) and in stomach, esophageal, rectal, gallbladder, and pancreatic cancers (Weiderpass et al. 2003) were observed among Finnish women. A marginally significant increase in rectal cancer (Dumas et al. 2000) and colon cancer (Goldberg et al. 2001) was observed among men in Montreal with “substantial” estimated exposure to glass wool. [Note that statistically nonsignificant increases in rectal cancer were also seen in the cohort study of Shannon et al. (2005), and in pancreatic cancer in the cohort study of Gustavsson et al. (1992).] Finally, a marginally significant increase in non-Hodgkin’s lymphoma was observed by Hardell and Ericksson (1999).
4 Studies of Cancer in Experimental Animals

The carcinogenicity of glass wool fibers has been investigated in experimental animals (primarily rats and hamsters) by several routes of administration. Furthermore, published reviews covering several decades of research are available (Bunn et al. 1993, Davis 1986, Ellouk and Jaurand 1994, Enterline 1991, Gross 1986, Hesterberg and Chase 1996, Hesterberg and Hart 2001, IARC 1988, 2002, Miller et al. 1999a, Pott et al. 1989, Roller and Pott 1998, Rossiter and Chase 1995, WHO 1988, 2000). The data and findings from these reviews and other publicly available, peer-reviewed carcinogenicity studies in experimental animals are summarized in this section. Inhalation studies are discussed in Section 4.1, intraperitoneal (i.p.) injection studies are discussed in Section 4.2, and studies that used other routes of administration (i.e., intrathoracic, intratracheal, or intrapleural injection or implantation) are discussed in Section 4.3. Section 4.4 describes studies that evaluated fiber characteristics and tumorigenicity, Section 4.5 provides a brief summary of the IARC evaluations (IARC 1988, 2002), and Section 4.6 summarizes the information in this section.

This document discusses carcinogenicity data for a wide variety of glass fibers. Some of the studies used fibers derived from commercial products made in the United States or Europe, while some used experimental fibers. Even when commercial products were used, fibers were often size-separated, ball-milled, coated, uncoated, or chemically treated to increase the number of respirable fibers or to examine effects of other fiber properties. In a number of cases, test fibers were identified with generic terms such as fiberglass, glass fibers, borosilicate glass fibers, or glass microfibers. A few studies investigated many different types of synthetic vitreous fibers (SVFs) covering a broad range of fiber dimensions and other properties. The general categories and descriptions of glass fibers discussed in this section are provided in Table 4-1. More information on the properties and uses of these glass fibers was provided in Sections 1 and 2.

*a This table is not intended to be exhaustive but provides a list of the types of fibers used in the experimental animals studies reviewed in this section.

#### 4.1 Inhalation studies

Doses in inhalation studies are expressed as the concentration (usually in mg/m³) and/or fiber number (fibers/cm³). It is generally accepted that fiber number rather than mass is the better measure of dose because equal masses of fibers with different dimensions will have large differences in the number of fibers. Fiber numbers are frequently expressed as the number of WHO fibers (the number of fibers ≥ 5 μm in length, < 3 μm in diameter, and having an aspect ratio of at least 3:1) or the number of fibers > 20 μm in length. The number of WHO fibers is believed to represent the number of respirable fibers while the number of fibers longer than 20 μm represents fibers that are the most biopersistent.
(Hesterberg and Hart 2001). Nevertheless, as long fibers can be broken into short fibers, biopersistence of short fibers may be greater than that of longer fibers.

Inhalation studies of fibers present specific challenges. Ideally the system should be capable of generating a consistent cloud of respirable fibers without breaking, grinding, or contaminating the fibers. Exposures may be whole body or nose only. The advantage of nose-only systems is that they allow greater control of exposure levels and provide more uniform dosing. Exposures in most of the earlier studies were whole body while most of the later studies used nose-only systems.

4.1.1 Early studies in rodents
Schepers and Delahant (1955) conducted the first chronic inhalation study of insulation glass wool. Fifty (50) white rats and 100 guinea-pigs were exposed in inhalation chambers to medium-caliber (~6 μm diameter) glass wool (0.14 mg/ft³ [4.9 mg/m³]) for up to 20 months. At 20 months, the glass wool was replaced with glass cotton (maximum diameter 3 μm) at 0.03 to 0.07 mg/ft³ [1.1 to 2.5 mg/m³] for another 20 months (guinea-pigs) or 4 months (rats). [No controls were mentioned.] The animals were sacrificed in groups of three to five at various intervals throughout the study. Seventeen (17) guinea-pigs and 20 rats died before the end of the study. Early deaths in guinea-pigs were due to pneumonia and, in rats, were due to lung inflammation. Bronchitis was observed after 12 months, and bronchial epithelial hyperplasia was reported at 18 months. No tumors were reported, and the authors concluded that, unlike asbestos, glass wool was not fibrogenic (i.e., did not cause fibrosis). In a subsequent study, Schepers (1974) exposed 100 guinea-pigs for 44 months and 50 rats for 28 months to aerosols of glass wool (0.15 mg/m³) and cotton dust (0.03 mg/m³). Fiber diameters in the aerosol were mostly in the range of about 2 to ≥ 10 μm with 20% ≤ 2 μm. Fiber lengths were mostly in the range of about 5 μm to more than 50 μm with 30% ≤ 5 μm. Non-neoplastic lesions of the bronchial epithelium, peribronchiolar structures, and pulmonary parenchyma were observed in 57 guinea-pigs. No pulmonary lesions were reported in 300 controls. Pulmonary lesions (macrophage accumulation in subpleural alveolar spaces) occurred in 16 rats compared with 2 out of 310 controls. No neoplastic lesions occurred in either species.
Gross et al. (1970) studied the pulmonary reactions in rats [strain not provided] and hamsters exposed to high concentrations of specially prepared fibrous glass dust obtained from the three largest producers of fibrous glass. One batch was coated with a phenol-formaldehyde resin, another batch was coated with a starch binder, and a third batch was left uncoated. Groups of 30 rats or hamsters were exposed in inhalation chambers for 6 hours per day, 5 days per week for 24 months to concentrations of 106 to 135 mg/m$^3$ [fiber numbers not provided]. Control groups included 20 rats and 20 hamsters. [No hamsters or rats were exposed to asbestos (positive controls).] Samples collected during the experiment indicated that 70% to 76% of the dust was fibrous. The average diameter was 0.5 μm and the average length was about 10 μm (range 5 to 20 μm). Interim sacrifices of 5 animals each were conducted at 6 months and 12 months. The remaining animals were held until their deaths. There were no differences in tissue reactions for the three types of fibrous dusts. Pulmonary response to the three types of fibrous dusts was similar in both species and was characterized by relatively small accumulations of macrophages without significant stromal change. At 6- and 12-months exposure in rats, phagocytic cells filled with glass dust were noted in moderately enlarged satellite lymph nodes and by 24 months, there was some evidence of collagen formation in the stroma. In contrast, hamster lymph nodes containing glass-dust–filled phagocytic cells were not enlarged, and there was no apparent change in the stroma at 24 months. Pneumonia and the endemic presence of chronic bronchitis and its sequelae were observed in rats. Some hamsters died from pneumonia [number not provided]. [No tumors were reported.]

Mitchell et al. (1986) and Moorman et al. (1988) (reporting on the same data) conducted a chronic inhalation study using commercial grade Owens-Corning insulation fiberglass with binder or Tempstran Code 100/475 special-purpose glass fibers without binder. Groups of 50 male and 50 female F344 rats were exposed (whole body) for 7 hours/day, 5 days/week for 86 weeks and held until 80% mortality. The target concentrations were 15 mg/m$^3$ for the Owens-Corning insulation and 5 mg/m$^3$ for the 475 glass. There were two exposure groups for each type of glass fiber. One group was exposed to Owens-Corning fibers 4 to 6 μm in diameter and > 20 μm in length, and another group was exposed to shorter and thinner fibers (> 10 μm in length and 0.5 to 3.5 μm in diameter). For the 475 glass, the average fiber diameter was < 3.5 μm, but average fiber lengths
were > 10 μm in one group and < 10 μm in the other. A control group included 50 male and 50 female rats exposed to filtered and conditioned air.

Pulmonary macrophage aggregates and granulomas that contained glass fibers were observed in treatment groups. A moderate to severe inflammatory response in the region of fibrous glass-laden macrophage aggregates was present in lung and pleural tissue. Glass-laden macrophages were also evident in thymic and tracheobronchial lymph nodes. Pleural and subpleural plaques resulted from accumulations of granulomatous foci but there was no evidence of treatment-related neoplastic lesions in the respiratory tract.

Mononuclear-cell leukemia incidence in the treatment groups ranged from about 35% to 42% compared with 21% in the controls and was statistically significant (Table 4-2). The authors speculated that the presence of the glass fibers in the lung and lymphoid tissue might have stimulated cells with a high spontaneous incidence of neoplasia or might have a direct genotoxic effect on stem leukocytes in the pulmonary and/or lymphoid tissue resulting in an increased incidence or probability of cancer (Moorman et al. 1988).

Several inhalation studies of glass fibers in rodents were conducted in the 1980s and reviewed by IARC (1988, 2002). None of these studies showed significantly increased incidences of neoplastic lesions in the respiratory tract. However, all of these studies were considered inconclusive by IARC (2002) because of several technical limitations. In many cases the test fibers were too short, too thick, or were inadequately characterized. Other study limitations included small numbers of animals, inadequate survival data, lung burdens of fibers that were too small or were not reported, whole body instead of nose-only exposure, or the absence of a strong tumorigenic response in positive control groups exposed to asbestos fibers. These studies are not reviewed in detail but are summarized in
Table 4-3. Subsequently, a series of inhalation studies in rodents specifically designed to address the limitations of these earlier studies was conducted, and those studies are reviewed in Section 4.1.2. Inhalation studies in primates are reviewed in Section 4.1.3.

F = females; M = males; NR = not reported.

<sup>a</sup> The IARC Working Group (IARC 2002) considered these studies inconclusive because of several technical limitations, including inadequate characterization of test fibers, test fibers that were too short or too thick, small numbers of animals tested, inadequate survival data, short exposure periods, lung burdens of fibers that were too small or were not reported, whole body instead of nose-only exposure, or the absence of a strong tumorigenic response in positive control groups exposed to asbestos fibers.

<sup>b</sup> Whole-body exposures in inhalation chambers unless otherwise noted.

<sup>c</sup> With phenol-formaldehyde binder.
4.1.2 Later studies in rodents

Beginning in 1988, a series of subchronic and chronic inhalation studies was initiated at the Research and Consulting Company in Geneva, Switzerland to address the limitations of the earlier studies (Bunn et al. 1993, Hesterberg et al. 1999, Hesterberg et al. 1997, Hesterberg et al. 1993, Hesterberg et al. 1995, McConnell 1994, McConnell et al. 1999). The subchronic studies supported a maximum tolerated dose (MTD) of 30 mg/m$^3$ (250 to 300 WHO fibers/cm$^3$) for chronic studies in rats and hamsters (Hesterberg et al. 1999, Hesterberg et al. 1996a). These studies used nose-only exposure, examined several different types of synthetic fibers in male F344 rats and Syrian golden hamsters, used preparations that contained a large proportion of long fibers (mean length of about 20 μm) and respirable fibers (mean diameters of 1 μm or less), used an exposure protocol (6 hours/day, 5 days/week for 18 months to 2 years) designed to mimic occupational exposure, included at least three exposure concentrations, and included sham-exposed negative controls and asbestos-exposed positive controls (Hesterberg and Hart 2001). Rats were 8 weeks old at the beginning of these studies and hamsters were 9 to 15 weeks old. Fibers used in these studies were size separated from commercial glass wools to achieve the desired properties. Approximately 2,000 pounds of bulk insulation product were needed to obtain 20 pounds of size-separated fibers used in the inhalation studies (Hesterberg et al. 1993). Hesterberg and Hart (1994) also compared human occupational exposures to glass fibers with exposures used in one of the chronic rat studies and reported that the aerosol used in the rat study was 30-fold more concentrated than the highest human occupational exposures (blowing insulation of unbound fiber glass).

Two other inhalation studies with glass microfibers (100/475 and 104E) and amosite asbestos were conducted at the Institute of Occupational Medicine, Edinburgh, Scotland (Cullen et al. 2000, Davis et al. 1996). The primary focus of these studies was to compare methods for determining and predicting fiber pathogenicity. The pathogenicity and durability of the different fibers were examined by conducting long-term inhalation and injection studies, in vitro tests, and several short-term tests.
Rat

Groups of 112 to 120 male F344 rats were exposed to the respirable fraction of Manville 901 glass wool (MMVF10) or CertainTeed B glass wool (MMVF11) at 3, 16, or 30 mg/m$^3$ (~30, 150, 240 WHO fibers/cm$^3$) for 2 years (Bunn et al. 1993, Hesterberg et al. 1993, Hesterberg et al. 1995, McConnell et al. 1994). In addition, a recovery group was exposed for 1 year and then held for 1 year without further exposure. The fibers were processed from commercial insulation wools to meet the length and diameter criteria mentioned above. Six animals per group were sacrificed at 3- to 6-month intervals to assess gross and microscopic changes in the lung. Chrysotile and crocidolite asbestos were used as positive controls in studies conducted by the same researchers with partially overlapping study times beginning in 1988 and ending in 1993 (Rossiter and Chase 1995). The authors stated that fiber-to-fiber comparisons between chrysotile or crocidolite and SVFs are not appropriate because of major differences in fiber dimensions and aerosol concentrations (Hesterberg and Hart 2001). The lungs of groups exposed to MMVF10 or MMVF11 showed minimal progression of reversible cellular changes, and the recovery group showed that alveolar bronchiolization (change from the normal flat to cuboidal epithelium) and granular formation were partially or totally reversed. Bronchoalveolar adenomas occurred in the non-exposed control group and in all but one treatment group. Exposure to insulation glass wools did not cause a significant increase in lung tumors or mesotheliomas in this study. [However, NTP calculated an apparent positive trend for both adenomas and combined tumors in male F344 rats exposed to MMVF10 ($P = 0.041$ and $P = 0.047$, respectively, for one-tailed Cochrane-Armitage trend test.)] Incidences of total lung tumors and lung carcinomas were significantly increased in rats exposed to 10 mg/m$^3$ chrysotile or crocidolite asbestos (Table 4-4). The authors reported that many rats in the control and exposed groups showed evidence of mononuclear-cell leukemia involvement of the lung after 24 months, [but incidence data were not provided, and no analyses were reported] (Hesterberg et al. 1993). The authors noted that this is a common spontaneous cancer in F344 rats and also occurred in rats that died or were killed in a moribund condition during the study. [Refractory ceramic fibers also were tested in these studies at similar fiber concentrations and dimensions as
MMVF10 and MMVF11 (data not shown), and induced significantly increased incidences of lung tumors and mesotheliomas.]

Infante et al. (1994) conducted a reanalysis of the Hesterberg et al. (1993) data in an attempt to increase the statistical power. Data for the unexposed control group in the glass wool study were pooled with data for unexposed controls from a study of refractory ceramic fibers that overlapped with the study reported by Hesterberg et al. for 24 months of a 28-month study (Rossiter and Chase 1995). Data also were combined across all three dose groups within each glass-wool type or within dose groups for the two insulation glass wools (MMVF10 combined with MMVF11). Results of pairwise comparisons (Fisher’s exact test performed by Infante et al.) indicated that rats exposed to MMVF11, but not MMVF10, had significantly increased incidences ($P = 0.027$) of lung tumors (16/350, 4.6%) compared with the pooled controls (7/382, 1.8%). In addition, significant dose-related trends (Cochran-Armitage) were reported for rats exposed to MMVF10 ($P = 0.01$) or MMVF10 and MMVF11 combined ($P = 0.016$). However, Chase and colleagues (Hesterberg and Chase 1996, Rossiter and Chase 1995) have questioned the validity of these statistical reanalyses, arguing that it is inappropriate to ignore inter-study variability and to pool tumor incidences from concurrent and non-concurrent controls and that the lung tumor incidence observed in the concurrent controls was consistent with NTP historical control data.

Davis et al. (1996) exposed groups of male Wistar rats to JM100/475 fibers (mean diameter of 0.32 μm) or amosite asbestos. Exposures occurred in inhalation chambers for 7 hours per day, 5 days per week for one year, and the animals were followed for their full life-span. The target concentrations were 1,000 fibers/m$^3$ > 5 μm in length. Four animals from each group were sacrificed after 12 months and examined for lung pathology and fiber burdens. Fewer long fibers (> 20 μm) remained in the glass fiber-exposed group compared with the amosite group after 12-months exposure. Amosite produced rapid pulmonary inflammation and marked fibrosis and was carcinogenic (7 carcinomas, 9 adenomas, and 2 mesotheliomas). Glass fibers produced less inflammation and very little fibrosis. Animals exposed to JM100/475 developed lung tumors (11%, adenomas), but the increase was not statistically significant (Table 4-4). The adenomas
were small (< 1 mm in diameter) and were found only by microscopic examination following layered sectioning of the lung. In a subsequent study from the same group (Cullen et al. 2000), exposure to E-glass microfiber (104E) resulted in 23% total lung tumors (7 lung carcinomas and 3 adenomas) and 2 mesotheliomas (Table 4-4). One lung adenoma and one lung carcinoma occurred in the controls (5.3%). The number of fibers (length 15 to 20 µm and > 20 µm) present in the lung after 12 months of exposure was lower in the 100/475 group than in the 104E group (11 × 10^11 fibers/lung and 8 × 10^12 fibers/lung, respectively). The authors noted that the latency period for mesothelioma was shorter with 104E fibers than with amosite asbestos fibers tested in this study.

**Hamster**

The inhalation carcinogenicity of MMVF10a, MMVF33, and amosite asbestos was investigated in male Syrian golden hamsters (Hesterberg et al. 1997, McConnell et al. 1999). (Hesterberg et al. presented the preliminary data through 12 months, and McConnell et al. presented the final data.) Groups of 125 male hamsters were exposed to the respirable fraction of Manville 901 insulation glass wool (MMVF10a) at 30 mg/m^3 (~300 WHO fibers/cm^3 and ~100 fibers longer than 20 µm per cm^3), 6 hours per day, 5 days per week for 78 weeks. MMVF10a was a mixture of two types of 901 fiberglass; one of the 901 glasses contained fluorine and was the same as the one used in previous studies while the other did not contain fluorine. The average aerosol fiber diameter (arithmetic mean ± SD) was 0.95 ± 0.45 µm, and the average length was 19.4 ± 20.8 µm. Five animals per group were sacrificed at 13, 26, 52, and 78 weeks to assess gross and microscopic changes in the lung and lung fiber burdens. Recovery groups were removed from exposure after 13 weeks and 52 weeks and held until 78 weeks. Animals remaining after 78 weeks were maintained for a recovery period of about 6 weeks, or until 20% survival. The average diameters of MMVF10a and MMVF33 (0.9 µm) were 1.5 times greater than that of amosite (0.6 µm). Moreover, asbestos fibers form bundles of fibrils that may split longitudinally in the lung, while glass fibers do not [increased fiber burden after recovery might be accounted for by this process.] The initial lung deposition of long fibers (> 20 µm) was similar for glass wool and asbestos, but at the end of the study the lung burden was much less for the MMVF10a group compared with the asbestos groups. After a 6-week recovery period, lung fiber burdens of MMVF10a had declined to near...
control levels, while amosite fiber burdens had remained the same or increased. Hamsters exposed to MMVF10a showed inflammation which regressed in recovery groups, but no pulmonary or pleural fibrosis or neoplasms. Amosite asbestos induced dose-related inflammation and fibrosis by 13 weeks, which progressed until the end of the study. No lung tumors were observed in the asbestos-treated groups, but incidences of mesotheliomas were increased [no statistical comparisons reported]. Data are summarized in Table 4-5.

\(^a\) Nose only exposure in studies with F344 rats and whole-body exposures with Wistar rats.

\(^b\) Number of WHO fibers per mg dry lung at 24 months for F344 rats; total lung fiber burden > 20 μm at 12 months in Wistar rats.

\(^c\) WHO fibers in the F344 study were similar to total exposure mass of fibers in fibers/cm\(^3\).

\(^d\) Statistics were not reported by the study authors; Fisher’s exact test conducted by NTP.

\(^*\) \(P < 0.05\) vs. controls; \(^***\) \(P < 0.001\) vs. controls (Fisher’s exact test).

NR = not reported; WHO fibers/cm\(^3\) = the number of fibers ≥ 5 μm in length, < 3 μm in diameter, with an aspect ratio ≥ 3:1.
No lung tumors were observed in groups of hamsters similarly exposed to MMVF33 (special-purpose glass fibers prepared by mixing three types of commercially manufactured 475 glass [codes 104, 108B, and 110]) (McConnell et al. 1999). Exposure groups included 125 animals each. The unexposed chamber control group included 140 animals. Fiber concentrations were comparable in all groups (~250 to 300 WHO fibers/cm$^3$) with two lower exposure groups for amosite. Lung clearance was suppressed in the amosite-exposed groups but not in the MMVF33-exposed group. The number of WHO fibers and fibers > 20 μm in length increased in the lung during the 18-month exposure period but were higher in the mid- and high-dose amosite groups than in the MMVF33 group. After 6 weeks of recovery, lung fiber burdens decreased by about 40% in the MMVF33 group compared with a 21% decrease in the high-dose amosite group. Fiber burdens measured in the diaphragm or thoracic wall were lower in the MMVF33 group than in any of the amosite-exposed groups, but were higher than with MMVF10a. [This may be linked to a higher fiber deposition.] A six-hour deposition study showed a greater deposition of MMVF33 compared with MMVF10a. MMVF33 did produce more severe inflammation than MMVF10a and some mild fibrosis that progressed in severity from week 26 to 52 before leveling off. Lung fiber burden with MMVF33 was higher than with MMVF10a. Incidences of mesothelioma in positive controls were 22 of 85 and 17 of 87 (mid- and high-dose amosite, respectively) compared with 1 of 83 in the MMVF33 group (Table 4-5). Mesothelial hyperplasia was found in 21.7% of hamsters after exposure to MMVF33 compared with 1.2% in both control and MMVF10a groups. [Differences between MMVF33 compared with MMVF10a (more severe inflammation, some mild fibrosis, one mesothelioma) might be related to the different deposition. Hyperplasia may reflect early signs of cell transformation.]

WHO fibers/cm³ = the number of fibers ≥ 5 μm in length, < 3 μm in diameter, with an aspect ratio ≥ 3:1.

#### 4.1.3 Studies in primates

Goldstein et al. (1983, 1984) compared the effects of inhaled fibrous-glass dust and crocidolite in baboons. Ten male baboons were exposed to 7.5 mg/m³ (1,100 fibers/cm³) of glass fibers (a blend of Johns-Manville sample references C102 and C104) or 15.8 mg/m³ crocidolite. Animals were exposed 7 hours per day, 5 days per week for up to 35 months. Lung biopsies were taken in two animals after 8-, 18-, and 30-months exposure and after 6-, 8-, and 12-months postexposure. Surviving animals were kept under observation. The dimensions of the glass fibers were log-normally distributed and were similar to the dimensions of the crocidolite fibers. The diameters ranged from about 0.06 to 8 μm (mean < 1 μm) and lengths ranged from about 0.8 to 58 μm (mean > 5 μm). Fiber content of lung tissue was much higher in crocidolite-exposed baboons \((5.6 \times 10^{10}\) fibers/g) than in glass fiber-exposed baboons \((5.0 \times 10^7\) fibers/g). Baboons exposed to fibrous-glass dust developed focal peribronchiolar fibrosis with scant ferruginous body formation, but the lesions were much less extensive than observed in the crocidolite-exposed animals. No neoplasms were observed in either group, but the authors noted the relatively short exposure and observation periods.

Mitchell et al. (1986) and Moorman et al. (1988) reported results from a chronic inhalation study using commercial grade Owens-Corning insulation fiberglass with binder or Tempstran Code 100/475 special-purpose glass fibers without binder (results for...
1 studies in F344 rats with the same fibers are reported in Section 4.1.1). Groups of 15 male
cynomolgus monkeys were exposed 7 hours/day, 5 days/week for 72 weeks and held until
80% mortality. The target concentrations were 15 mg/m$^3$ for the Owens-Corning
fiberglass and 5 mg/m$^3$ for the 475 glass. Two exposure groups for each glass fiber type
were used. Pulmonary macrophage aggregates and granulomas that contained glass fibers
were observed in treatment groups, but no pleural plaques were observed. There was no
evidence of fibrosis or neoplastic lesions in the respiratory tract of any treatment group.

4.2 Intraperitoneal administration
were administered by intraperitoneal injection were described by their authors as designed
to examine the relationship between fiber characteristics and tumorigenicity. The results
for glass fibers reported from those studies are discussed in Section 4.4 and Table 4-9,
and results for all fiber types are discussed in Section 5.3.2 and Tables 5-2 through 5-10.
Other studies with intraperitoneal injection of glass fibers are reported below.

Two of the studies that reported results for inhalation exposure to glass fibers tested the
same fibers by intraperitoneal injections (Muhle et al. 1987, Pott et al. 1987, Smith et al.
1987). These studies are reviewed in this section, along with a study by Pott et al.
(1976a), which is reported based on the English abstract [paper published in German],
and a study by Pott et al. (1984a) that reported results for JM100 and JM104 (several
preparations, including some ball milled for 1 to 4 hours) but with limited data on fiber
characteristics. Data for JM104/1974 fibers from two separate experiments reported by
Pott et al. (1987) are also reported in Table 4-6 because the experiments with those fibers
did not include any comparison with other glass fibers or vary the fiber characteristics.

Most studies included both saline-injected controls and asbestos-exposed groups;
however, since high-tumor incidences were observed in glass fiber-exposed groups,
tumor incidences for asbestos-treatment groups are not shown in the tables in Section 4,
but they are reported in Tables 5-2 through 5-10. The test fibers were administered in 1 to
2.5 mL of saline in the studies reported here. In most cases, tumor incidences in asbestos-
exposure groups were similar to those reported for glass fiber-treated animals with two
notable exceptions. Muhle et al. (1987) [Pott et al. 1987 reported the same tumor data
with an additional dose (2 mg) for JM104/475] and Smith et al. (1987) reported tumor
incidences in asbestos-treatment groups that were about 2.5- to 5-fold higher than in glass
fiber-treatment groups. Mesotheliomas were the most common tumor type, but some
studies reported sarcomas and carcinomas in a few animals. In many cases, doses
exceeded one billion fibers. The strain, sex, number of animals, fiber types, dose and
dosing schedule, and results are provided in Table 4-6. Animals were held until their
death (generally within 1 to 2.5 years), or sacrificed when moribund.

Smith et al. (1987) injected groups of 25 female Osborne-Mendel rats with JM100 and
crocidolite asbestos. Test animals received a single injection of 25 mg and were then held
until their death. Abdominal mesothelioma occurred in 32% of the animals injected with
JM100 and in 80% of the asbestos group. No tumors occurred in the untreated cage
controls or saline controls.

The details for the materials and methods used in the Pott et al. (1976a) study are limited
because the paper was published in German, but the results shown in Table 4-6 are highly
significant ($P < 0.001$) for S&S106 fibers (up to 72% tumor incidence) compared with the
saline control and for the trend for increasing tumor incidence with dose. The results for
MN104 (up to 71% tumor incidence) and MN112 fibers (38% tumor incidence at a single
dose) were not reported with concurrent controls, but the tumor incidences were similar to
those for S&S106 fibers.

Pott et al. (1984a) reported results for JM100 and JM104 glass fibers, as well as other
synthetic and natural fibers injected intraperitoneally to female Wistar and Sprague-
Dawley rats, but the authors described most of the results as either unfinished
experiments (data after 15 months) or as possibly having a reduced tumor rate due to an
infection in the twenty-first month of the experiment. Due to these limitations and the
lack of sufficient information on the materials and methods used [published in German in
Pott et al. 1976a], the results are not reported in Table 4-6 or 4-9. Results for three groups
of Wistar rats unaffected by either of the limitations noted above had tumor incidences for
JM104 fibers that decreased as the time of milling (in a ball mill in distilled water)
increased. Wistar rats injected with 10 mg of JM104 fibers after 1 hour of milling had a
73% (27/37) incidence of sarcoma or mesothelioma, while a 66% (29/44) incidence was
observed with 2 hours of milling, and 49% (19/39) with 4 hours of milling.

* P < 0.05, compared with combined saline and TiO2 control groups; χ²-test reported by authors.
* P < 0.05, ** P < 0.01; [compared with saline control by NTP, Fisher’s exact test].
*** P < 0.001; [compared with TiO2 control by NTP, Fisher’s exact test].
NR = not reported.

Most tumors were abdominal sarcomas or mesotheliomas. Pott et al. (1987) also reported a few carcinomas.
No concurrent controls reported by study authors, but results highly significant (P < 0.001) compared with other
controls in the same paper.
The trend for tumor incidence for MN104 fibers was highly significant (P < 0.001) compared with the saline control
for S&S106 from the same paper.

4.3 Other exposure routes
Glass fibers also have been tested for carcinogenicity in experimental animals through
several other parenteral exposure routes. These include intratracheal instillation,
intrathoracic implantation, and intrapleural inoculation. All but one of these studies was
conducted in the 1970s and 1980s. Studies were available in rats, hamsters, guinea-pigs,
mice, and rabbits. [Results from these studies provide further support for the hypothesis
that fiber dimension and durability are important factors in fiber-induced neoplasms.

Studies in rats are summarized in Section 4.3.1. Section 4.3.2 includes studies in hamsters, guinea-pigs, mice, and rabbits. The data from all studies are summarized in Table 4-7.

4.3.1 Rats

In addition to the inhalation study reviewed in Section 4.1.1, Gross et al. (1970) exposed groups of 15 to 30 rats and 12 hamsters (discussed in Section 4.3.2) to uncoated, phenol-formaldehyde–coated, or starch-binder–coated glass dust by intratracheal injection. Untreated control groups included 20 rats. Fiber dimensions, dosing, and study duration are described in Table 4-7. No differences in pulmonary reaction to coated and uncoated glass dust were noted, and no tumors were observed. Furthermore, no alveolar fibrosis or other significant septal changes in rat lung were reported.

Schepers (1974) summarized about three decades of work investigating the comparative pathogenicity of glass fibers derived from a number of sources. Many of these studies used fiberglass plastic dust where the polymerized resin accounted for 60% to 65% of the total material, while only about 25% of the material was glass fibers. The studies with fiberglass plastic dust are not included in this review. However, several intratracheal injection studies of glass wool or fibrous glass in rats, guinea-pigs, and rabbits were included. These studies used 10 to 21 animals in the exposed groups. No tumors were reported after 12 or 20 months, and the average lung reactions were considered mild in rats.

Pott et al. (1987) treated a group of 34 female Wistar rats with 20 intratracheal instillations of 0.5 mg JM104/475 glass fibers. Treatments were given weekly, and the animals were followed for life. A control group of 40 female rats was treated with saline, and another group was treated with crocidolite. Lung tumors (1 adenoma, 2 adenocarcinomas, and 2 squamous-cell carcinomas) occurred in the treatment group but not in the controls. The tumor incidence in the crocidolite group was about 43%, or about three times higher than in the glass-fiber–exposed group. In a similar experiment, 5 weekly intratracheal instillations of 2 mg JM475 glass fibers did not produce tumors in female Osborne-Mendel rats (Smith et al. 1987).
Two studies by Stanton et al. (1977, 1981) evaluated synthetic glass fibers of different dimensions implanted intrathoracically on the pleural surface, and these studies are discussed in Section 4.4 with other studies that examined a range of fiber characteristics in relation to tumorigenicity. Some, but not all, fibers induced tumors in these studies.

Four intrapleural injection studies in rats were reviewed (Monchaux et al. 1981, Wagner et al. 1973, 1976, 1984a). No tumors occurred in Wistar rats administered a single injection of 20 mg of JM110 fibers in two experiments; however, 4 of 32 rats injected with 20 mg of JM100 fibers developed mesothelioma (Wagner et al. 1976, Wagner et al. 1973). Because the JM110 fibers were thicker than the JM100 fibers, the number of injected fibers was about 30 million for JM110 compared with 30 billion for JM100 (Wagner et al. 1976). Wagner et al. (1984a) treated groups of 48 Sprague-Dawley rats [sex not specified] by intrapleural injection of resin-coated or uncoated English glass wool and JM100 glass microfiber. Rats received a single injection of 20 mg dispersed in 0.5 mL saline, and a control group of 24 rats was injected with saline. Incidences of mesothelioma were 1 of 48 (glass wool group) and 4 of 48 (JM100 group) (Wagner et al. 1984a). Six (6) of 45 Sprague-Dawley rats given a 20-mg dose of JM104 fibers developed mesothelioma (Monchaux et al. 1981). Tumor incidences were generally higher in asbestos-exposed groups in each of these studies and ranged from 12.5% to 66%.

4.3.2 Hamsters, guinea-pigs, mice, and rabbits

Vorwald et al. (1951) primarily studied the effects of asbestos in long-term inhalation studies using rats, mice, guinea-pigs, rabbits, cats, and dogs, but one intratracheal injection study included a small group of guinea-pigs (6 to 9 [exact number not specified by authors]) exposed to two injections of 25 mg of glass wool. Most of the fibers were 20 to 50 μm in length and were about 3 μm in diameter. Neither lung fibrosis nor tumors were reported after 12 months. [This study did not include positive controls, the number of animals was limited, the fiber diameter was large, and the delay post inoculation was limited to 12 months.]

Gross et al. (1970) also exposed groups of 12 hamsters to uncoated, phenol-formaldehyde–coated, or starch-binder–coated glass dust by intratracheal injection. Untreated control groups included 20 hamsters. There were no apparent differences in the
pulmonary reaction following exposure to coated or uncoated glass dust, and no tumors were observed. A diffuse, acellular, collagenous pleural fibrosis was noted in some hamsters. [This study did not include positive controls, and the number of animals was limited.]

No tumors were reported in guinea-pigs following three intratracheal injections of 75 mg of glass wool, or in rabbits following three intratracheal injections of 300 mg of fibrous glass (Schepers 1974). However, the average lung reactions were considered mild to moderately severe in guinea-pigs and mild in rabbits. No tumors were observed after single intrapleural injections of 10 mg of borosilicate fibers of varying diameters and lengths in groups of 25 mice (Davis 1976, as cited in IARC 2002).

Kuschner and Wright (1976) and Wright and Kuschner (1977) treated groups of 30 guinea-pigs by intratracheal injection of glass fibers of different dimensions. The number of injections varied from two to six, and the total amount injected varied from 12 to 25 mg. Glass fibers were sorted into six groups: short, thin fibers; long, thin fibers; short, very thin fibers; long, very thin fibers; short, thick fibers; and long, thick fibers. The animals were observed for 24 months. No tumors were reported in any of the groups, but the authors noted that the long glass fibers were fibrogenic.

Two intratracheal instillation studies of JM104 fibers were conducted in hamsters. Pott et al. (1984b) and Mohr et al. (1984) reported increased incidences of lung carcinoma, mesothelioma, and thoracic sarcoma following eight weekly treatments with 1 mg, while Feron et al. (1985) reported no increase in tumors in hamsters receiving 1 mg every 2 weeks for one year.

4.4 Studies of fiber characteristics and tumorigenicity for glass wool fibers

A number of studies have been carried out to compare various fiber types in order to determine how characteristics of fiber dimensions and durability/biopersistence relate to tumorigenicity. The data from these studies of glass fibers are reported in this section and in Tables 4-8 and 4-9, while the data for all fiber types, which included natural fibers like asbestos and other synthetic mineral fibers like stone wools, that were tested in these studies are reported in Section 5.2. When the chemical compositions of fibers were reported by the authors, the Z-score or Soluble Components Index (KNB) was calculated using the formula reported in Section 1.4. In addition, data on either the biopersistence of fibers, expressed as the half-life in vivo, or the dissolution coefficient (K_c) determined in vitro and reported in units of ng/cm² per hour are reported in Tables 4-8 and 4-9 when available.

The studies by Stanton and Wrench (1972) in the early 1970s compared the tumorigenicity of glass fibers and asbestos applied directly to the lung pleura of rats. Based on incidences of mesotheliomas in the range of 12% to 18% for rats exposed to an especially fine fibrous glass, compared with tumor incidences of 58% to 75% for standard reference samples of amosite, chrysotile, and crocidolite, the authors concluded that long, thin glass fibers were as carcinogenic as similarly sized asbestos.

Stanton et al. (1977, 1981) extended these studies with experiments testing the tumorigenicity of 22 glass fiber preparations and other fiber types (see description below and in Section 5.2.1). Based on induction of significant numbers of pleural sarcomas by fine, durable fibers of glass and other fiber types, Stanton et al. concluded that fiber dimensions and durability were important in determining the tumorigenicity of the material. [The parameters used to define durability in these studies were not reported.]

Stanton et al. implanted one of either 18 (1977 study) or 22 (1981 study) types of synthetic glass fibers on the pleural surface of the thoracic cavity in groups of 30 to 50 female Osborne-Mendel rats. Other experiments conducted with various natural and synthetic fibers are reviewed in Section 5.2.1. A standard dose of 40 mg of fibers was suspended in gelatin and spread over the surface of flat, 45-mg pledgets composed of autoclaved, binder-coated, coarse fibrous glass (designated as glass #17), which also
served as a control treatment. [This sample was designated glass #18 in Stanton et al. (1981).] The pledgets were implanted on the pleural surface via a left-sided open thoracotomy. Most of the glass fibers were flame-attenuated or rotary-processed borosilicate fibrous glasses and were derived from commercial products as received from the manufacturers. The numbers of animals, fiber characteristics, and results are reported in Table 4-8. The samples are identified according to the numbering reported in Stanton et al. (1981), which differed slightly from the numbering reported in Stanton et al. (1977) because of the addition of a new glass fiber sample identified as Glass #2 in the later paper. The reported tumor incidences were the same in both studies. Tumor incidences were adjusted for survival based on a life-table analysis. Rats were killed when moribund or at 25 months. Incidences of pleural sarcoma were based on animals surviving the first 52 weeks after treatment and ranged from 0% to 85%.

The statistical comparisons were different in the two studies, in part because the first study examined only glass fibers, while the later study also included a large number of other natural and synthetic mineral fibers. Stanton et al. (1977), which examined only glass fibers, divided their experiments into three groups: high-risk, intermediate-risk, and low-risk groups. Incidences of pleural sarcoma in the low-risk group were significantly different from untreated controls, but the authors considered the data to be insufficient to distinguish differences from the treated control group (Glass #18 in Table 4-8). The low-risk group included experiments 9 to 16 (glasses 10 to 17 in Table 4-8). Tumor incidences in the high-risk group (glasses 1, 3, 4, 5, and 6) and intermediate-risk group (glasses 7, 8, and 9) were significantly higher than in the control group ($P < 0.001$ and $P < 0.01$, respectively). Since the authors drew conclusions based on the dimensions (diameter and length) of the fibers, the fibers are listed in Table 4-8 by decreasing percentage of fibers with diameter $> 1.5 \mu m$ or $> 2.5 \mu m$.

The results for the 18 glass fiber types tested in the 1977 paper were reported again in Stanton et al. (1981) together with one additional glass fiber (designated #2 in that paper) and $\sim 50$ additional natural and synthetic fibers (see Section 5.3 and Table 5-2). Stanton et al. (1981) concluded that the best fit for probability of tumor formation was found for fibers $< 0.25 \mu m$ in diameter and $> 8 \mu m$ in length. Another correlation was found for
fibers with a diameter of up to 1.5 µm and > 4 µm in length. Experimental data from the
Stanton et al. publications were re-analyzed by other authors. Bertrand and Pezerat
(1980) confirmed the dependence with fiber dimensions. Oehlert (1991) also confirmed
the hypothesis that the logarithm of the number of fibers < 0.25 µm in diameter and > 8
µm in length were predictive of tumor yield. Stanton et al. acknowledged that some
samples did not fit well, especially some asbestos samples. This point was studied by
Wylie et al. (1987). These authors first confirmed that the number of index fibers
(defined as those < 0.25 µm in diameter and > 8 µm in length) reflected differences in
carcinogenic potency, but that the outliers were related to the mathematical calculations
when samples contained a low number of fibers of such dimensions (see Section 5.3.2 for
further discussion of these studies).
Table 4-8. Carcinogenicity studies of glass wool (40 mg per animal) administered by intrathoracic inoculation with results arranged by percent of fibers below the cutoff values for diameter

<sup>a</sup> Number of fibers administered not reported; no data reported for biopersistence or dissolution rate.

<sup>b</sup> Z-score calculated from glass composition reported by authors (see Section 1 for formula).

<sup>c</sup> Adjusted for survival by life-table analysis. Animals were followed for up to two years, and tumor incidences were based on animals surviving at least one year.

<sup>d</sup> Glass 18 served as the control group and was the vehicle for the implants.
Following the studies by Stanton and co-workers, most investigators studying the relationship between fiber characteristics (diameter, length, and durability or biopersistence) have tested fibers by intraperitoneal injection. The authors of these studies generally agreed with the concept put forward by Stanton and co-workers that carcinogenicity is related to fiber dimensions and biopersistence, but the authors’ conclusions are discussed further below and in Section 5.2.2. The results of the studies with glass fibers are reported in Table 4-9.

Pott et al. (1974) investigated the tumorigenic effects of various fibrous dusts, including sodium-calcium borosilicate glass fibers, in Wistar rats. About 73% of the fibers were < 5 μm in length and the average diameter was about 0.5 μm. A group of 40 rats [sex not specified] was given four weekly injections of 25 mg of glass fibers. The control group received four injections of saline. No tumors occurred in the control group, but more than half of the treatment group (23/40) developed mesotheliomas. Based on their results the authors suggested that fibers less than 10 μm in length could still be carcinogenic, and similarly, they proposed that carcinogenicity could not be limited to fibers with diameter less than 0.5 μm.

Pott et al. (1976a) investigated the carcinogenicity of a number of fibrous dusts in groups of female Wistar rats. [The paper was published in German with an English abstract.] Rats were administered single injections of 2 or 10 mg of S&S106 glass fibers (59% fibers < 3 μm long) or MN104 [identified as JM104 by IARC 2002] (mean fiber dimensions 10 μm × 0.2 μm). [The S&S 106 glass fibers were identified as German glass wool by IARC 2002 and reported in a section with insulation glass wools; however, the source of these fibers was the German company, Schleicher and Schuell, of Dassell, Germany, which is now part of the Whatman Group and manufactures glass fibers for filtration (i.e., special-purpose fibers). No other information on the characteristics of these fibers was identified.] Other groups were treated with four weekly injections of 25 mg of glass wool, two weekly injections of 25 mg of MN104, or a single injection of 20 mg of MN112 [identified as JM112 by IARC 2002] (mean fiber dimensions 30 μm × 1 μm). In addition, several groups were treated with various doses of chrysotile asbestos. Hamsters were administered single injections of 2 or 10 mg of glass wool. The animals
were held until natural death. Dose-dependent increases in incidences of mesothelioma were reported, ranging from 3% to 72% in glass wool treatment groups, 27% to 71% in MN104 treatment groups, and 38% in the MN112 group. Other tumor types also were reported. Spindle-cell sarcoma was the most common tumor type, occurring in most treatment groups at 4% to 8% incidence. Tumor incidences in asbestos-treated groups ranged from about 16% to 81%. No tumors were reported in 72 saline-treated rats. [The English abstract reported that i.p. injection of fibrous dusts also induced mesothelioma in mice, but not in Syrian golden hamsters or guinea-pigs. However, no data were presented for these species.]

Pott et al. (1984a) tested some of the same fibers as in their previous publications, but they also injected JM100 and JM104 glass fibers into female Wistar or Sprague-Dawley rats. The percentage of either Wistar or Sprague-Dawley rats that developed abdominal tumors after i.p. injection of JM104 glass fibers decreased after pretreatment of the fibers for 2 or 24 hours with 1.4 N NaOH, which resulted in loss of 1.7% to 6.8% of the starting weight of the fibers. Pretreatment with 1.4 N HCl for 24 hours, which resulted in the loss of approximately one third of the starting weight of the fibers, almost totally eliminated tumor development in either strain of rats followed for more than 450 days after injection (see Figure 4-1). The fiber dimensions were affected only slightly by the pretreatments, and the authors reported that the loss of fiber weight was not associated with any discernible corrosion of the fibers examined by scanning electron microscopy. (The authors noted that two different batches of JM104 fibers differed in the amount of weight lost after treatment with hydrochloric acid, which led them to conclude that the two samples must have had different chemical compositions.) Pott et al. did propose that the considerable reduction in carcinogenicity with HCl pretreatment might have been due to alterations in the rate of dissolution or disintegration of the fibers or their migration within tissues, but they did not consider these hypotheses as proven by their data.
A series of other experiments by Pott and co-workers (Muhle et al. 1987, Pott 1989, Pott et al. 1984a, 1987) was conducted specifically to investigate the relationship of fiber dimensions and durability with carcinogenic potency. These studies examined the carcinogenicity of JM100 and JM104 microfibers as well as several other types of mineral fibers, including asbestos. In the first study, groups of 37 to 45 female Wistar rats were given single i.p. injections of 2 mg of JM100 or JM104 microfibers (Pott et al. 1984a). Other groups received 10 mg of JM104. Two batches of JM100 fibers were used that had slightly different size distributions. Several batches of JM104 fibers that were used were subjected to 1 to 4 hours of milling in a ball mill before use. The authors reported incidences of mesothelioma and sarcoma combined. JM100 fibers induced a low incidence of tumors (5%). The authors noted that these fibers were relatively short (90% were < 7.3 μm in one batch and < 3.1 μm in the other batch). Tumor incidences were higher in the JM104-treatment groups, presumably due to longer fibers. The lowest tumor
incidence in rats treated with JM104 (9%) occurred with shorter and thicker fibers relative to the other JM104 groups. The authors also noted in a footnote to one table that the tumor incidence could have been reduced in this group due to an infection at 21 months, but no other details were provided. Subsequent studies with JM104 fibers in male and female Wistar rats and female Sprague-Dawley rats resulted in tumor incidences of about 17% to more than 80%. Tumor incidences in the saline controls ranged from about 2% to 6%. All abdominal tumors (including mesothelioma, sarcoma, and carcinoma) were combined; however, very few carcinomas occurred. The authors noted that the three tumor types could not always be differentiated.

Pott et al. (1991) conducted a comparative carcinogenicity study of some experimental fibers having a relatively low biodurability (B-1 and B-2) and fibers having greater biodurability (B-3 and M-475 code 104). The mean half-lives were 38 days for B-2 glass wool, 107 days for B-1 glass wool, and 238 days for B-3 glass wool. [No half-life was reported for M-475 fibers.] Female Wistar rats received one to three injections of experimental fibers (B-1, B-2, and B-3) at the doses and numbers of fibers shown in Table 4-9, or a single injection of 2 mg of M-475. The median diameters of the fibers were 0.14 μm (M-475), 0.35 μm (B-3), 0.5 μm (B-2), and 1.5 μm (B-1). Both the dose and length of the fibers were varied, with fibers designated either as K (kurz, German for short), M (medium), or L (lange, German for long). The Z-scores calculated for the fibers were lowest for B-3 fibers (20.7) and highest for B-1 and B-2 fibers (35.8), which had the same chemical composition (see Section 1, Table 1-4). The authors concluded that a carcinogenic effect could be detected only in groups injected with durable glass fibers (B-3 or M-475), and that slightly durable glass fibers (B-1 and B-2) did not induce a carcinogenic effect at the doses and fiber sizes tested, which included up to 5.80 × 10^9 B-2 fibers with median length of 6 μm and median diameter of 0.51 μm. [The most carcinogenic B-3 fibers were also the thinnest.]

Roller et al. (1996) conducted a study designed to examine the dose-response relationship for fiber types of different dimensions and in vivo durabilities. Incidences of mesothelioma ranged from 3% to 70% for glass fibers, while incidences of mesothelioma in asbestos-treated groups ranged from 23% to 80%. These studies investigated several
types of SVFs, including samples from at least four commercial insulation wools, and an experimental glass fiber type (B-01) of low biodurability (mean T_{1/2} = 32 days). Each of these studies followed the same general design. Groups of at least 32 Wistar rats (usually female) were given single or multiple i.p. injections of \( \sim 10^7 \) to \( > 10^{10} \) fibers (length > 5 \( \mu \)m) and were observed for 30 months. Results are reported in Table 4-9, and discussed below.

The relationships between fiber dimensions and tumorigenicity were discussed in Roller et al. (1997). The fibers were divided into groups of relatively long, thick fibers (aspect ratio > 5:1, median length 8–17 \( \mu \)m, median diameter 0.7–1.2 \( \mu \)m) and short, thin fibers (aspect ratio > 5:1, median length 2–4 \( \mu \)m, median diameter 0.2–0.5 \( \mu \)m). The long, thick fibers included the following glass fiber types: B-09-0.9, B-09-2.0, B-20-2.0, and MMVF11. The short, thin fibers included the following glass fiber types: B-09-0.6, B-20-0.6 [reported as B-0.9-0.6 in Table #1 in Roller et al. (1997), but the doses matched the results reported for fiber type B-20-0.6 in Table #4 in Roller et al. (1996)] and M-753-105. The overall conclusion by Roller et al. (1997) was that the mechanism responsible for mesotheliomas in their experimental system was specific to the fibrous shape of the particles administered based on parallelism of the probit lines calculated for each fiber type (see Section 5.3.1 and Figure 5-3).

Lambré et al. (1998) evaluated the carcinogenic potential of two glass wools (Fiber A and Fiber C) described as sodium-modified borosilicates (see Tables 1-4 and 4-9). The samples had been specially manufactured and processed to produce fibers in the size range with median diameter less than 1 \( \mu \)m and median length between 10 and 15 \( \mu \)m. Fiber durability (K_{dis}) was 129 ng/cm² per hour for Fiber A and 309 ng/cm² per hour for Fiber C. Both fiber types had a Z-score of 26.7. These fibers were administered to groups of 51 female Wistar rats by i.p. injection (one or two injections) at 0.7, 2.1, 7, or 17.5 mg/dose. Crocidolite (0.005, 0.05, or 0.5 mg) was used as a positive control. The study was stopped at week 130 when the survival rate had reached 20% in the control groups. Survival was the same in groups injected with glass fibers as in the negative control groups. Adhesions involving various abdominal organs were noted in the treatment groups. Fibrosis increased with dose, and a few mesotheliomas occurred in the groups.
treated with Fiber A or Fiber C. Incidences of mesothelioma in asbestos-treated groups ranged from 7.8% to 39.2%. (Tumors were induced by several stone wools tested in the same study [see Section 5.3.1]). The authors concluded that the glass fibers tested in this study did not show a carcinogenic potential at the tested doses, and their general conclusion was that fibers with a high dissolution rate \textit{in vitro} at pH 7.4 along with low biopersistence for fibers with length > 20 µm tended to have a low carcinogenic potency in the i.p. assay. [This study was initiated when the recommended dose was $0.5 \times 10^9$ critical fibers (defined by length > 5 µm, diameter < 2 µm, and an aspect ratio (L/D) > 5); however, this recommendation was subsequently increased to $5 \times 10^9$ critical fibers (see Grimm \textit{et al.} 2002).]

Miller \textit{et al.} (1999b) and Cullen \textit{et al.} (2000) investigated the carcinogenic effects of a number of SVFs, including MMVF10 glass wool and two special-purpose glass microfibers (JM100 and 104E) (see Table 4-9). Durability ($K_{dis}$) was 122.4 ng/cm$^2$ per hour for MMVF10 and 9.1 ng/cm$^2$ per hour for JM100. The i.p. dose was selected as a mass sufficient to contain $10^9$ fibers > 5 µm in length. Treatment groups consisted of 18 to 24 male Wistar rats. Positive controls were treated with 6.1 mg of amosite asbestos. These studies did not include negative controls. Animals were maintained until they showed signs of debilitation. Miller \textit{et al.} (1999b) reported that carcinogenicity was linked to the number of injected fibers > 20 µm in length and the biopersistence of fibers > 5 µm in length. The incidence of mesotheliomas was 59% in the glass wool group, 33% in the JM100 group, 88% in the 104E group, and 88% in the asbestos group. Although tumor incidences were similar for the 104E and asbestos groups, tumors appeared earlier in the 104E group. In particular, Cullen \textit{et al.} (2000) speculated that differences in surface properties (i.e., selective leaching of some glass components) might also be important for explaining the greater effect of 104E glass compared with 100/475 fibers.

Adachi \textit{et al.} (2001) administered glass wool or micro glass fibers to groups of female F344 rats by i.p. injection (10 to 20 mg) and observed the animals for 2 years. Chrysotile asbestos and several SVFs were included in this study. No tumors were reported for the groups exposed to glass wool or micro glass fiber, but very few details were provided, and this study is not included in Table 4-9.
In the most recent study, Grimm et al. (2002) investigated the carcinogenic potential of three newly developed biosoluble insulation glass wool fibers (designated M, P, and V) and compared these with a previously developed soluble B glass fiber (reported by the authors as non-carcinogenic by the German TRGS 905 fiber regulations) (see Table 4-9). The dissolution coefficients ($K_{\text{dis}}$) for the fibers were $580 \, \text{ng/cm}^2 \, \text{per hour}$ for B, $103.7 \, \text{ng/cm}^2 \, \text{per hour}$ for M, $610 \, \text{ng/cm}^2 \, \text{per hour}$ for P, and $450 \, \text{ng/cm}^2 \, \text{per hour}$ for V. Calculated Z-scores are 34.42 for B fibers, 30.04 for M, 45.45 for P, and 26.35 for V.

Prior to administration, the fibers were processed to reduce the amount of non-WHO fibers and nonfibrous particles. Groups of 50 to 53 female Wistar rats were given 2, 8, or 20 i.p. injections of the various glass fibers. Crocidolite (0.5 or 5 mg) was used as a positive control. The study was terminated after 123 weeks. Fiber M did not show a carcinogenic response, while Fibers P and V showed a slight carcinogenic response similar to that for B fibers. The high doses of fibers B (17%), P (15%), and V (27%) significantly increased tumor levels [statistical test and level of significance not reported by the study authors]. [However, according to Fisher’s exact test, $P$ values for the high-dose were 0.0016 for B fibers, 0.003 for P, and < 0.001 for V (see Table 4-9). Hence, fiber B cannot be considered as non-carcinogenic in this study.] Incidences of mesotheliomas in the asbestos groups were about 53% to 88%.

\(\text{a}\) P < 0.05; \(\text{**}\) P < 0.01; \(\text{***}\) P < 0.001; [compared with controls by NTP, Fisher's exact test].

NR = not reported; Z-score = sum of the percent composition of alkali and alkaline earth oxides (Na$_2$O + K$_2$O + CaO + MgO + BaO) (see Section 1.3.1 and Table 1-4) [calculated by NTP].

a Most tumors were abdominal mesotheliomas or carcinomas. Some studies (Pott et al. 1976a, 1984a, 1987, 1989, 1991) also reported a few carcinomas.

b No concurrent controls.

c B-1 and B-2 are experimental low-durability glass wool; B-3 is an experimental durable glass fiber. K, M, and L designate short, medium, and long fiber ranges, respectively.

d $K_{dis}$ = dissolution coefficient in vitro, reported in units of ng/cm$^2$ per hour.

e [Cochran-Armitage test performed by NTP.]

f Data also reported by Davis et al. (1996) and Cullen et al. (2000).
4.5 Routes of exposure

Three primary test models have been used to evaluate the toxicity and carcinogenicity of fibers in rodents: inhalation exposure, intratracheal instillation of fiber suspensions, and direct exposure of the pleura or peritoneum by injection of fiber suspensions into the thoracic or abdominal cavity (see Sections 4.1, 4.2, and 4.3). IARC (2002) acknowledged that “there is no general agreement on which of these routes of administration best predicts human cancer risk.” However, the available data demonstrate that chronic i.p. injection studies and inhalation toxicity studies provide the same relative ranking of fiber pathogenic potential (Bernstein 2001a,b, 2007a). This section discusses interspecies comparisons between rats and humans, and the different types of animal models used to test for carcinogenicity.

4.5.1 Interspecies comparison

There is debate on whether humans are more sensitive to fiber carcinogenicity (from inhalation exposure) than rats (Maxim and McConnell 2001, Muhle and Pott 2000, Roller and Pott 1998). This debate stems from evaluation of the body of literature on asbestos. Various investigators have compared the sensitivity of humans and rats to asbestos-induced carcinogenicity and have arrived at different conclusions. Muhle and Pott (2000) and Roller and Pott (1998) compared cancer risks for humans using the epidemiologic data (primarily from Health Effect Institute-Asbestos Research and Doll and Peto (1985); data from U.S. EPA and U.S. OSHA provide a similar risk estimate) and animals using data on asbestos inhalation studies. They concluded that rats required more than 100 times higher fiber concentrations to match the lung cancer risk (Figure 4-2) of asbestos workers and 1,000 times higher to match the mesothelioma risk. In a later publication (Wardenbach et al. 2005), these authors created a scatterplot of the tumor response in rat inhalation studies from several studies and human and epidemiological data from multiple studies (in response to criticism for using a single point, see below) for amphibole and chrysotile asbestos. According to the authors, this analysis still showed a greater sensitivity for humans compared with rats for both amphibole asbestos and chrysotile asbestos (when compared with textile studies, which were considered by the authors to have the purest asbestos exposure). They did not think that the shorter exposure duration in the animal studies should be taken into account when comparing
sensitivities since comparisons should be based on lifespan rather than absolute time units. These authors concluded that the rat inhalation model is not sufficiently sensitive to show a carcinogenic response for fibers.

Figure 4-2. Tumor incidence for epidemiologic studies (humans) and chronic inhalation studies (rats) for exposure to asbestos.

Source: Muhle and Pott (2000), used with permission.

Dotted curve on the left-hand side = increasing tumor risk from asbestos fibers for workers (excluding mining and milling) after 25-years occupational exposure when the fiber concentration increases from 1 to 5 fibers per mL (Doll and Peto 1985, HEI-AR 1991). Measurement points on the right-hand side = association between much higher fiber concentrations in the air of chronic inhalation studies with rats and tumor response. Exposure in the majority of the experiments: 35 hours/week for one year. Data of Davis et al. (1986a, 1978), Davis and Jones (1988), Mast et al. (1995a, 1995b), McConnell et al. (1994, 1984), Wagner et al. (1984b, 1985). The fiber concentration in the workplace atmosphere and in the inhalation chambers of Davis and co-workers are related to light microscopical (LM) measurements; electron microscopy (EM) has been used in the other inhalation experiments. The regression line has been calculated from the results of Davis et al. (black dots).

In contrast to this conclusion, Maxim and McConnell (2001) conducted an interspecies comparison of the toxicity of asbestos and SVF and concluded that “there is no reason to conclude that humans are more sensitive to fibers than rats with respect to the development of lung cancer.” They stated that a comparison of tumor data from several animal studies with only one estimate of potency in humans could be misleading, given that potency estimates in human epidemiologic studies vary substantially, and that some of the apparent differences in sensitivity might be explained by the synergistic effects of
asbestos exposure and smoking. They also thought exposure duration should be
considered when conducting interspecies analyses. They cited an analysis conducted by
Rowe and Springer (1986) that used data from 5 epidemiologic studies and animal data
from one publication (Wagner et al. 1974) in an analysis that included exposure duration
(working lifetime of 45 years with 8 hours per day and 250 days per year). This analysis
found that risks estimated by the animal study were within the range of the risk estimates
from the human studies. [Wardenbach et al. criticized the use of only the Wagner data in
this analysis since the study provided mass concentrations rather than fiber number, and
in general the high tumor incidences in this study have not been replicated in other
studies in experimental animals.]

Maxim and McConnell (2001) also discussed factors related to dosimetry (exposure and
lung burden) and fiber toxicity and concluded that the rat is preferable as a model for
lung cancer. In addition to the points discussed above, they drew the following
conclusions:

1. Deposition and clearance: Modeling studies that normalize for lung weight show
   that the relative deposition of SVFs (number of fibers per unit time) in humans is
   smaller than that for rats, and that fiber clearance (based on models and data using
   refractory ceramic fiber) is faster in rats than humans. The authors also pointed
   out that clearance can be reduced by high particle overload, which has been
demonstrated in rats.

2. The sensitivities of human and rodent cells appear to have comparable sensitivity
   with regard to fiber-induced cytotoxicity, production of inflammatory components
   (i.e., cytokines), transformation, and proliferation.

3. The available data suggest that lung fiber burdens associated with fibrosis are
   similar in rats and humans, although exact comparisons are limited by the paucity
   of information on the [asbestos] fibers’ length, diameter, and distribution in the
   lung.

4. Humans and rats are equally sensitive to development of fiber-induced lung
cancer based on studies with asbestos and refractory ceramic fibers (see above).
5. Lifespan of animals: The authors stated that the rate of dissolution of fibers is similar in rats and humans, and since humans live longer, the rat model might not take into account the effects of clearance.

4.5.2 Animal models

Inhalation studies

In principle, the most relevant route of administration used in animal studies is the route that mimics human exposure. Inhalation is the primary route of exposure to fibers; however, inhalation experiments with fibers present some unique challenges. These include sample preparation, size selection, and aerosol generation methods; determination of the MTD; whole-body or nose-only exposure; differences in the respiratory tract and respiration in rodents and humans; differences in respirable fiber dimensions, deposition, clearance, and retention in rodents and humans; selecting the best animal model; and sensitivity and potency issues. All of these are relevant factors for interpreting results from the available inhalation studies (Oberdörster 1996).

The primary advantages of fiber inhalation studies include use of a natural route of exposure: lung defenses are not bypassed, and lung biopersistence and toxicity and mechanisms for lung tumor induction can be examined. The disadvantages are that inhalation studies are complex, time-consuming, costly, and may lack sufficient sensitivity for detecting fiber-induced cancers under experimental conditions. Furthermore, there is no general consensus on which animal species is (are) best for predicting effects in humans (Oberdörster 1996). Although the rat model is the most common, there is some evidence that the hamster might be more appropriate for detecting mesotheliomas (Kane 1996a).

A number of problems with the early inhalation studies (generally those conducted prior to 1988) were identified by IARC (2002) (see Section 4.1 and Table 4-3), but these problems were generally addressed in later studies. Nevertheless, several questions remain regarding respirability, dosing, and sensitivity. Biopersistence of fibers can be affected by the presence of particles in the exposure dose, leading to particle overload. Particle overload is a condition noted primarily from inhalation studies in the rat and occurs when the deposition rate of poorly-soluble, low toxicity particles exceeds the
normal macrophage-mediated clearance rate (ILSI 2000). Clearance mechanisms can become impaired under high-exposure conditions resulting in chronic alveolar inflammation, fibrosis, and lung tumors. IARC (2002) reported that overload occurs in the rat when 1 to 3 mg of particles are deposited per gram of lung tissue. This condition leads to non-specific lung injury and possibly lung tumors (Hesterberg and Hart 2001, IARC 2002).

Oberdörster (1996) noted two important differences between humans and rats that relate to respiratory tract dosimetry: (1) most of the lung tumors develop in the conducting airways of humans but develop only in the peripheral region in rats; therefore, respirable fibers appear to be more important in the rat; and (2) because of the differences in respiratory physiology, respirable fibers represent very different fractions in humans and rats (see Section 5.1). Therefore, Oberdörster recommended enrichment of the inhaled aerosol with long fibers in order to deposit enough of them into the respiratory tract of the rat. Pertinent questions for inhalation studies of fiber carcinogenicity were also addressed and included the following: (1) should rat respirable or human respirable samples be used, (2) is it possible to test the longer human respirable fibers (i.e., the most potent fibers) in the rat inhalation model, and (3) are chronic inhalation studies in rats sensitive enough to detect lung tumors below the MTD for any fiber type?

The conventional definition of the MTD is *a dose that produces no increased mortality compared with controls, no shortening of life span other than that resulting from tumor development and no more than a 10% weight gain reduction compared with controls* (Kane *et al.* 1996b). However, the conventional definition might not be adequate for fiber studies. Muhle *et al.* (1990) introduced the concept of the *maximal functionally tolerated dose* (MFTD) for particulates. The MFTD was defined as the lung burden associated with a two- to four-fold decrease in particle clearance. Other indicators that could be useful in identifying the MTD for fiber inhalation studies include the following: increased lung weight, increased inflammatory parameters, increased target cell proliferation, altered histopathology other than carcinogenicity, impaired lung clearance function, and non-linear fiber retention kinetics (Greim 2004, Oberdörster 1996). Hesterberg *et al.* (1996a) used lung toxicity and particle clearance to estimate the MTD for glass wool and
concluded that 30 mg/m\(^3\) (~230 to 300 fibers/cm\(^3\)) was an appropriate MTD for MMVF10 in their chronic inhalation studies (see Section 4.1.1).

Ellouk and Jaurand (1994) noted that for animal models to be relevant to human exposures, inhalation studies require the use of fibers or particles that are respirable in the species tested. However, it may not be possible to increase the respirable dose beyond the MTD for an animal model. Therefore, investigations by the inhalation route should be reserved for respirable fibers, i.e., thin fibers of a diameter allowing lung deposition.

Wardenbach et al. (2005) noted that humans are more sensitive to asbestos-induced carcinogenicity by inhalation than rats (see above for a discussion of this opinion and opposing views) and presented arguments in favor of using intraperitoneal injection to test for fiber carcinogenicity. In a comparison of recent chronic rat inhalation studies using special-purpose fibers and insulation wool fibers, differences between the exposure concentrations of these two types of fibers decreased with fiber length and barely existed for fiber lengths > 20 μm (Figure 4-3). However, at every length category examined (total, > 5 μm, > 20 μm) special-purpose fibers had a higher concentration of lung fibers (per dry lung weight) as compared with insulation glass wool fibers (Figure 4-4). The special-purpose fibers induced tumors, whereas the glass wool fibers did not. These results suggested that special-purpose fibers are more respirable than glass wool fibers. Previous studies had shown that almost all of the special-purpose fibers were respirable; however, data were not available on the respirability of insulation glass wool fibers.

[Table 4-4 reports data that show that for glass wool fiber exposure concentrations of 3 to 30 mg/m\(^3\), there are 29 to 232 WHO fibers/cm\(^3\). In these studies, these fibers were approximately 81% to 90% of the total mass of fibers in the exposure aerosol. No lung tumors were detected above control values. These exposure concentrations are in contrast to the crocidolite positive control (10 mg/m\(^3\)), which had an exposure concentration of 1,600 WHO fibers/cm\(^3\) and a significant increase in lung tumors.] Because of the low sensitivity of the inhalation model and the possible differences in respirability and outcome in the rat model, the intraperitoneal model was proposed (see below).
Figure 4-3. Exposure concentration vs. size categories of fibers from rat inhalation studies conducted at two different laboratories

Source: Wardenbach et al. 2005 (authors reported that some points were estimated from diagrams), used with permission.

Closed symbols = statistically significant induction of lung tumors; open symbols = nonsignificant for lung tumors. Triangles = MMVF except RCFs, circles = amphibole asbestos. L = Length, D = Diameter.

RCC = Research and Consulting Company (Geneva, Switzerland) experiments with insulation glass fibers; IOM = Institute of Occupational Medicine (Edinburgh, Scotland) experiments with special-purpose fibers.

[The data for 104/475 fibers > 20 µm in length from Davis et al. 1996 do not appear in the figure. It should be an open triangle. In addition, the closed triangle at 38 fibers/mL and L > 20 µm likely refers to the 100/475 fibers in Cullen et al. 2000 and should be an open triangle.]
Figure 4-4. Concentration of fibers in lung tissue vs. size categories of fibers from rat inhalation studies conducted at two different laboratories

Concentration of fibers is in mg/dry weight of tissue.
Closed symbols = statistically significant induction of lung tumors; open symbols = nonsignificant for lung tumors. Triangles = MMVF except RCFs, circles = amphibole asbestos. L = Length, D = Diameter.
RCC = Research and Consulting Company (Geneva, Switzerland) experiments with insulation glass fibers; IOM = Institute of Occupational Medicine (Edinburgh, Scotland) experiments with special-purpose fibers.

Intratracheal instillation
One of the advantages of intratracheal instillation is that selected doses of human respirable fibers can be delivered directly to the lung (Oberdörster 1996). Although the delivered fibers are then subject to the lung’s normal defense mechanisms, these mechanisms might be adversely affected if the doses were too high. The primary differences between intratracheal instillation and inhalation studies are the delivery of the entire dose in seconds rather than over several hours, bypassing of the defense
mechanisms of the extrathoracic region, and the lack of even distribution of the dose within the lung. Although multiple treatments are generally used, the dosing interval is typically one week. Therefore, the exposure protocol does not mimic normal human exposure. Careful selection of dose is required because high local doses can cause an acute inflammatory effect (bolus effect) that would likely not occur during inhalation exposure. Oberdörster (1996) concluded that this method was well suited for comparative studies of dose response and toxicity ranking of different fiber types, but a well-conducted multidose asbestos study is needed to validate this method for carcinogenicity assessment.

**Intracavity injection**

Intracavity injection studies, particularly i.p., are commonly used to evaluate the carcinogenicity of fibers. The primary advantages of these studies are that they are less labor intensive, are easy to perform, and have been successfully used to investigate the carcinogenic potential and potency of fibers (Oberdörster 1996). Repeated injections at weekly intervals over several months have been performed, but most studies used single injections. The disadvantages of intracavity injection studies are similar to those mentioned above for intratracheal instillation studies and include the following: (1) these methods are nonphysiological in that the lung is completely bypassed, (2) the peritoneal and pleural cavities do not have the same defense mechanisms as the lungs and might be overwhelmed following intracavity injections of large doses, and (3) intracavity injection completely circumvents the fiber selection process that occurs during translocation of fibers from the alveolar region of the lung to the pleura (Kane 1996a). Further, the relationship of fiber durability to the incidence of peritoneal tumors needs to be addressed (Ellouk and Jaurand 1994).

Oberdörster (1996) noted the importance of the MTD in intracavity injection studies, as the bolus delivery of fibers to the peritoneal cavity can result in toxicity due to high local doses.

Wardenbach et al. (2005) supported the use of the intraperitoneal injection model because the carcinogenic potency of various MMVF can differ by three orders of magnitude. The increased sensitivity of the i.p. route would enable the selection of less
potent MMVF5s [see Table 4-6 for i.p. doses (in mg) of glass wool fibers (which have a
ten-fold dose range) and tumor incidences]. They also stated that there was no evidence
that i.p. injection studies would be biased towards producing false positive results since
no mesotheliomas were induced in rats given a high mass of granular silicon carbide dust
by i.p. injection.

4.6 IARC evaluations
The IARC (1988) review concluded that there was sufficient evidence for the
carcinogenicity of glass wool in experimental animals. Later, IARC (2002) evaluated
insulation glass wools and special-purpose glass fibers separately as part of a review of
man-made vitreous fibers and concluded that there was limited evidence in experimental
animals for the carcinogenicity of insulation glass wools but sufficient evidence in
experimental animals for the carcinogenicity of special-purpose glass fibers. The data and
findings from these reviews and publicly available, peer-reviewed carcinogenicity studies
in experimental animals were summarized in this section.

4.7 Summary
Numerous studies of various types of commercial insulation glass wools, special-purpose
glass fibers, and some experimental fibers have been conducted for carcinogenicity in
experimental animals by inhalation, i.p. injection, intrapleural injection, intratracheal
instillation, and intrathoracic injection or implantation. Findings from these studies are
summarized by fiber type, species, and route of exposure in Table 4-10.

Although all inhalation studies conducted prior to the late 1980s were negative, the
results were considered inconclusive because of various study limitations recognized by
researchers in the field, including a failure in some studies to produce tumors in positive
control groups exposed to asbestos fibers. A series of long-term inhalation studies were
conducted in rats and hamsters in the late 1980s and early 1990s to address the
limitations of the earlier studies. Two glass wool fibers (MMVF10 and MMVF11) and
two special-purpose fibers (JM100/475 and 104E) were tested in separate studies.
Significantly increased incidences of lung carcinomas combined with adenomas occurred
in male Wistar rats exposed to 104E microfibers but not to JM100/475 fibers; no
significant increases in lung tumors or mesotheliomas were reported for male F344 rats.
exposed to MMVF10, or MMVF11. However, there were apparent positive trends for both adenomas and combined tumors in male F344 rats exposed to MMVF10. Mononuclear-cell leukemia incidence was statistically significant for F344 rats exposed to Owens-Corning or JM100/475 glass fibers for 86 weeks. In the most recent inhalation study in male hamsters, a mesothelioma was observed in 1 of 83 animals exposed to JM100/475 glass fibers for 78 weeks. Although this result was not statistically significant, the authors considered it treatment related.

Significantly increased incidences of peritoneal tumors (primarily mesothelioma) were reported in almost all i.p. injection studies in rats using different types of fibers including insulation fibers such as MMVF10 and MMVF11 and special-purpose fibers such as JM475 (various diameters), M753, and E glass. However, no tumors were observed in some studies testing experimental fibers that have low biodurability. In most cases, tumor incidences were similar to those seen in the asbestos treatment groups. In addition, increased incidences of pleural sarcomas occurred in rats following intrathoracic implantation of some glass fibers (depending on the fiber dimensions) but not others.

Increased incidences of neoplasms (mesothelioma, pleural sarcoma, and lung carcinoma) were observed in some intrapleural or intratracheal instillation studies in rats exposed to JM100 or JM104 microfibers and in intratracheal instillation studies in hamsters exposed to JM104 microfibers. No tumors were reported following intrapleural or intratracheal instillation of glass wool in mice, guinea-pigs, or rabbits.

A number of studies, including both intrathoracic implantation and i.p. injection of fibers, have been conducted with the intent of comparing fibers with different characteristics, such as differing fiber dimensions and biopersistence/durability. The earliest of these studies by Stanton and co-workers using intrathoracic implantation of glass fibers and other natural and synthetic fibers led the authors to conclude that fiber dimensions and durability were important in determining the tumorigenicity of the material. Later studies using i.p. injection reached similar conclusions in many cases, but some data suggest that the relationship might not be completely defined by those fiber characteristics.

* The only positive study (reported by both Hesterberg *et al.* 1997 and McConnell *et al.* 1999) reported that 1 of 83 hamsters developed a mesothelioma. Although this result was not statistically significant, the authors considered it treatment related.
5 Other Relevant Data

This section discusses the respirability, deposition, clearance, and retention of glass fibers (Section 5.1); their durability and biopersistence (Section 5.2); studies of fiber characteristics and tumorigenicity of synthetic vitreous fibers (SVF) (Section 5.3); toxicity (Section 5.4); genetic and related effects (Section 5.5); and the mechanisms of potential fiber-induced carcinogenesis (Section 5.6). A summary is provided in Section 5.7. Much of what is known about fiber carcinogenicity was discovered in studies with asbestos, and the general principles are relevant for glass fibers. Therefore, this section includes some discussion of asbestos carcinogenicity with comparisons to glass fibers.

5.1 Respirability, deposition, clearance, and retention

Two important concepts relating to exposure to airborne particulates are inhalability and respirability. Inhalability is the ratio of the particle concentration in the inhaled air to that in the ambient air and decreases with increasing particle size. Larger particles settle out of the air faster and are more readily deposited in the extrathoracic region. Respirability refers to the relative amount of airborne particles reaching the alveolar region of the lung and generally increases with decreasing particle size (Hesterberg and Hart 2001).

Variations in fiber density, length, and diameter can be normalized using the equivalent aerodynamic diameter ($D_A$) for $D_{AS}$ above 0.5 µm. $D_A$ is expressed as the diameter of a spherical particle that has the same terminal settling velocity in still air as the fiber and is calculated as follows: $D_A = 1.3\rho^{1/2}d^{5/6}L^{1/6}$ (where $D_A =$ aerodynamic diameter, $\rho =$ density, $d =$ diameter, $L =$ length) (Hesterberg and Hart 2001). In humans, fibers with a $D_A < 1$ µm are 100% respirable, fibers with a $D_A$ of about 4 µm are 50% respirable, and fibers with a $D_A$ of 9 to 10 µm are non-respirable (Hesterberg and Hart 2001). Morgan et al. (1980) reported that respirability in the rat peaked at a $D_A$ of approximately 2 µm and decreased markedly between 2 and 3 µm, with $D_A < 6$ µm being the limit of respirability (no fiber alveolar deposition). Dai and Yu (1998) calculated respirability of inhaled fibers in rats based on deposition models. They reported the limit of respirability in the rat at $D_A > 3.5$ µm and aspect ratios ($L/D$) > 10, and noted that there was appreciable fiber deposition in humans at this fiber size. Respirable fibers can cause adverse effects in the lung such as pulmonary inflammation, cell proliferation, pulmonary fibrosis (collagen
depiction) and neoplasia (Oberdörster 2000). Fibers that are inhalable but non-respirable
can deposit in the extrathoracic and tracheobronchial regions and can cause adverse
effects including acute nasal effects, chronic inflammation, and bronchogenic carcinoma
(Churg 1988).

There are marked species differences in the amount of fibers retained in the airway for a
given exposure concentration with both anatomic and physiologic factors influencing the
dose retained (IARC 2002, Oberdörster 2000). It is important to note that exposure
concentration in ambient air is not equivalent to the dose deposited in the lung.
Deposition is the actual dose deposited in the lung from the inspired air as a result of
inelastic encounters of the particles with the respiratory epithelium and is influenced by
the anatomy and physiology of the airway, respiratory rate, and physical properties of the
fiber. Once deposited, fibers can be removed or cleared from the respiratory tract.
Clearance is defined as the amount of fibers eliminated (cleared) from the lung over a
time period and is influenced by both the physical properties of the fiber and the
physiologic response of the host. Retention is defined as the dose retained within the lung
and is equal to deposition minus the amount cleared. This section briefly reviews some of
the primary concepts relating to deposition, clearance, and retention of fibers in the
respiratory tract.

There are three general anatomic regions of the respiratory tract where inhaled particles
deposit. These are the extrathoracic region (mouth, nose, pharynx, and larynx), the
tracheobronchial region (trachea, bronchi, and ciliated bronchioles), and the alveolar-
interstitial region (respiratory bronchioles, alveolar ducts, alveoli, and pulmonary
interstitium) (IARC 2002).

5.1.1 Deposition
Respirability determines the concentration of particles in the air reaching the alveolar
interstitial region, whereas deposition is the actual dose deposited in the lung. In humans,
40% to 80% of fibers with $D_A < 1 \mu m$ that are inhaled into the alveolar interstitial region
are not deposited and are subsequently exhaled from the lung (Hesterberg and Hart
2001). Deposition is a function of the physical characteristics of the particle, such as size,
shape, and density, and the anatomical and physiological parameters of the respiratory
tract. Distribution of fibers within an alveolar interstitial region is dependent on airway geometry and the composition and physical properties of alveolar fluid. Alveolar fluid consists of an aqueous layer over the pulmonary epithelium covered by a surfactant layer at the air-liquid interface (Geiser et al. 2003).

Fibers deposit in the respiratory tract by impaction, sedimentation, diffusion, and interception (see Glossary for definitions). All four deposition mechanisms occur in humans and experimental animals. Impaction and sedimentation are most effective for particles with $D_A$ of 0.5 to 1 $\mu$m. Deposition due to aerodynamic behavior becomes less important as particle size decreases below 1 $\mu$m, and for particles with $D_A$ less that 0.5 $\mu$m, deposition is mainly determined by diffusional displacement induced by Brownian motion. Interception is more important for deposition of fibrous particles than of spherical particles because it occurs when one end of the particle touches the epithelium of the airway (Bernstein et al. 2005).

Although mechanisms of deposition are similar between humans and experimental animals, there are some important interspecies differences that can influence fiber deposition (IARC 2002, Maxim and McConnell 2001):

- Rats are obligate nose breathers; humans can breathe through the mouth and nose.
- Nasal turbinates in rodents are more complex than in humans and deposit fibers more efficiently; this, along with other differences in size and physiology, results in more and larger fibers depositing in human extrathoracic airways than in the rodent.
- The conducting airways in humans are more dichotomous and symmetrical resulting in greater impaction of fibers at branch points, while in rodents they are monopodial and asymmetrical favoring a more uniform airflow resulting in more distal deposition of fibers.
- In humans, the deposition fraction in the extrathoracic and tracheobronchial regions increases with workload (minute ventilation), and deposition increases when switching from nose to mouth breathing.
Dai and Yu (1998) studied alveolar deposition in rodents and humans and found that aerodynamic fiber diameters between 1 and 2 μm result in peak lung deposition in rodents and humans and that increasing the aspect ratio (ratio of fiber length to fiber diameter) of the fibers decreases the peak deposition. Further, alveolar deposition in rodents does not occur when $D_\lambda$ is greater than 3.5 μm and the aspect ratio is greater than 10. Considerable alveolar deposition occurs in humans with particles having aerodynamic diameters less than 5 μm.

5.1.2 Clearance

Clearance mechanisms vary from region to region within the respiratory tract. Ciliary movement in the extrathoracic region clears deposited particles cranially, primarily towards the pharynx where they may be swallowed or cleared by coughing. Particles within the anterior nasal cavity may be cleared by nose-blowing or sneezing. Ciliated epithelial cells line the lung conductive airways from the pharynx caudally to the terminal (respiratory) bronchioles and clear the airway by moving particles, fibers, cells, and fluids back to the pharynx where they can be swallowed or coughed out. This system, known as the mucociliary escalator, is an important clearance mechanism for the tracheobronchial region. Mucociliary clearance usually takes less than 24 hours. Airway macrophages can clear many particles through phagocytosis and subsequent mucociliary clearance. Phagocytosis is the primary clearance mechanism in the alveolar region and is slower than clearance from other regions of the respiratory tract. The presence of fibers on the lung epithelium stimulates the release of chemotactic factors that attract alveolar macrophages, neutrophils, and other cells involved in inflammation (Wilson and Wynn 2009). These activated cells also release chemotactic, inflammatory, and other factors. Fiber length is known to be an important factor for effective phagocytosis, and there are species differences in alveolar macrophage size and number. Fibers that are too long to be fully phagocytized and too durable to be broken down may remain in the alveolar region with macrophages attached to the fibers (a phenomenon called “frustrated macrophages”) or can translocate to interstitial and pleural sites (Oberdörster 1996). In general, small particles in the alveoli are phagocytized, but they have also been found in alveolar capillaries (Geiser et al. 2003).
The clearance of fibers in the lung over time has been studied by Bernstein et al. (2001a). Tracking percent fiber retention in the lung over time (days following cessation of exposure) resulted in a bi-phasic clearance curve. The rate of fiber clearance (slope of the line) is initially fast and then decreases markedly, resulting in a bi-exponential curve. The fast clearance phase is proposed to represent clearance of short fibers from either the tracheobronchial or alveolar regions, and clearance of long fibers (> 20 μm) from the tracheobronchial region. The slow clearance phase is proposed to describe dissolution of shorter fibers that have accumulated in microgranulomas or the bronchial-associated lymphoid tissue and lymph nodes, or dissolution of fibers that were too long to be phagocytized by macrophages. Because of the importance of alveolar macrophages, species differences in macrophage size and number might affect fiber clearance. Macrophages in humans have an average diameter of about 21 μm compared with about 13 to 14 μm in rats and hamsters (Hesterberg and Hart 2001).

Zeidler-Erdely et al. (2006) investigated the influence of JM100 fiber length on lactate dehydrogenase release in primary cultures of human alveolar macrophages. Human macrophages completely engulfed glass fibers up to 20 μm in length, with no evidence of incomplete phagocytosis or length-dependent toxicity. However, in a study of cytotoxicity using code 100 (JM100) glass fibers and rat alveolar macrophages (Blake et al. 1998), evidence of a length-related toxicity was seen with fibers of 17 and 33 μm. (see Section 5.4.3 for study details.)

Differences in the phagocytic response of rat and hamster alveolar macrophages to SVFs have been investigated by Dörger et al. (2000). Alveolar macrophages were obtained by bronchoalveolar lavage, and macrophage-enriched cell cultures were exposed to either MMVF10 (glass wool, median length 16.3 μm) or MMVF21 (rock wool, median length 19.4 μm) for 20 hours. The phagocytic response was video recorded. Rat macrophages had a significantly ($P < 0.05$) greater percentage of cells with partial phagocytosis than hamster macrophages for MMVF10 (27% for rats vs. 2% for hamsters) and MMVF21 (30% for rats vs. 1% for hamsters). Also, a higher percentage of hamster macrophages completely phagocytized both types of fibers compared with rat macrophages (18% vs. 9% for MMVF10 and 33% vs. 16% for MMVF21 for hamsters and rats, respectively).
After a 2-hour exposure to the fibers, superoxide anion production was also measured by a cytochrome c reduction assay. Rat alveolar macrophages released significantly higher amounts of superoxide anion than hamster macrophages with MMVF21 exposure, but not with MMVF10 exposure. The authors concluded that there were species differences in the phagocytic response that could result in more efficient clearance of inhaled fibers from hamster lung than from rat lung.

Using the same methods and fibers, Dörger et al. (2001) also compared superoxide anion production and phagocytic response of rat alveolar macrophages with rat peritoneal macrophages. Alveolar macrophages had a greater number of partly incorporated fibers than peritoneal macrophages (41% vs. 10%, respectively, for MMVF10; 34% vs. 12%, respectively, for MMVF21) and had a lower percentage of fiber-free macrophages (9% vs. 50%, respectively, for MMVF10, 9% vs. 29%, respectively, for MMVF21). Alveolar macrophages produced significantly greater amounts of superoxide anion than peritoneal macrophages when exposed to MMVF21 (approximately 150 vs. 10 nmol/mg protein per 2 hours), but exposure of alveolar or peritoneal macrophages to MMVF10 did not result in production of superoxide anions. The authors concluded that these data are consistent with a higher biopersistence of mineral fibers in the peritoneal cavity as compared with the lung.

5.1.3 Retention
Retention is defined as deposition minus clearance. Chemical composition, fiber size distribution, number of fibers in the lung, and time since the last exposure are important factors. Based on the experimental data, two possible mechanisms have been proposed to explain the length-related patterns of fiber retention (Oberdörster 2002). Short fibers are expected to be efficiently phagocytized by the alveolar macrophages and transported from the alveoli to bronchioles where they are cleared by the mucociliary escalator. Long fibers are resistant to effective phagocytosis but may be subject to dissolution or transverse breakage. As the long fibers break, the population of short fibers is increased; therefore, the population of long fibers typically decreases faster than the population of short fibers for nondurable types of fibers (see Section 5.2). If long fibers are resistant to transverse breakage or dissolution (e.g., amphibole asbestos), they are retained. The
second possible mechanism is based on differences in the intracellular and extracellular compartments of the lung. Long fibers tend to remain in the extracellular compartment because they cannot be completely phagocytized by macrophages. The extracellular compartment is at near-neutral pH, whereas phagocytosis by alveolar macrophages exposes the fibers to the acidic pH and digestive factors within the phagolysosomes. Thus, the solubility of long fibers at neutral pH would be an important factor in retention of the fiber.

A limited number of studies are available regarding retention of fibers in humans; however, the average overall retention half-time for poorly soluble fibers has been reported to be hundreds of days. In one study (McDonald et al. 1990), which used a subset of the Marsh et al. cohort (see Section 3.1.1), analytical transmission electron microscopy was used to determine fiber retention in lung tissue. The selected population consisted of 112 MMVF workers (101 glass wool workers and 11 rock or slag wool workers) that had died between 1952 and 1979, and for whom tissue was available from autopsies. The unexposed group consisted of 112 autopsies from the same hospital. There was no significant difference in retention of fibers in the 112 exposed workers as compared with the unexposed group. The exposed workers had a mean exposure duration of 11 years and a mean elapsed time since last exposure of 12 years. Fibers were detected in 29 of the 112 production workers compared with 28 of 112 in the unexposed group. Fiber numbers detected in the exposed workers and the unexposed group were similar to those found after environmental exposure. However, 10 of the 112 exposed workers and 2 of the 112 unexposed group had more than 1 million asbestos fibers/g dry lung tissue. The authors concluded that either the synthetic fibers disappeared from the lung in less than 12 years, or the exposed workers did not inhale enough respirable SVF fibers to show a difference from controls; alternatively, fixative fluids might have altered some retained fibers in the lung.

5.2 Biodurability and biopersistence of glass fibers

This section reviews several studies that illustrate the differences in biodurability and biopersistence among fiber types and the various ways these properties are measured.
The relationship between fiber biopersistence and pathogenicity in experimental animal models and humans is also discussed.

5.2.1 Definitions

Biodurability describes the rate of removal of a fiber from the lungs by dissolution or disintegration, the latter due to partial dissolution. It is assumed that biodurability is similar in rats and humans since the ionic milieu in the lung is also relatively similar. On the other hand, biopersistence also includes the removal of fibers from the lung by physical clearance of entire fibers, *e.g.*, by ciliary or macrophage-mediated clearance. Therefore, biopersistence is equal to biodurability plus physiological clearance and refers to the capacity of a fiber to persist and to conserve its chemical and physical features over time in the lung (Hesterberg and Hart 2001).

5.2.2 Fiber dissolution

Physico-chemical processes can act on fibers in the lung resulting in chemical dissolution, leaching, and mechanical breaking (IARC 2002). Dissolution occurs when water molecules attack the surface of the fiber. For many SVFs, certain components dissolve more rapidly than others (leaching). Leaching results in changes in fiber composition over time. As the zones of leached-out, lower-density material expand, fiber weakness (*e.g.*, fractures, peeling, and pitting) and breakage occur. Therefore, chemical composition and surface reactivity of the fiber affect its dissolution rate. Maxim *et al.* (2006) reported that fluorine and oxides of boron, magnesium, calcium, sodium, and barium increase the dissolution rate, while aluminum oxide decreases the dissolution rate of borosilicate glass fibers.

Experimental dissolution rates of various fibers have been studied in a number of *in vitro* and *in vivo* systems. Cell-free systems typically use balanced salt solutions to simulate lung fluids and are conducted at near neutral pH (to simulate the pH of extracellular fluid) or at a pH of 4.5 (to simulate the pH of the phagolysosomes of macrophages). Results with cell-culture studies are generally consistent with results from the cell-free systems, but dissolution of glass wool is faster in cell-free systems. Reported *in vitro* dissolution rate constants in cell-free systems at neutral pH are < 1 ng/cm² per hour for crocidolite, 8 to 12 ng/cm² per hour for E-glass and 475 glass, and 100 to 300 ng/cm² per
hour for building insulation glass wools (Zoitos et al. 1997). Although experimental
dissolution rates for glass fibers show considerable variability (up to a 30-fold range),
they generally show some correlation with clearance rates of long fibers from the lung in
short-term biopersistence studies (see next section). Therefore, in vitro dissolution tests
have been used to screen for toxicity.

Luoto et al. (1994, 1995b) studied the effect of fiber length on the dissolution of
commercial glass wool and rock wool fibers in cell-culture medium with and without rat
alveolar macrophages present. Atomic absorption spectroscopy was used to determine the
amount of iron, aluminum, or silicon remaining in original and tested fibers. More iron
and aluminum dissolved from fibers in culture with macrophages, while more silicon was
dissolved from fibers in culture medium without cells. Further, they found that glass wool
fibers (MMVF10, MMVF11) dissolved more readily at pH 7 in culture medium alone
than did rock wool fibers, whereas rock wool fibers dissolved more readily when
macrophages were present in the culture medium (Luoto et al. 1995a). These authors
concluded that the intracellular and the extracellular dissolution of the fibers differ, and
that cell-culture systems were preferable to cell-free systems for assessing in vivo fiber
durability and dissolution.

The in vivo clearance of fibers > 20 μm in length from the lungs of F344 rats has been
reported to result from the dissolution of the fibers in extracellular fluid at approximately
the same rate as the dissolution rate (k_{dis}) measured in simulated lung fluid in vitro, a
process that depends on the chemical composition of the fibers (Eastes and Hadley 1995,
Eastes et al. 1995). The predicted dissolution rates were similar for inhalation studies of
MMVF10 and MMVF11 glass fibers, MMVF21 rock wool, MMVF22 slag wool, and
crocidolite asbestos (Eastes and Hadley 1995) and for intratracheal instillation studies of
MMVF10 and MMVF11 glass fibers and three experimental glass fibers, X7779, X7753,
and X7484, with k_{dis} values of 2, 100, and 600 ng/cm² per hour, respectively (Eastes et
al. 1995). For fibers < 20 μm in length they proposed that physical removal occurred by a
macrophage-mediated process that did not differ by fiber type. The authors also reported
that computer simulations of fiber clearance based on these processes agreed well with in
vivo measurements of fibers remaining in the lung up to a year after exposure.
The dependence of the in vitro $k_{\text{dis}}$ of fibers on their chemical composition was the basis for a method of calculating those rate constants by Eastes et al. (2000a). The individual dissolution rates for the oxides were summed based on their weight percent multiplied by a coefficient ($P_i$) determined by fitting experimental data for $k_{\text{dis}}$ measured in vitro for a set of 62 fiber types, which resulted in a correlation coefficient ($r^2$) of 0.96 for the calculated versus the measured values. The authors also calculated $k_{\text{dis}}$ values for approximately 30 additional fiber types not used to determine the coefficients for the oxides and reported that they provided “a reasonable estimate of $k_{\text{dis}}$” over a range of 100,000, much larger than the range of approximately 100 for the $k_{\text{dis}}$ values on which the coefficients were based. The same authors also estimated dissolution rates from in vivo biopersistence data obtained from published intratracheal instillation and short-term inhalation studies, as well as for an unpublished inhalation biopersistence study of six fiber types, and they reported good agreement with dissolution constants measured in vitro for the same fiber types (Eastes et al. 2000b). The dissolution rates were estimated from the decrease in diameter of fibers > 20 μm retained in the lungs. The authors noted that the majority of datasets (19 of 31) for different fiber types had $r^2$ values above 70%, and the overall correlation between in vivo $k_{\text{dis}}$ and $k_{\text{dis}}$ measured in vitro for the same fibers was 0.727, which the authors considered to be in reasonably good agreement.

Nguea et al. (2008) proposed an in vitro test for fiber degradation using a human monocytic cell line (U-937). Crocidolite fibers (asbestos), glass wool fibers (CM44), and rock wool fibers (HDN) were tested. After a 24-hour incubation of U-937 cells with each of the fibers, phagocytosis was observed; however, dissolution of the fibers (as observed by scanning electron microscopy) did not occur. Degradation of CM44 and HDN fibers occurred only with activation of the monocytes with E. coli bacteria, E. coli culture media, IL-6, or TNF-alpha, but not with lipopolysaccharide (LPS), B. subtilis, S. aureus, or heat-inactivated E. coli. Asbestos fibers did not degrade in the presence of E. coli. The pattern of HDN fiber degradation observed in vitro was in accord with that observed in rats after a one-month intratracheal exposure.

In general, biodurability of various fibers in the lung have been ranked as follows: glass fibers < refractory ceramic fibers < chrysotile asbestos < amphibole asbestos (Collier et
Collier et al. (1994, 1995) compared the durability of an experimental glass fiber (X7753) of uniform diameter (2 μm) by injecting fibers into the peritoneal cavity and by intratracheal instillation to the lung of female Fischer rats. Scatter plots of fiber diameter vs. fiber length were produced to estimate the injected fiber size distribution and the size distribution for the fibers recovered 150 days after either intratracheal instillation or intraperitoneal injection. After 150 days of exposure, fibers were recovered from the tissues by lavage. Fiber diameters by both routes of exposure had decreased, whereas there was an apparently greater decrease in fiber length by the intratracheal route of exposure. [These conclusions were based on a qualitative assessment of the scatterplots by the authors.] Peak diameters of fibers > 20 μm and < 20 μm in length were plotted against days after administration by both routes. The diameters of long fibers (> 20 μm) declined from 2 μm to below 0.4 μm by 50 days after administration by the intratracheal instillation route, but remained above 1 μm for intraperitoneal exposure. Diameters of short fibers (< 20 μm) remained above 1 μm for both injection routes [diameters estimated from graphs]. Their results suggested that dissolution rates of long fibers were slower in the peritoneal cavity compared with the lung. In the peritoneal cavity, diameters of both short and long fibers declined at a rate similar to that of short fibers in the lung. Doses greater than 1.5 mg in the peritoneal cavity resulted in clumps of fibers (nodules) that were either free in the cavity or bound to peritoneal organs and were associated with classic foreign body reactions.

5.2.3 Biopersistence studies
Yu et al. (1998) evaluated the biopersistence of MMVF10 glass wool, MMVF11 glass wool, MMVF21 rock wool and MMVF22 slag wool and developed a clearance model in the rat lung using experimental data from short-term, nose-only inhalation biopersistence studies. Crocidolite asbestos was used as a positive control. Their model accounted for differential mechanical clearance by alveolar macrophages, in vivo dissolution of fibers, and breakage of long fibers. The in vitro dissolution rate was correlated with the in vivo dissolution rate, although the in vivo rate was much lower. Fiber breakage was related to dissolution. The breakage rate of the more soluble fibers was higher. MMVF10 had the highest dissolution and breakage rate followed closely by MMVF11 and MMVF22. Because crocidolite fibers are highly durable, the authors assumed that removal was by
macrophage-mediated mechanical clearance alone. Different half-times were calculated for different fiber lengths. For crocidolite fibers shorter than 5 μm, mechanical clearance was about the same as for nonfibrous particles but decreased with fiber length. For crocidolite fibers longer than 20 μm, the average mechanical clearance rate was 0.001 (1/day) and corresponds to a half-time of 693 days (Muhle and Pott 2000).

A different approach for the calculation of half-times was used by Bernstein et al. (1996). The authors examined the biopersistence of nine SVFs in the rat. These included MMVF11, three experimental glass wools (including B-01-0.9), one commercial stone wool, and four experimental stone wools. Groups of 56 male F344 rats were exposed (nose only) to a well-defined, rat-respirable aerosol (mean diameter < 1 μm) at a concentration of 30 mg/m^3 for 6 hours per day for 5 days. Groups of eight animals were sacrificed at 1 hour, 1 day, 5 days, and 4 weeks following the last day of exposure and at 13, 26, or 52 weeks following the first day of exposure. Clearance, when modeled with a single exponential curve, did not provide a good fit to the experimental data for many of the fibers. Both a fast-clearance phase and a slow-clearance phase were observed for many of the fibers; therefore, a weighted clearance half-time (WT½) was calculated. This method provided a much better fit to the data. The WT½ for World Health Organization (WHO) fibers was 28 days for MMVF11 and ranged from 11 to 15 days for the three experimental glass wools. WHO fiber clearance was shown to represent clearance of shorter fibers (5 to 20 μm) but was not a good indicator of the clearance of the more biologically relevant longer fibers (> 20 μm). The WT½ for the longer fibers was 13 days for MMVF11 and only 2 to 4 days for the experimental glass wools, indicating that clearance of long glass fibers was rapid due to dissolution and breakage. For comparison, the WT½ for crocidolite fibers longer than 20 μm was 536 days. [This approach uses the fraction of the short half-time that does not contribute to fiber accumulation in the lungs, but some have suggested that only the slow phase of the half-time should be used.]

Hesterberg et al. (1998) used the rat inhalation model to compare biopersistence of long amosite with five SVFs. The test fibers included two special-purpose fibers, MMVF32 (E

---

4 WHO fibers are respirable fibers with lengths greater than 5 μm, diameters less than 3 μm, and aspect ratios (ratio of fiber length to diameter) ≥ 3:1 (ATSDR 2004).
glass) and MMVF33 (475 glass). Fischer rats were exposed for 6 hours per day for five
days and followed for one year. Mass concentrations were adjusted to achieve target
concentrations of 150 fibers/cm\(^3\) > 20 \(\mu\)m. Groups of five to eight rats were sacrificed at
nine post-exposure time points (1, 2, 7, 14, 30, 60, 90, 180, and 365 days) to evaluate
lung fiber burdens, dimensions, and morphology. Lung deposition of fibers > 20 \(\mu\)m was
similar for amosite and the five SVFs, while deposition of WHO fibers was more
variable. The authors used a two-pool, first-order kinetic model to describe removal of
fibers from the lung. Lung burdens for all six fibers were reduced about 35% during the
first 90 days compared with day 1 levels. However, during the subsequent slower
clearance phase (~275 days), the number of long amosite fibers was 80% of the 90-day
value while the number of glass fibers was about 25% of the 90-day value. For amosite
fibers > 20 \(\mu\)m the half-times of the fast pool and slow pool were 20 and 1,160 days,
respectively, while the \(WT_{1/2}\) was 418 days. For MMVF32 and MMVF33, the half-times
were, respectively, 7 and 5 days (fast pool), 179 and 155 days (slow pool), and 79 and 49
days (\(WT_{1/2}\)). Amosite fibers did not show any surface deterioration during the 365 days
of lung residence, while slight surface etching was noted for the glass fibers. The authors
noted that in this study (and previous studies) between 20% and 60% of long fibers
typically cleared from the lung during the first two weeks regardless of the dissolution
rate of the fiber. This rapid removal indicates that these fibers likely deposit in the upper
airways and are cleared by ciliary action. The authors noted that the half-times for the
slow pool suggest that glass fibers were subject to dissolution and transverse breakage
during lung residence while amosite was not.

5.3 Studies of fiber characteristics and tumorigenicity of SVF

5.3.1 Intrathoracic and intraperitoneal studies
Most studies that have examined fiber characteristics and tumorigenicity have used
intrathoracic implantation or i.p. injection. Stanton et al. (1977, 1981) conducted
experiments testing the tumorigenicity of 22 glass fiber preparations, including 18
borosilicate glass fibers, 13 samples of crocidolite, 8 samples of aluminum oxide
whiskers, 7 talcs, 7 dawsonites, 4 wollastonites, 2 tremolites, 2 attapulgites, 2 halloysites,
2 crystals of silicon carbide and potassium titanate, and 1 crystal of nickel titanate in the
same pleural implantation model. [The results for glass fibers were reported in Section 4,
and all results are summarized here. The tumor incidences and percent tumor probabilities, and common log of the fibers/μg with diameter < 0.25 μm and length > 8 μm are shown in Table 5-1. Based on induction of significant numbers of pleural sarcomas by fine, durable fibers of chrysotile, crocidolite, amosite, tremolite, glass, attapulgite, dawsonite, aluminum oxide, silicon carbide, and potassium titanate, Stanton et al. concluded that “the carcinogenicity of fibers depends on dimension and durability rather than on physicochemical properties.”

</table>
1 Stanton et al. (1981) examined 22 glass fiber types (including the 17 fibers tested in the 2 1977 paper) along with 50 natural and synthetic fibers not tested in the earlier study and 3 reported incidences of pleural sarcomas in various control groups (Table 5-1). These 4 included untreated controls (3 of 488), noncarcinogenic pulmonary implants (9 of 432), 5 and noncarcinogenic pleural implants (17 of 598). The authors reported a combined 6 incidence of pleural sarcomas in all control groups of 7.7% based on the life-table
method. Tumor incidences in the individual experiments that exceeded 30% were considered significantly different from the combined controls by the authors. The authors reported that the incidence of malignant mesenchymal neoplasms correlated with fiber dimensions. The correlation coefficient ($r^2$) was 0.8 for fibers < 0.25 µm in diameter and > 8 µm in length, but high correlations also were noted in categories with diameters < 1.5 µm and lengths > 4 µm ($r^2 = 0.45$ to 0.68). The authors also suggested that their experiments could simply be measuring the efficiency of phagocytosis of fibers of different dimensions since short and large-diameter fibers were avidly phagocytosed, while long, thin fibers showed negligible phagocytosis.

As noted above and in Section 4.4, Stanton et al. (1981) reported correlations between fiber dimensions and the probability of tumor formation, with the best fit for fibers < 0.25 µm in diameter and > 8 µm in length and another correlation for fibers with a diameter of up to 1.5 µm and > 4 µm in length. Experimental data from the Stanton et al. publications were re-analyzed by Bertrand and Pezerat (1980), Oehlert (1991), and Wylie et al. (1987).

Bertrand and Pezerat (1980) confirmed the dependence with fiber dimensions. Those authors used the data from Stanton et al. and looked for other relationships between carcinogenicity and fiber size distribution using a new statistical approach (correspondence analysis, multiple regression on fiber length and diameter, and linear regression on the average aspect ratio). They reported a strong positive correlation between tumor probability and long fibers with a small cross-section, and almost no correlation with small fibers with a large cross-section. Bertrand and Pezeret concluded that the carcinogenicity of fibers is a continuous, increasing function of the aspect ratio, and thus show that it is not possible to separate the effects of length and diameter.

Oehlert (1991) also confirmed the hypothesis that the logarithm of the number of fibers < 0.25 µm in diameter and > 8 µm in length were predictive of tumor yield. Based on a reanalysis of the Stanton et al. pleural sarcoma data, Oehlert reported that the log mean aspect ratio was not as good a predictor of tumor incidence as the number of index particles and reconfirmed the number of index particles as the primary dimensional
predictor of tumor incidence. However, in contrast to the “Stanton hypothesis,” which states that dimensional properties alone determine carcinogenicity, there was evidence that mineral type is important. Significant improvements in fit were accomplished by allowing separate curves for the different mineral types and by including additional covariates. Thus, using a single criterion (i.e., number of index particles) for all mineral types could result in large overestimates or underestimates of tumor potential. Oehlert concluded that dimensional properties are not the sole determinant of carcinogenicity.

Wylie et al. (1987) studied a point raised by Stanton et al. acknowledging that some samples did not fit well, especially some asbestos samples. Wylie et al. first confirmed that the number of index fibers [particles] (defined as those < 0.25 μm in diameter and > 8 μm in length) reflected differences in carcinogenic potency, but that the outliers were related to the mathematical calculations when samples contained a low number of fibers of such dimensions. They then determined the frequency distributions of length and width of seven crocidolite samples that were used by Stanton et al. to evaluate possible sources of measurement error, and to discuss the effects of these errors on the utility and reliability of using the number of index particles as a measure of mineral fibrosity and carcinogenicity. Although there were some differences in the frequency distributions compared with Stanton et al., the authors concluded that the index number (log of the number of index particles) was reproducible and relatively insensitive to variations in technique using the same instrumentation. The population of mineral fibers studied by Stanton fell into two groups: those whose index number was indeterminant (no index particles) and those whose index numbers fell between 2.5 and 6.0. Wylie et al. noted that Stanton assigned an index number of 0 to those populations without index particles, thus creating a bimodal distribution rather than a continuous function throughout the range of the independent variable. Therefore, Wylie et al. reanalyzed the data using only those populations that contained index particles. The correlation coefficient of logit of tumor probability with index number was 0.307 (r² = 0.094) and was not significant. However, the correlation coefficient derived from a linear regression of tumor probability with index number was 0.53 (r² = 0.281), which was significant but lower than reported by Stanton. Wylie et al. concluded that the correlation coefficients were low enough to
suggest the possibility that factors other than size and shape play a role in mineral fiber carcinogenicity.

Many studies have investigated the tumorigenic properties of fibers in rats by i.p. injection and are reviewed below. Where possible, the tables include information on fiber dimensions (diameter and length), durability (*in vitro* dissolution rates, $k_{\text{dis}}$, or *in vivo* half-lives, $T_{1/2}$), dose (in mg and number of fibers) and Z-scores [calculated by NTP based on the reported composition (see Section 1.3.1)].

Pott *et al.* (1974) compared the carcinogenic effects of glass fibers (average diameter of 0.5 $\mu$m) with chrysotile, gypsum, nemalite, and palygorskite following i.p. injection into Wistar rats [sex not specified] (Table 5-2). Based on their results they suggested that fibers less than 10 $\mu$m in length could still be carcinogenic. Similarly, they proposed that carcinogenicity could not be limited to fibers with diameter less than 0.5 $\mu$m based on the size distribution of fibers in their sample.

*No information available on durability or number of fibers injected.

Pott *et al.* (1987) reported results from 15 different experiments with approximately 50 fibrous dusts prepared from synthetic and naturally occurring fibers. Experiments 1 through 13 are summarized in Table 5-3. Experiment 14 involved i.p. injections of cadmium and nickel compounds and is not summarized here. Preliminary results from experiment 15 (which was still in progress) were reported through 28 months, but the complete results were reported in a subsequent publication (Pott *et al.* 1989) and are presented below (see Table 5-4). Rats were reported as tumor bearing if they were
diagnosed with either sarcoma, mesothelioma, or carcinoma of the abdominal cavity, but
the authors noted that only a few carcinomas were found, and the three tumor types could
not always be differentiated histologically with certainty. The overall conclusion by Pott
et al. was that length and durability of fibers are significant determinants of carcinogenic
potency; however, they pointed out that relatively thick rock and ceramic fibers were
“unexpectedly strong” as carcinogens. [The authors did not report any measures of
durability for the fibers that they tested, however.] They did recommend re-measuring
several of the fiber samples tested to confirm the relationship between fiber dimensions
and carcinogenic effects.

*No information available on durability or number of fibers injected.*

*b Relatively large diameter fibers inoculated in 4 mL saline “by laparotomia [laparotomy] in nembutal anesthesia.”

Pott *et al.* (1989) tested 104/475 glass fibers by i.p. injection in female Wistar rats along with 10 other fibrous dusts and 3 granular dusts (not reported here) (Table 5-4). The authors expressed concern about their ability to compare the dose-response relationship between asbestos fibers and man-made mineral fibers because of uncertainty about the number of fibers in each size category, their durability, and their surface properties. They did point out that actinolite and 104/475 glass fibers had similar size distributions based on the available data, and both fibers were durable in rats; however, the number of fibers that induced tumors at approximately a 60% rate was much greater for the glass fibers than for the actinolite fibers. They also found high tumor incidences for the relatively thick basalt fibers and one of the ceramic fibers (Fiberfrax) even though the number of fibers injected per rat was smaller for these fiber types than for the glass fibers. Further, the number of fibers longer than 5 µm was similar in 0.25 mg of actinolite and 75 mg of basalt fibers, and these preparations resulted in similar tumor incidences (56% for actinolite and 57% for basalt). The authors suggested that the carcinogenic potency of the
fibers did not decrease with increasing diameter as would have been expected based on earlier publications, and they proposed that either the percentage of very long (> 20 μm) fibers in the two preparations or some unknown surface properties might explain the unexpected results.

F.R.G. = Federal Republic of Germany; NR = not reported; PVNO = polyvinylpyridine-N-oxide; UICC = Union Internationale Contre le Cancer (International Union Against Cancer).

aNo information available on durability of fibers injected.
bOnly a single value was reported for fiber number, and the authors did not relate that number to the dose in mg.

Pott et al. (1991) injected female Wistar rats with 3 different glass fibers with different half-lives in vivo (Table 5-5). The mean half-lives ranged from 38 days for B-2 glass wool to 107 days for B-1 glass wool and 238 days for B-3 glass wool. Pott et al. noted that only the most durable of the fibers caused tumors. Both the dose and length of the fibers were varied, with fibers designated as either K (kurz, German for short), M (medium), or L (lange, German for long). In the additional experiments reported in Table
5-5, Pott et al. injected a number of different fibrous dusts i.p. They summarized the main results of these experiments for glass fibers as demonstrating that slightly durable glass fibers (B-1 and B-2) did not induce a carcinogenic effect at the doses and fiber sizes tested, which included up to $5.80 \times 10^9$ B-2 glass fibers with median length of 6 μm and median diameter of 0.51 μm.

NA = not available; NR = not reported; Z-score = sum of the percent composition of alkali and alkaline earth oxides (Na<sub>2</sub>O + K<sub>2</sub>O + CaO + MgO + BaO) (see Section 1.3.1 and Table 1-4) [calculated by NTP].

*No information available on *in vitro* dissolution rate of fibers injected.
They illustrated the relationship between fibers with long half-life that induced tumors compared with fibers with short half-life that were not carcinogenic after i.p. injection (Figure 5-1).

![Diagram depicting relative difference in fiber half-lives and carcinogenicity](image)

**Figure 5-1. Diagram depicting relative difference in fiber half-lives and carcinogenicity**

Source: Pott et al. 1991, used with permission.

Data shown are relative percentage of fibers > 5 μm long vs. time after intratracheal instillation.

Pott et al. also plotted the dose-response relationship between fiber types and percent tumor incidence as shown in Figure 5-2. They noted that the regression lines for the amphibole fibers (actinolite and crocidolite) differed in dose by a factor of about 20 compared with the regression line for the 6 different glass fibers tested, but they did not have an explanation for the difference.
Figure 5-2. Exposure dose by i.p. injection of different fiber types and percent tumor incidence

Source: Pott et al. 1991, used with permission.

A = actinolite, K = crocidolite, B = basalt, D = diabase, C = ceramic (2 types); open squares = chrysotile, closed circles = silicon carbide, 1-6 = glass microfibers (1-3 & 6 = Manville; 4 & 5 = Bayer): 1 = M-104/E, 2 = M-100/475, 3 = M-104/475; 4 = B-3K, 5 = B-3L, 6 = M 106.

Roller et al. (1996) conducted a study designed to examine the dose-response relationship for fiber types of different dimensions and in vivo durabilities (Table 5-6). The relationships were discussed in Roller et al. (1997). The fibers were divided into groups of relatively long, thick fibers (aspect ratio > 5:1, median length 8 to 17 μm, median diameter 0.7 to 1.2 μm) and short, thin fibers (aspect ratio > 5:1, median length 2 to 4 μm, median diameter 0.2–0.5 μm). The long, thick fibers included the following: fibers B-01-0.9, B-09-2.0, B-20-2.0, glass wool fibers MMVF11, stone wool fibers MMVF21, slag wool fibers MMVF22, M-stone 3, and R-stone-E3. The short, thin fibers included the following: glass fibers B-09-0.6, B-20-0.6 [reported in Table 1 of Roller et al. (1997) as B-0.9-0.6, but the doses matched the B-20-0.6 fiber type], glass fibers M-753-104, and crocidolite and tremolite asbestos. The probit model was fitted to the data, and each data set was constrained to a common slope (Figure 5-3).
Figure 5-3. Probit analysis of the number of fibers injected (i.p.) and the frequency of peritoneal mesothelioma in rats

Source: Roller et al. 1997, reproduced with permission from Environmental Health Perspectives.

Combined data from three experiments (1990–1992). Combined results of asbestos studies (actinolite and crocidolite; combined historical data) are presented in the top panel, broken line. Data are presented in 2 panels for clarity.

L = length, D = diameter.

1 Data from crocidolite, R-Stone-E3, and MMVF21 were not included in the probit analysis because the results for these fibers were at the extremes of either no response for R-Stone-E3 or a near maximal response at the lowest dose tested for MMVF21 and crocidolite. The normalized data for the various dusts also were plotted with a linear scale for frequency of mesothelioma, which resulted in a slightly superlinear curve (Figure 5-4). The authors fitted a curve separately to the data for the B-01-0.9 data, which resulted
in a sublinear shape. The authors noted that this dust has a relatively low durability and was tested with the highest dose of 1,000 mg.

Figure 5-4. Percent incidence of mesothelioma after i.p. injection of various fiber dusts

Source: Roller et al. 1997, reproduced with permission from Environmental Health Perspectives.

Shape coefficient is calculated from the Weibull model and fitted to normalized data. Insert is for B-01-0.9 fiber (sublinear curve; dose values normalized so that scale of the x-axis is comparable with the larger plot).

The overall conclusion by Roller et al. (1997) was that the mechanism responsible for mesotheliomas in their experimental system was specific to the fibrous shape of the particles administered based on parallelism of the probit lines calculated for each fiber type.

NA = not available; Z-score = sum of the percent composition of alkali and alkaline earth oxides ($\text{Na}_2\text{O} + \text{K}_2\text{O} + \text{CaO} + \text{MgO} + \text{BaO}$) (see Section 1.3.1 and Table 1-4) [calculated by NTP].

*a*No information available on *in vitro* dissolution rate of fibers injected.
Lambré et al. (1998) conducted a study to evaluate five newly developed MMVF\textsubscript{s}, two glass wools (A and C) and three stone wools (F, G, and H) (Table 5-7) using a testing protocol and dose selections (0.5–2.0 × 10\textsuperscript{9} Pott fibers [defined as \(L > 5 \text{µm}, D < 2 \text{µm}\) and \(L/D > 5\)]) recommended by the German MAK (Maximale Arbeitsplatz Konzentration [maximum workplace concentration]) Commission (intraperitoneal test in female Wistar rats using a single injection, for a long duration). [The highest dose technically injectable for glass and stone fibers was 35 mg and 55, which was the lower limit of the MAK Commission requirement, so two successive injections were required.] The fibers were characterized by high dissolution rates (\(k_{\text{dis}}\) \textit{in vitro} and short biopersistence (\(t_{1/2}\) in the inhalation test from 3.5 up to 13 days for fibers with length > 20 µm. The samples had been specially manufactured and processed to enrich for fibers with lengths (median length between 10 and 15 µm) and diameters (medium less than 1 µm) that are considered to be the most toxic. The stone wool fibers designated H had the highest weighted half-time (13 days) for persistence for fibers > 20 µm, although only slightly higher than the range of the other 4 fibers, which was 3.5 to 8.5 days (Bernstein et al. 1996). The H fibers caused 7/51 (14%) mesotheliomas and 9/51 (17.6)% intra-abdominal tumors with serosal spread [IATSS], which included all malignant tumors (mesothelioma, carcinoma, and sarcoma beginning and/or spreading in the abdominal cavity) at the highest dose (55 mg) tested, while none of the other fibers caused more than 2/51 (4%) mesothelioma at any dose tested. The positive control, crocidolite, caused 20/51 (39%) mesothelioma and 25/51 (49%) IATSS at the highest dose of 0.5 mg, and showed a dose response relationship with tumor development. The authors summarized the findings as showing that the i.p. test tended to demonstrate a low carcinogenic potency (except for fiber H) for the fibers that they studied, which all had high dissolution rates \textit{in vitro} at pH 7.4 along with low biopersistence for fibers with length > 20 µm.

\textsuperscript{a}Weighted half-life reported by Bernstein et al. 1996.

\textsuperscript{b}k\textsubscript{dis} = \textit{in vitro} dissolution rate, measured at pH = 7.4; NA = not available; NR = not reported; Z-score = sum of the percent composition of alkali and alkaline earth oxides (Na\textsubscript{2}O + K\textsubscript{2}O + CaO + MgO + BaO) (see Section 1.3.1 and Table 1-4) [calculated by NTP].

\textsuperscript{c}IATSS = International Agency for Research on Cancer (IARC) Total Slope Score.
Critical fibers (also called Pott fibers by some authors) are defined by $L > 5 \, \mu m$, $D < 2 \, \mu m$, $L/D > 5$.

IATSS are defined by the authors as intra-abdominal tumors with serosal spread, which included all malignant tumors (mesothelioma, carcinoma, and sarcoma) beginning and/or spreading in the abdominal cavity.

Results for Fiber B were reported by Grimm et al. (2002) who noted that the fiber type was used in the Lambré study as an internal comparison, but the results were not published by Lambré et al. “due to the commercial competitive situation at that time.”
Miller et al. (1999b) tested the carcinogenicity of 100/475 glass microfibers, amosite, MMVF10 glass wool, MMVF21 and MMVF22 stone wool, and RCF1, RCF2, and RCF3 refractory ceramic fibers by i.p. injection to male Wistar rats. The authors stated that the objectives of their study included comparing the abilities of a range of mineral fibers to produce mesothelioma in rats by i.p. injection and to relate the dimensions and durability of the fibers with their carcinogenic potential. The set of fiber samples was selected to represent a range of physico-chemical properties. [A silicon carbide whisker was also tested, but the results are not reported here; no control group was included.] The fiber characteristics and the tumor incidences resulting from the i.p. injections are reported in Table 5-8. No statistical comparisons were reported, but the highest tumor rate was reported for MMVF21 (19/20) followed by amosite and RCF1 (21/24 for both fiber types). Tumor rates for the glass wool-treated groups were 13/22 for MMVF10 and 8/24 for 100/475 glass. One refractory ceramic fiber (RCF4) produced no tumors (0/22), and the authors noted that this sample, which was derived from RCF1 by heat treatment, had “many fewer long fibres than RCF1.” The authors used stepwise regression models with mass dose injected, estimated numbers of injected fibers for various length and diameter categories, estimated rates of biopersistence in the lung after intratracheal injection, and estimated coefficients of dissolution in vitro. At step 2, the model predicted decreasing survival (the response variable was median lifetime) with increasing numbers of longer fibers and increasing biopersistence (the authors noted that the model preference for biopersistence over in vitro dissolution rate was “consistent with the belief that dissolution is not the sole factor governing biopersistence”). However, at step 3, the model predicted increasing survival with increasing fiber numbers over 10 μm in length, which the authors considered “more problematic” because of the direction of the effect. The authors noted that they preferred the first model on the basis of plausibility, but they also suggested that step 3 might represent “overfitting” based on the size of the dataset and the fact that step 2 represented the largest gain in variance explained for the model.
Table 5-8. Fibers tested by Miller et al. (1999b) (sorted by \( k_{\text{dis}} \) in descending order)*

\( k_{\text{dis}} = \text{in vitro} \) dissolution rate; NA = not available; RCF = refractory ceramic fiber; Z-score = sum of the percent composition of alkali and alkaline earth oxides (Na\(_2\)O + K\(_2\)O + CaO + MgO + BaO) (see Section 1.3.1 and Table 1-4) [calculated by NTP].

*No information available on \textit{in vivo} half-life (\( T_{1/2} \)) of fibers injected.

** Injected doses were selected to provide an estimated \( 10^6 \) fibers > 5 \( \mu \)m in length.

* Fiber numbers provided for each diameter class (reported separately for < 0.95 \( \mu \)m and > 0.95 \( \mu \)m); target dose was a total of \( 1,000 \times 10^6 \) fibers.

* Different \( k_{\text{dis}} \) values for MMVF10 were reported by Hesterberg and Hart (2001) (300 ng/cm\(^2\) per hour) and McConnell et al. (1999) (259 ng/cm\(^2\) per hour).
Grimm et al. (2002) tested 3 newly developed biosoluble insulation glass wool fibers (M, P, and V) and 1 newly developed biosoluble insulation stone wool fiber along with a previously developed biosoluble glass fiber (B) (Table 5-9). Values for the biopersistence of three of the glass wool fibers (B, M, P) and the stone wool fibers (O) were reported, with P fibers having the longest biopersistence (21 days), followed by B fibers (17 days), and the M and O fibers (8.5 days). [No biopersistence data were reported for V glass fibers.] The authors considered that, “the physical-chemical properties and biopersistence of these fibers are similar and therefore little difference in the fundamental biological reactions would be expected;” [however, the highest tumor incidences among the B, M, P, and O fibers were for the P and B fibers, which have the longest biopersistence.] Grimm et al. suggested that fiber length as well as biopersistence could help explain the increased tumorigenic response in their study. Tumor levels were increased significantly [statistical test and level of significance not reported by the study authors] for the high doses of fibers B (17%), P (15%), and V (27%). [According to Fisher’s exact test performed by NTP, P values were 0.0016 for the high-dose B fibers, 0.003 for P, and < 0.001 for V (see Table 4-9). Hence, fiber B cannot be considered as non-carcinogenic in this study.] Incidences of mesothelioma in the asbestos groups were about 53% to 88%.

k_{dis} = *in vitro* dissolution rate; NA = not available.

5.3.2 Inhalation studies

Chronic inhalation studies with glass wool fibers (microfibers and insulation glass wool fibers) were described in detail in Section 4.4. Several of these studies also evaluated fiber characteristics, such as fiber length, \textit{in vitro} dissolution, and biopersistence and tumorigenicity (see Section 5.3.4 for modeling studies).

Cullen \textit{et al.} (2000) and Davis \textit{et al.} (1996) reported results of a chronic inhalation study with an E-glass microfiber (104E) and another microfiber type (JM100/475). The 104E fibers caused increased incidences of lung carcinoma and adenoma combined compared with controls, but the JM100/475 fibers did not (see Section 4.1.2 and Table 4-4). The authors reported that long fibers (15 to 20 µm and > 20 µm) of the JM100/475 sample persisted longer than those of 104E. However, fiber analyses after 12-months exposure and 12-months recovery periods showed a decrease in Ba, Ca, K in JM100/475. These elements were not present in native 104E fibers. The authors suggested that the different pathogenicity between the two fiber types was partly due to differences in numbers of long fibers and to differences in surface properties, possibly due to dissolution of 100/475 fibers. The authors also noted that the latency period for mesotheliomas was shorter with 104E fibers than with amosite asbestos fibers tested in this study.

In an inhalation carcinogenicity study conducted in male Syrian golden hamsters, McConnell \textit{et al.} (1999) presented data for MMVF10a, MMVF33 (special-purpose glass fibers prepared by mixing three types of commercially manufactured 475 glass [codes 104, 108B, and 110]), and amosite asbestos. The aerosol dimensions and lung doses of the asbestos (0.6 µm diameter) and the test fibers (MMVF10a and MMVF33) (0.9 µm diameter) were comparable (Hesterberg and Hart 2001). No lung tumors were observed in any group, but incidences of mesothelioma were increased in positive controls (amosite asbestos; 22/85 for mid-dose and 17/87 for high-dose) compared with 1 of 83 in the MMVF33 group (see Section 4.1.2 and Table 4-5). McConnell \textit{et al.} concluded that the severity of the lung and pleural lesions in their study increased as the cumulative fiber burden (particularly fibers > 20 µm in length) increased in the lung, thoracic wall, and diaphragm. The severity of the lesions also was inversely related to the \textit{in vitro} dissolution rates, i.e., the faster the dissolution, the lower the cumulative fiber burden.
Accordingly, dissolution rates (in this study) for MMVF10, MMVF33, and amosite were 259, 12, and 0.2 ng/cm$^2$ per hour, respectively. [However, it should be noted that dissolution rates for the same fibers can vary between researchers, depending on the methodology used. For example, Hesterberg and Hart (2001) reported the dissolution rate for MMVF10 fibers as 300 ng/cm$^2$ per hour, McConnell et al. (1999) reported a rate of 259 ng/cm$^2$ per hour, and for Miller et al. (1999b) the rate was 122.4 ng/cm$^2$ per hour (see Tables 5-8 and 5-10). The dissolutions rates also vary depending on the pH at which the assay is performed.]

Hesterberg and Hart (2001) reviewed data from various inhalation studies in rats and compared lung deposition, biopersistence, and in vitro dissolution with pathogenicity of various fiber types. The authors reported that the results of these studies clearly indicated a relationship between biopersistence in the lung and pathogenicity (see Table 5-10). Characteristics of the more pathogenic fibers included little or no change in chemical composition, morphology, or fiber dimensions (which the authors interpreted as suggesting no significant dissolution or transverse fragmentation), and preferential clearance of shorter fibers. The nonpathogenic fibers showed chemical composition and surface changes, a decrease in average fiber dimensions, and a more rapid decrease in the number of long fibers compared with short fibers. Data from the biopersistence studies for amosite and crocidolite asbestos are compared with special-purpose fibers (MMVF32 and MMVF33), glass wool (MMVF10 and MMVF11), refractory ceramic fibers (RCF1a), rock wool (MMVF21), slag wool (MMVF22), HT stonewool (MMVF34), and a hybrid fiber (X607) in Table 5-10. The clearance half-times for insulation glass fibers MMVF10 and MMVF11, slag wool MMVF22, stone wool MMVF34, and hybrid fiber X607 are faster than special-purpose glass fibers MMVF32 and MMVF33, and RCF1a, and rock wool MMVF 21; clearance half-times for asbestos are slower than for the SVFs. The fibers had different in vitro dissolution rates; the lowest dissolutions rates were found for asbestos, and the highest for the hybrid fiber. However, as noted above, dissolution rates for the same fibers can vary between researchers, depending on the methodology used, and three different estimates were identified for MMVF10 fibers.

Source: (Hesterberg and Hart 2001).

\(^a\) Rats were exposed 6 hours/day for 5 days. Reported lung burdens were determined one day after exposure stopped.

\(^b\) units = ng/cm\(^2\) per hour.
Miller et al. (1999a) examined the influence of fiber characteristics on tumor development in rat lungs for inhalation studies with the same set of nine fiber types that they reported on for intraperitoneal studies (Miller et al. 1999b) (see Table 5-9). Data for modeling was obtained from studies carried out by the Colt Fibre Research Programme and reported by Davis et al. (1996) (see Section 5.3.2), and by the Thermal Insulation Manufacturers Association and reported by Bunn et al. (1993) [an interim report of separate studies for refractory ceramic fibers, fibrous glass, and rock and slag wool], Hesterberg et al. (1993, 1995), Mast et al. (1995b) [studies on ceramic fibers only], and McConnell et al. (1994) (see Section 4.1.2 and Table 4-4 for results of Hesterberg et al. [1993, 1995] and McConnell et al. [1994]). The factors of fiber dimensions, persistence in the lung, dissolution *in vitro*, and cell toxicity *in vitro* were assessed. In the inhalation studies, the determining factors were the number of long, thin fibers (> 20 μm long and < 1 μm in diameter) and the dissolution rate adjusted for mass lost per unit initial mass. Short-term cell toxicity tests *in vitro* were not significantly related to cancer risks in any model tested. The authors noted that the effect of dissolution rate rather than biopersistence in the lung was contrary to expectations, but they suggested that larger measurement error for *in vivo* biopersistence compared with *in vitro* dissolution might be responsible. The authors noted that overall the results for modeling of inhalation studies were “broadly consistent” with the studies for intraperitoneal injection of the same fibers.

5.3.3 *Modeling studies: inhalation or intraperitoneal injection*

A model designed to predict the development of fibrosis or tumors after inhalation or intraperitoneal injection of fibers was developed based on the hypothesis that the effect of a rapidly dissolving fiber (> 20 μm in length) is equivalent to a smaller dose of a durable fiber (Eastes and Hadley 1996). As discussed in Section 5.2 fibers > 20 μm in length have been proposed to be cleared by dissolution in extracellular fluid, and Eastes and Hadley considered the dose of a fiber that dissolves in 1 year to have the same effect as half that dose for a fiber that dissolves in 2 years or more, which the authors considered the approximate lifespan for the rat. The authors noted that their model did not rely on adjustable parameters, but only on the dissolution rate constant (k_{dis}), which could be measured *in vitro* and used to estimate the lifetime for the fibers. An adjustment factor (α) was calculated as the ratio of the time the fiber would remain in the lung compared...
with the lifetime of the animal and introduced into the dose-response relation. The predictions of the model were compared with in vivo results obtained by the Research and Consulting Company in Geneva, Switzerland for seven fiber types, i.e., crocidolite asbestos, chrysotile asbestos, kaolin refractory ceramic fibers, MMVF10 and MMVF11 glass wools, MMVF21 rock wool, and MMVF22 slag wool, with endpoints of fibrosis and lung cancer after inhalation, and mesothelioma after intraperitoneal injection. The $k_{\text{dis}}$ values for these seven fiber types ranged from 0.1 ng/cm$^2$ per hour for crocidolite to 400 ng/cm$^2$ per hour for MMVF22 slag wool. The authors noted that the predicted response depended only on the dissolution rate of the fibers, and not on the fiber family, but they felt the model was limited in its ability to predict results for different durable fibers, which might differ in their tumorigenicity despite being similarly durable. When the predictions of the model with adjustments for dose were compared with the observed incidences of fibrosis or tumors, the values of $\chi^2$ were 109 ($P = 0.62$) for fibrosis by inhalation, 17 ($P = 0.16$) for lung tumors by inhalation, and 35 ($P = 0.051$) for mesothelioma by i.p. injection. The authors considered a $P$ value greater than about 0.05 to be good evidence that the model predicted the observed values to within the error involved in the experimental data.

In a review of the characteristics of various SVFs (including glass wool, stonewool, slagwool, and refractory ceramic fibers) and their influence on biopersistence and toxicity, Bernstein et al. (2001a) reported that biopersistence clearance half-time is a good predictor of both the pathological response (collagen deposition) observed in chronic inhalation studies and the tumor response observed in i.p. injection studies. In previous studies, Bernstein et al. (2001a, 2001b) investigated the relationship of fiber biopersistence with pathogenicity. Biopersistence clearance half-times (for fibers $> 20$ μm) from both inhalation and intratracheal instillation studies were used. Weighted half-times and slow clearance half-times were evaluated from inhalation biopersistence studies, while clearance half-times for various categories of fiber dimensions, including WHO fibers and fibers longer than 20 μm, were evaluated from intratracheal instillation biopersistence studies. One study examined the relationship of biopersistence with chronic inhalation toxicity in rats at 24 months (collagen deposition at the broncho-alveolar junction) while the other study used tumor response data from chronic i.p.
studies in rats. Collagen deposition was selected because it is a precursor to fibrosis, which is associated with tumor response. Five SVFs (including MMVF10 and MMVF11) from 15 exposure groups were available from inhalation studies, while 9 SVFs from 24 exposure groups were available from i.p. studies. Both weighted and slow-phase clearance times of long fibers from inhalation biopersistence studies were equally good predictors of lung fiber burdens and collagen score (Bernstein et al. 2001a). Clearance half-times of WHO fibers and long fibers from intratracheal instillation studies also were good predictors of collagen scores. The authors reported an apparent threshold for collagen formation of approximately 500,000 long fibers in the lung. Most of the animals examined (42 of 48) that had fewer fibers in the lung had a collagen score of 0.

Biopersistence half-times determined from inhalation or intratracheal instillation studies were equally good predictors of tumor response in chronic intraperitoneal injection studies (Bernstein et al. 2001b). The logistic regression analysis included median fiber length, number of fibers injected, and biopersistence half-times. The authors calculated $r^2$ (a measure of goodness of fit of the model) values for individual data and grouped (mean) data. The ranges of values reported for $r^2$ (grouped) were 0.860 to 0.901 for grouped data and 0.471 to 0.494 for individual data. Because the only difference between the models was whether intratracheal or inhalation measurements of WHO or fibers with length $> 20 \mu m$ (L20) were used, and the $r^2$ values were very similar, the authors concluded that the models are equally as good in predicting intraperitoneal results. The data demonstrated that there was little difference in the various measures of biopersistence and that fiber length and number were important to the analysis. Therefore the authors concluded that comparisons of potency between different fiber types must be based on studies that use fibers of the same length and that, unlike inhalation studies, there was no apparent threshold for intraperitoneally injected fibers.

Berry (1999) developed a model for cumulative mesothelioma incidence as it related to fiber biopersistence in humans and rats. The predicted effect of biopersistence was investigated using a mesothelioma incidence model that included an exponential term representing elimination over time. The incidences generated by the model were then applied over the lifetime of reference groups with mortality from other causes. For
humans, occupational exposure was taken as continuous from age 20 to 60 years or until death, if earlier, and the cumulative incidence of mesothelioma was calculated to 100 years for various elimination rates. For rats, exposure was a single injection [site of injection not stated] of fibers at 6 weeks of age and cumulative incidence of mesothelioma was calculated up to 160 weeks post injection. The model was standardized for cumulative incidence of mesothelioma for a durable fiber (elimination constant, 0.01/year) at 50% for 75-year-old men and 110 weeks post-injection for rats. The author reported that the predicted carcinogenic effect in humans dropped off rapidly as the dissolution rate increased, whereas the decrease only occurred with the least durable fibers in rats. The effect of fiber elimination rate on the mesothelioma rate was 17 times higher in humans than in rats. Berry concluded that relatively soluble fibers (e.g., glass wool) that do not produce disease in rats are even less likely to produce disease in humans, most likely because rats age and develop cancer at a much quicker rate than humans and further, that the influence of fiber dissolution is less in rats compared with humans.

Rödelsperger (2004) further evaluated the extrapolation of the carcinogenic potency of fibers from rats to humans. Using the Berry model, he compared predicted mesothelioma incidences in humans (at 85 years of age) and rats (at 136 weeks of age) from graphs of percent mesothelioma vs. elimination constant for highly durable crocidolite fibers (elimination constant of 0.1/year) with less durable refractory ceramic fibers (elimination constant of 1.0/year). The predicted tumor incidence for crocidolite was about 4,750 times higher than for the less durable fiber in humans but only about 3.2 times higher in rats; however, Rödelsperger noted that the uncertainty in the estimate for rats was large due to the life-span of rats being too short to measure the elimination rate of biopersistent fibers sufficiently. Rödelsperger also noted that the carcinogenic potency of refractory ceramic fibers and crocidolite were similar in rats when administered by inhalation or i.p. injection but concluded that this similarity cannot be assumed for humans because of the greater effect of the dissolution rate in humans compared with rats.
5.3.4 Summary of studies

The early studies with glass fibers and asbestos applied directly to the lung pleura (intrapleural implantation) of rats were interpreted by their authors as supporting the conclusion that long, thin glass fibers induced tumor formation as well as similarly sized asbestos. Based on induction of significant numbers of pleural sarcomas by fine, durable glass fibers and several other fiber types, including asbestos fibers, it was concluded that fiber dimensions and durability were important determinants of tumorigenicity.

Following these early studies, most investigators have tested fibers by intraperitoneal injection, but several studies also have been published in which fibers with different physico-chemical characteristics were tested by inhalation exposure. The authors of many of these studies concluded that there was a relationship between fiber dimensions (particularly fibers > 20 μm in length with diameters < 1 μm) and durability and tumorigenicity; [however, several studies have reported results that suggested that the relationship might not completely explain the data.]

Among the studies whose results suggested that the relationship between fiber dimensions and durability might not completely explain the tumorigenicity of various fibers, the authors of one that compared glass fibers with asbestos and other natural fibers suggested that fibers < 10 μm in length (with diameters < 0.5 μm) could still cause tumors by i.p. injection. Another set of studies reported “unexpectedly strong” tumorigenic effects of relatively thick rock and ceramic fibers even though the number of fibers injected per rat in one of the studies was smaller for these fiber types than for the glass fibers. The authors of another of the same set of studies also pointed out that actinolite and 104/475 glass fibers had similar size distributions based on the available data and that both fibers were durable in rats; however, the number of fibers that induced tumors at approximately a 60% rate was much greater for the glass fibers than for the actinolite fibers. In addition, the number of fibers longer than 5 μm was similar in 0.25 mg of actinolite and 75 mg of basalt fibers, and these preparations resulted in almost identical tumor incidences. In another study, pretreatment of fibers with HCl decreased the weight of glass fibers without changing the physical dimensions of the fibers measurably or visibly corroding them, but tumorigenicity was decreased markedly, which
the authors suggested might be due to alterations in the rate of dissolution or
disintegration of the fibers or their migration within tissues.

The conclusions reached by the authors of studies on inhalation studies with fibers with
different physical and chemical characteristics generally confirmed the interpretations of
the i.p. studies. The number of long fibers (particularly fibers > 20 \( \mu \text{m} \) in length) was
considered important as a determinant of pathogenicity, and the biopersistence of the
fibers as reflected in the \textit{in vitro} dissolution rate and the resulting effect of biopersistence
on cumulative fiber burden in the lung, thoracic wall, and diaphragm were also critical
factors. Modeling studies that looked at inhalation and intraperitoneal injection studies
separately came to similar conclusions that tumor incidence depended on the number of
long, thin fibers (> 20 \( \mu \text{m} \) long and < 1 \( \mu \text{m} \) in diameter), and that biopersistence can
predict pathological responses, such as collagen deposition or tumor response.

[The concept that fiber dimensions and durability/biopersistence are related to the
potential tumorigenicity of those fibers was developed using data from a broad range of
fiber types as summarized here, and that concept continues to be generally accepted. The
results summarized above that do not appear to fit neatly within that relationship are
possibly due to the difficulty of applying the general principle to data sometimes obtained
with a relatively narrow range of fiber characteristics under different experimental
conditions.]

\textbf{5.4 Toxic effects}

This section describes toxicity studies in humans and experimental animals.

\textbf{5.4.1 Humans}

Mortality from non-malignant diseases was also evaluated in some of the cohort and
nested case-control mortality studies of glass fiber production workers discussed in the
human cancer studies. (See Section 3.1 for a detailed description of the study population
and methodology). In addition several other studies evaluated respiratory disease
morbidity and are discussed below.
Respiratory effects: mortality studies

No significant increase in mortality from non-malignant respiratory disease (NMRD), excluding influenza and pneumonia, was observed among the 32,110 fiberglass and mineral production workers followed until 1992 (SMR = 0.92, 95% CI = 0.84 to 1.02, 440 deaths compared with local rates) or 4,008 female workers (SMR = 1.02, 95% CI = 0.74 to 1.37, 44 deaths) in the 10-plant U.S. cohort established by Marsh and colleagues (Marsh et al. 2001a, Stone et al. 2004). Earlier publications of an overlapping cohort (16,661 male mineral wool and fiberglass workers at 17 plants, and followed until 1977, 1982, or 1985) found significant SMRs for NMRD (excluding influenza and pneumonia) (SMR =1.30, P < 0.01, 129 deaths for the 1977 follow-up, SMR = 1.32, P < 0.01, 230 deaths for 1982, and SMR = 1.29, P < 0.01, 281 deaths for 1985); however, no relationship was observed with cumulative exposure to respirable fibers (Enterline et al. 1983,1987, Marsh et al. 1990). Among workers employed at the three plants manufacturing fine fibers, higher SMRs were found for ever-exposed workers (at each plant) compared with non-exposed workers. In a case-control study of employees at the Owens-Corning Fiberglass plant in Newark, Ohio (1 of the 10 plants in the Marsh cohort), a non-significantly increased risk (OR = 1.50, 95% CI = 0.55 to 4.08) of NMRD was observed among workers with cumulative exposure of > 300 respirable fibers/cm$^3$ in conditional regression analyses (Chiazze et al. 1993); however, no increased risk in mortality was found in a smaller case-control study (30 cases and 103 matched controls) at another plant in Kansas City, Kansas (Chiazze et al. 2002).

Nonsignificantly increased SMRs for respiratory disease were reported in the Canadian cohort (SMR = 1.19, 95% CI = 0.74 to 1.82; 21 deaths (Shannon et al. 2005) and among 5,275 glass wool workers in the European cohort (SMR = 1.18, 95% CI = 0.98 to 1.40; 127 deaths) (Sali et al. 1999).

Respiratory effects: morbidity studies

Several studies have evaluated adverse respiratory effects and exposure to glass wool fibers; these include studies measuring respiratory symptoms, lung abnormalities (monitored by chest radiographs), and pulmonary function. The findings from IARC
(1988) are summarized, and studies published after the IARC (1988) review on exposures specific to glass fibers are described in detail.

The IARC (1988) review stated that numerous studies have reported that exposure to SVF causes irritation and inflammation of the upper respiratory tract. Bronchitis was also associated with exposure to SVFs in one study. Abnormalities on chest X-rays were reported in some (Nasr et al. 1971, Valentin et al. 1977), but not all studies (Wright 1968). Pathological changes in the lung (parenchymal involvement or pulmonary fibrosis) or respiratory distress were reported in workers with prolonged exposure to glass fibers in one study (Chiappino et al. 1981), but not in another study (Gross et al. 1971).

No effects on pulmonary function were found in a study of six workers exposed to glass wool or rockwool or in two studies of sheet-metal workers (Bjure et al. 1964, Hill et al. 1984, Hill et al. 1973, Sixt et al. 1983).

Moulin et al. (1988a) conducted a respiratory health assessment of 2,024 workers in three glass wool (1,041 from Plant A) and two rock wool production plants in France. A standardized questionnaire that covered occupational history, smoking habits, respiratory symptoms, and upper airway irritation was administered by industrial physicians. After adjusting for age and current smoking, significantly elevated ORs related to exposure to fibers were observed for cough, phlegm, and symptoms of the pharynx-larynx among workers at Plant A, but not among workers at the other two glass wool plants. ORs increased with exposure duration for symptoms of the pharynx-larynx (not statistically significant) and for sinus and nasal cavity complaints (e.g., sinusitis, nasal congestion, and nosebleed) \( P = 0.02 \); however, no exposure response was observed for cough and phlegm. IARC (2002) reported that a nested case-control study (Moulin et al. 1987, published in French ) did not confirm these results.

Hunting and Welch (1993) investigated the occurrence of lung disease among sheet metal workers from the United States and Canada exposed to asbestos and fiberglass. The workers were selected from a larger study of workers with 20 years of experience with high use of fiberglass. The selection criteria for this study were workers who had participated in medical screening, worked in the sheet metal industry for at least 70% of
their working career (or removal for 40% of their career) and were not welders for more
than 20% of their career. Occupational exposure history was obtained by telephone
interview for 333 workers (out of 407 who met the selection criteria), and cumulative
exposure models were developed for high-, medium-, and low-intensity exposure to
fiberglass. In multiple logistic regression analyses, smoking, years of asbestos exposure,
and high intensity exposure to fiberglass (OR = 2.28, 95% CI = 1.07 to 4.86) were
associated with chronic bronchitis risk, but only smoking and welding were risk factors
for obstructive lung disease.

Kilburn and Warshaw (1991) investigated respiratory effects in 175 fiberglass production
workers (12 women and 163 men) from a group of 500 U.S. workers who underwent
medical examination. Most of the workers (137/175, 78%) reported a history of asbestos
exposure, but 38 workers were identified without known asbestos exposure; however, all
had worked in a facility where ovens insulated with asbestos were cleaned, repaired,
dismantled, and rebuilt. Chest radiographs, lung function measurements, and
occupational and medical histories were taken. Pulmonary flows and volumes were
adjusted for age, height, ethnicity, and smoking. Chest radiographs revealed small,
irregular opacities in 31 men; 16.8% (23/137) of the workers were exposed to asbestos
and fiberglass, and 21% (8/38) to fiberglass only. After adjusting for age and smoking,
workers with abnormal radiographs (31/175) had greater functional pulmonary
impairment than workers with normal radiographs (63/175). [No unexposed control
group was included in this study.] The authors concluded that it was possible that the men
who did not report exposure to asbestos were actually exposed since they shared a similar
air environment, and thus the effects of fiberglass exposure could not be estimated
independently of the effects from asbestos exposure.

Kilburn et al. (1992) examined pulmonary effects in 284 (182 men and 102 women) of
500 workers (end-users) who had worked for at least 20 years and completed medical
examinations. The workers were employed in fiberglass sheeting and rotary spun
fiberglass insulation. Pulmonary effects were determined using spirometry, lung volumes,
chest radiographs, and occupational questionnaires. Air sampling showed that 49% to
83% of the fibers had diameters < 5 μm and 23% to 71% were < 3 μm; no asbestos fibers
were identified. Chest radiographs revealed abnormalities in 43 workers; 17 reported
previous exposures to asbestos and 26 were without reported exposure to asbestos.
Pulmonary function was reduced in the workers with abnormalities (detected by
radiographs) attributed to glass fiber exposure compared with workers without
abnormalities and who were not exposed to asbestos. [There was no unexposed control
group in this study.] The authors concluded that exposure to commercial rotary spun
fiberglass used for insulating appliances appeared to produce pulmonary effects similar to
asbestosis.

Hughes et al. (1993) also conducted a study of SVF workers at seven plants (five fibrous
glass and two mineral wool manufacturing plants) in the United States. [These plants
might be the same plants studied by Marsh and colleagues.] Workers underwent a chest
X-ray (1,449), interview, and spirometry (1,030). Comparison (blue collar) workers were
identified for each plant from the communities where the plants were located and
participated in the spirometry (386), interview, and chest X-ray (305, no radiographs
were available for comparison workers for two plants). The prevalence of respiratory
symptoms (such as chronic bronchitis and cough) was higher in three of the seven plants
(one glass and two mineral wool) than in the comparison group. Among SVF workers,
there were significant differences in pulmonary function (spirometric measurements)
across the plants (highest for the very fine fiber plant); however, when asthmatic workers
or workers with previous chest surgery were omitted from the analyses, no significant
differences in pulmonary function were observed compared with the comparison group.
The prevalence of small opacities (detected by radiographs) was higher among SVF
workers (23/1435) than the comparison groups (2/305), and most (98%) of the opacities
were found at two glass fibers plants with the highest average and cumulative exposures;
one of these plants made small fibers. Analyses of all workers (controlling for film
quality, smoking, and age) found a significant association for opacities with cumulative
exposure, average exposure, and time in job, although only duration of exposure was
significant after allowing for plant effect. Phase two of the study evaluated workers (157)
at the two plants with the higher prevalence of opacities using pre-employment
radiographs of each worker as the comparison; none of the workers with pre-employment
radiographs had participated in the main part of the study. No significant differences in
opacities were found between pre-employment and workers’ films, and the prevalence of opacities was not significantly related to any exposure indices in regression analyses.

Guber et al. (2006) reported a case of pulmonary fibrosis in a patient with exposure to glass wool fibers; the patient denied exposure to asbestos and did not smoke. Fibers with a chemical composition consistent with typical glass wool insulation were identified in sputum and biopsy samples.

Abbate et al. (2006) investigated changes in the respiratory system induced by occupational exposure to production dust from glass fiber-reinforced plastics. This study included 29 male subjects with a mean length of employment of 11 years. Heavy smokers (> 15 cigarettes/day) were excluded from the study. The subjects were given a medical examination, chest X-rays, and spirometric and other tests. Bronchoalveolar lavage fluid was submitted for microscopic and biochemical analysis. The respiratory function tests confirmed obstructive syndromes in the workers. There were qualitative and quantitative alterations of the alveolar macrophages and evidence of intense and active phlogosis (external inflammation). Biochemical analysis indicated an increase in protein content that was associated with a significant decrease in glutathione, suggesting alterations of the lung oxidant/antioxidant status. Antioxidant enzymes (catalase [CAT] and superoxide dismutase [SOD]) were increased three to five fold. Alterations of the cellular and humoral components of the pulmonary interstitium were identified as acute alveolitis.

Other effects
Several studies have also evaluated non-respiratory effects and exposure to glass wool. In the cohort mortality studies, no significant increases in SMRs from non-malignant diseases were observed in the latest update of the U.S. workers (Marsh et al. 2001a, Stone et al. 2004), glass wool workers in the European cohort (Sali et al. 1999) or in the Canadian cohort (Shannon et al. 2005). In an earlier update of the U.S. glass wool cohort (16,661 workers followed until 1985), a significantly increased SMR for nephritis and nephrosis was observed (SMR = 1.46, $P < 0.01$, 56 deaths) (Marsh et al. 1990). In a case-control study of glass wool workers from three plants (Newark, Ohio; Kansas City, Kansas; and Santa Clara, California) in the U.S. cohort assembled by Marsh, no association between exposure to respirable fibers and mortality from nephritis or
nephrosis was reported. This study used two case-control analyses that evaluated deaths from nephritis or nephrosis as the underlying cause only (15 deaths) or underlying and contributing cause (47 deaths) (Chiazze et al. 1999).

IARC (2002) also reviewed several morbidity studies showing an association between mineral fiber exposure and dermal irritation and skin disease. One of these studies reported that 25% of 259 workers in a manufacturing and processing plant for mineral wool insulation presented with a skin disease that was attributed to an allergy related to MMVF additives. Other studies reported high incidences of skin and eye irritation or positive patch tests with mineral fibers among construction workers or workers investigated for sick-building syndrome.

5.4.2 Experimental animals
Toxic effects in experimental animals that are potentially important to the carcinogenic process include inflammation and fibrosis (IARC 2002). These effects are commonly graded according to the Wagner scale (Table 5-11). Other effects, such as genotoxic or mitogenic affects are discussed in Section 5.6 as they relate to potential mechanisms of carcinogenicity.

Studies with MMVF10 and MMVF11 in F344 rats exposed 6 hours/day, 5 days/week for up to 24 months have shown exposure-dependent responses in lung pathology that
peaked at a Wagner score of 3 (Hesterberg et al. 1993). In this same study, a Wagner score of 4 was observed in rats exposed to chrysotile asbestos for only three months.

Cullen et al. (2000) reported on the pathogenicity of 104E-glass fibers, code 100/475 microfibers, and amosite asbestos in Wistar rats exposed 7 hours/day, 5 days/week for one year. Fibrosis (Wagner score of 4) was evident in four rats exposed to 104E fibers after the 12-months exposure period, but the lesions were small and only 0.3% of the lung parenchyma was involved. In the nine animals that survived for another 10 to 12 months without further exposure, significant areas of advanced fibrosis and bronchoalveolar hyperplasia were evident. Instead of Wagner scores, the authors reported the mean level of advanced fibrosis as the percentage of lung area affected. The values were 0.08% (controls), 0.2% (100/475 glass), 8.0% (104E glass), and 7.6% (amosite). The authors noted that there were greater numbers of long fibers in the lungs of animals exposed to 104E glass for 12 months compared with the other fiber types.

Hesterberg et al. (1999, 1997) investigated the effects of inhalation exposure in Syrian golden hamsters. Animals were exposed for 6 hours/day, 5 days/week for periods of 13 to 52 weeks. MMVF10a, MMVF33, and amosite asbestos were used in the studies. Time-dependent increases in pathology were noted with Wagner scores after 52 weeks of 0 (controls), 2.3 (MMVF10a), 4.0 (MMVF33 and low-dose amosite), and 6.0 (high-dose amosite). McConnell et al. (1999) reported on a similar study design in Syrian golden hamsters exposed to these same test fibers for 78 weeks. The fibrosis index in hamsters exposed to MMVF10a or MMVF33 was not significantly different from controls but was significantly elevated in hamsters exposed to amosite.

Hesterberg et al. (2002) used a short-term assay to evaluate the toxicity of MMVF10, JM475, amosite asbestos and two new biosoluble glass wool fibers (JM902 and JM901F). MMVF10 and JM902 were tested concurrently, while JM901F, JM475, and amosite asbestos were tested in a separate study. Size-separated fiber samples were tested for lung biopersistence and their potential to induce persistent pulmonary inflammation in rats. Groups of 82 to 105 male F344 rats were exposed by nose-only inhalation for 6 hours/day for 5 days. The control groups included 45 to 55 rats exposed to filtered air.
The geometric mean dimensions of the fibers were similar, and the mean concentrations of WHO fibers ranged from 321 to 443 fibers/cm$^3$. In addition, intratracheal instillation biopersistence studies were conducted with JM902 fibers. Dissolution rate constants were measured \textit{in vitro}. Histopathological effects were limited to fiber-containing microgranulomas and alveolar macrophage aggregation in rats exposed to JM902, JM901F, or MMVF10 on recovery day 1. After 30 days recovery, no adverse symptoms were noted, while some inflammatory symptoms were still present in rats exposed to JM475 or amosite.

Bellmann \textit{et al.} (2003) conducted a subchronic inhalation study in male Wistar rats to investigate the biological effects of E-glass microfiber, stone wool (MMVF21), and a new high-temperature application fiber (calcium-magnesium-silicate fiber). Results are reported here for the E-glass microfiber. Rats were exposed 6 hours/day, 5 days/week for 3 months to aerosol concentrations of approximately 15, 50, and 150 fibers/cm$^3$ (fiber length $> 20 \mu m$). For the E-glass microfiber, the highest gravimetric concentration was 17.2 mg/m$^3$. Recovery effects were studied during a 3-month postexposure period. The lung burden of the long-fiber fraction of E-glass declined 38.4\% after 3 months recovery. The estimated half-times were 55 to 157 days for WHO fibers and 57 to 63 days for fibers $> 20 \mu m$ in length. Dose-dependent effects included an increase in lung weight in the mid- and high-dose groups at 1, 7, and 14 weeks after exposure. Biochemical analysis of bronchoalveolar lavage fluid indicated a significant increase in lactate dehydrogenase, $\beta$-glucuronidase, and total protein after 1 and 7 weeks in the mid- and high-dose groups; however, at 14 weeks, total protein was the only parameter that remained elevated. Cytokine analysis (TNF-$\alpha$ and IL-6) did not show any significant changes. Histopathological findings included accumulation of fiber-laden macrophages, bronchoalveolar hyperplasia, microgranulomas, and interstitial fibrosis in all exposure groups. The authors concluded that the effects induced by E-glass were more pronounced than those induced by the other fibers.

Bermudez \textit{et al.} (2003) investigated toxicity of MMVF10a fiberglass in male F344 rats and Syrian golden hamsters using pleural dosimetry. Animals were exposed (nose-only) to a target concentration of 45 mg/m$^3$ for 4 hours/day, 5 days/week for up to 12 weeks.
Animals were killed following 4 or 12 weeks of exposure or after 12 weeks of exposure followed by a 12-week recovery period. The geometric mean length and diameter of the fiber samples were 12.5 μm and 0.93 μm, respectively. Lung fiber burdens (calculated as total number of fibers per lung, averaged over the three time points) were greater in rats (50.1 × 10^6 fibers/lung) than in hamsters (6.4 × 10^6 fibers/lung). When lung fiber burdens were normalized based on lung surface area, rats had significantly higher lung burdens than hamsters. Fibers recovered from the lungs of both species were shorter and thinner than those in the aerosol. Lung fiber burdens decreased about 90% in hamsters following 12 weeks of postexposure recovery compared with 44% in rats. Average fiber burdens in the pleural compartment were about the same in rats and hamsters but were at least three orders of magnitude lower than found in the lung. When normalized based on surface area, pleural fiber burdens > 5 μm in length were significantly higher in the hamster at 12 weeks of exposure. Fibers in the pleural compartment were longer than those found in the lung but were about the same diameter. Mild pulmonary inflammation was observed in both species and characterized by increased numbers of macrophages and neutrophils, and an increase in mesothelial cell replication. The neutrophil response was correlated with lung fiber burdens in the rat but not in the hamster. All the biochemical markers examined in the rat bronchoalveolar lavage fluid were elevated after 4-weeks exposure, and lactate dehydrogenase (LDH) and alkaline phosphatase levels remained elevated and unchanged through 12-weeks recovery. There were no significant increases in the biochemical markers of toxicity in bronchoalveolar lavage fluid in hamsters.

5.4.3 Cytotoxicity

Similar to the IARC (2002) review, this section is limited to studies that met several criteria, including: (1) the dose was expressed as number of fibers administered, (2) fiber length was specified so that false-negative results from preparations of short fibers could be excluded, (3) adequate documentation of fiber source was supplied, (4) studies involving instillation of fibers directly into the lungs were screened to exclude those with excessive doses, and (5) control fibers were used or different categories of fiber length were used.
One study used Chinese hamster ovary cells to assess cytostatic effects of MvL 901 glass fibers (Hart et al. 1994). Fibers with an average length of 25 μm inhibited cell proliferation to approximately 25% of control levels, whereas fibers with an average length of 3.5 μm did not inhibit cell proliferation. A modest effect was also seen for fiber thickness, with thinner fibers being more effective inhibitors of cell proliferation than thicker fibers. The authors noted that this study showed that long fibers were toxic per se, in addition to their ability to accumulate in the lung due to slower clearance rates.

Blake et al. (1998) assessed the ability of code 100 glass fibers, at varying lengths, to inhibit lucigenin chemiluminescence and to cause release of LDH from rat alveolar macrophages. A length-related toxicity was seen, with fibers of 17 μm and 33 μm showing similar high potency, while fibers less than or equal to 7 μm showed markedly lower potency. The authors suggested that the increased toxicity of long fibers was due to frustrated phagocytosis leading to leakage of oxidants and enzymes from a macrophage trying to engulf a fiber.

Zeidler-Erdely et al. (2006) investigated the influence of fiber length on primary human alveolar macrophages. JM100 glass fibers were sorted into four length categories (8, 10, 16, and 20 μm). Macrophages were obtained by bronchoalveolar lavage of healthy, non-smoking volunteers and treated with three different concentrations of the sized fibers in vitro. Cytotoxicity was determined by monitoring cytosolic lactate dehydrogenase release and loss of function (decrease in zymosan-stimulated chemiluminescence). In contrast to the study in rats (Blake et al. 1998), human macrophages completely engulfed glass fibers of all length categories with no evidence of incomplete phagocytosis or length-dependent toxicity. All fiber length fractions exhibited equal cytotoxicity on a per fiber basis in a dose-dependent manner.

5.5 Genetic and related effects
This section reviews the available genetic and related effect studies for glass fibers, including those reviewed by IARC (2002) and those published subsequent to the IARC review. This review includes studies of oxidative and genetic damage (such as mutations, micronucleus formation, DNA damage) and also studies of related effects, such as production of reactive oxygen species and changes in gene expression. Some of the
studies were designed to evaluate the effects of fiber characteristics (diameter and length
and sometimes fiber composition) on the genotoxic endpoint. Some of the fibers used in
these studies were used in animal cancer studies or were manufactured to be similar to a
fiber used in the animal studies. These include the special-purpose fibers (e.g. Manville
codes JM100, JM100/475) and insulation glass wool fibers (e.g., MMVF10, MMFV11,
and Owens Corning general insulation fibers). However, as IARC noted, no studies are
available that correlated genotoxic endpoints and pathogenic effects in the same
experimental animal system.

5.5.1 Production of reactive oxygen species
The following sections discuss studies that investigated reactive oxygen species produced
by exposure to glass wool. Although ROS are not necessarily associated with
genotoxicity, they may damage DNA or chromosomes. This section discusses studies
conducted in cell-free systems, cultured cells, or experimental animals.

Cell-free systems
The ability of glass wool to produce reactive oxygen has been studied in cell-free systems
by measuring guanine hydroxylation in DNA or deoxyguanosine (an indication of
hydroxyl radical formation), studies using the salicylate assay to measure hydroxyl
radical formation, and studies measuring scission of plasmid DNA after incubation with
glass wool. These studies are summarized in Table 5-12.

All of the guanine hydroxylation studies were positive; [however, most studies did not
provide detailed information on fiber characteristics] (Adachi et al. 1992, Leanderson et
al. 1988, Leanderson and Tagesson 1992). Glass wool and JM100 glass fibers induced
hydroxyl radical formation in the presence of hydrogen peroxide (Maples and Johnson
1992). These authors reported a significant correlation between the capacity of natural
fibers (asbestos and erionite) to initiate hydroxyl radical formation and tumor rates in rat
i.p. studies or literature values for human mesothelioma mortality rates; however, no
correlations were found with glass fibers. In another study, JM100/475 and an insulation
glass wool fiber (MMVF10) did not induce hydroxyl radical formation; however, this
study was conducted at a lower pH (3.9) than the Maples and Johnson study (neutral pH)
and did not use hydrogen peroxide (Brown et al. 1998).
Several studies were conducted that reacted glass fibers with plasmid DNA and measured oxidative DNA damage to the plasmid (as assessed by a reduction in the percentage of supercoiled DNA) (Brown et al. 1998, Donaldson et al. 1995b, Gilmour et al. 1995, 1997). All of these studies were negative. However, Gilmour et al. (1995, 1997) reported that MMVF10 and MMVF11 did have a detectable, although not statistically significant, effect on plasmid DNA. In contrast, there was significant free radical damage with amosite asbestos. There was no correlation between iron release from the fibers and free radical activity. Although the authors demonstrated that iron at the surface of asbestos fibers had a role in generating hydroxyl radicals, some fibers released large quantities of iron without causing free radical damage. Thus, the exact role of iron in fiber reactivity is not completely understood.

---

1. **Cultured cells**
2. Most studies have reported that glass fibers cause oxidative damage in cultured cells.
3. These studies have used different types of fibers (varying in length and diameter) and assessed oxidative damage by different endpoints. These studies are summarized in Table 5-13.
4. Superoxide production induced by glass fibers (code 100/475 – either uncoated or coated with rat immunoglobulin [IgG]), was studied in rat alveolar macrophages (Donaldson et al. 1995b, Hill et al. 1996), and glass fiber code 100 was studied in rat alveolar
macrophages and hamster alveolar macrophages (Hansen and Mossman 1987, Mossman and Sesko 1990). Dörger et al. (2000, 2001) investigated the responses of rat alveolar and peritoneal macrophages and hamster alveolar macrophages exposed to MMVF10. All studies except Dörger et al. (2000, 2001) reported increased superoxide production in alveolar macrophages exposed to glass fibers. IgG opsonization of code 100/475 did not increase superoxide production.

Gilmour et al. (1997) reported that intracellular glutathione levels were significantly decreased in rat alveolar macrophages exposed to MMVF10; however, glutathione depletion was not related to free radical activities of the fibers (see “in vivo studies” in Section 5.5.1). The authors concluded that the decrease in glutathione was likely a result of exportation as a stress response rather than a direct free radical oxidation of glutathione. Wang et al. (1999b) reported that both a long glass fiber (GW1) and a microfiber (MG1) increased superoxide anion (as measured by cytochrome C reduction) and hydrogen peroxide production, and depleted glutathione in guinea-pig alveolar macrophages. GW1 induced levels of hydrogen production similar to that of asbestos (chrysotile). Glass wool also increased hydrogen peroxide production in human polymorphonuclear leukocytes (Leanderson and Tagesson 1992).

Nishiike et al. (2005) investigated the effects of asbestos and SVFs on nitrosothiol formation and glutathione levels in the murine macrophage cell line (RAW264.7). J774 cells were also used in some experiments. Glass wool and chrysotile asbestos significantly increased nitric oxide and superoxide anion production and decreased glutathione levels in RAW264.7 cells. S-nitrosothiol formation was increased in both cell lines by all fiber types tested.

Brown et al. (1986) reported no increase of malondialdehyde production (an indicator of lipid peroxidation) in human A549 cells exposed to 50 μg/cm² glass fibers; however, malondialdehyde was significantly increased in cell cultures treated with crocidolite asbestos. MMVF10 and MMVF11 (insulation glass wool fibers) caused dose-dependent increases in reactive oxygen species in human polymorphonuclear cells (Luoto et al. 1997). Fibers of different lengths (MG1, a short micro fiber; and GW1, a longer glass fiber) induced reactive oxygen species in human monocytes (Ohyama et al. 2000) and
guinea-pig alveolar macrophages (Wang et al. 1999b); however, the longer fiber (GW1) was more effective in inducing ROS than the shorter fiber (MG1) in human monocytes. Ruotsalainen et al. (1999) reported that fiber size did not appear to be important in inducing reactive species in human polymorphonuclear leukocytes; dose-dependent increases in production of reactive oxygen were induced by two glass fibers of different sizes. A similar observation was made between fiber lengths of other types of fibers (e.g., refractory ceramic fibers, rock wool). However, the glass wool fibers in the Ruotsalainen et al. (1999) study appeared to have a more heterogeneous size distribution than the GW1 and MG1 fibers in the Ohyama et al. study (2000). Ruotsalainen et al. (1999) also included other types of synthetic fibers and suggested that fiber composition might mediate production of reactive oxygen species because the amount of ROS production differed according to fiber types of similar dimensions.

Zoller and Zeller (2000) investigated the potential for four SVFs (including glass wool code A) and two natural mineral fibers (crocidolite and erionite) to induce ROS in a differentiated human promyelocytic cell line (HL-60-M cells). ROS production was measured by lumino-enhanced chemiluminescence. The influence of fiber preincubation in unbuffered saline also was investigated. Cell cultures exposed to 250 μg of glass fibers showed increased chemiluminescence; however, decreased ROS-generating potential was observed after preincubation in saline for 4 weeks. The authors thought that the decreased ROS-generating potential of code A fibers was likely due to surface alterations (leaching and initiation of dissolution).

In contrast to the cell-free studies using calf-thymus DNA, Murata-Kamiya et al. (1997) reported no increase in 8-OHdG formation when the DNA of a reticulum-cell sarcoma line (J774) was incubated with glass fibers (100 μg/mL).

1. **In vivo**
2. Schürkes *et al.* (2004) investigated the role of indirect (inflammation-driven) genotoxicity in fiber-induced carcinogenicity. Induction of the pre-mutagenic DNA-adduct 8-OHdG by MMVF11 or crocidolite asbestos (with and without reduced iron content) was measured and correlated with parameters of inflammation. Groups of female Wistar rats were injected i.p. with crocidolite (1 or 2 mg) or MMVF11 (14.7, 29.4, 50, and 100 mg). Previous i.p. carcinogenicity studies with these fibers (Roller *et al.* 1996), indicated that 1 mg of crocidolite and 50 mg of MMVF11 were associated with a
theoretical lifetime tumor risk of 25%. The two lower doses of MMVF11 were chosen to
give comparable fiber numbers relative to crocidolite. All fiber suspensions were given in
a single injection in a volume of 2 mL of PBS [not defined by the authors, but most likely
phosphate-buffered saline] except the high dose for MMVF11, which was given in two
injections. The control group was injected with 2 mL of PBS. There were significant
comparable increases in 8-OHdG in the greater omentum for all fiber treatment groups.
The percentage of macrophages and TNF-α secretion was significantly correlated with
induction of 8-OHdG 10 weeks after treatment. The authors concluded that this study
supported the hypothesis of persisting inflammation as an important parameter for fiber-
induced mutagenesis.

Kováčíková et al. (2004) investigated the antioxidant status of the lung in male F344 rats
administered stone wool or glass fibers by intratracheal instillation. Animals were
exposed to 2 mg or 8 mg of fibers for 4 or 16 weeks. The high dose was administered in 4
doses at weekly intervals. All doses were administered in 0.2 mL of saline, and control
groups were administered saline. The activity of superoxide dismutase, glutathione
peroxidase, and total glutathione was measured in lung tissue and in cell-free fractions of
bronchoalveolar lavage fluid. Ascorbic acid was measured in lung tissue. In rats exposed
to glass fibers, there were no statistically significant differences in lung tissue except an
increase in ascorbic acid in the group exposed to 8 mg for 4 weeks. Superoxide dismutase
also was significantly decreased in bronchoalveolar lavage fluid from this group. Only
mild dose-dependent histological alterations were seen in the exposed groups.

5.5.2 Genetic damage: prokaryotic systems
Manville code 100 glass fiber (JM100) and code 110 coarse glass fiber (JM110) did not
cause reverse mutations in Salmonella typhimurium TA1535 and TA1538 or in
Escherichia coli B/r, WP2, WP2 uvrA and WP2 uvrA polA (Chamberlain and Tarmy
1977). These fibers differ in both length and diameter (code 110 are much longer and
thicker than code 100) (see Table 5-14).

5.5.3 Genetic damage: mammalian in vitro systems

DNA damage, repair, and cross linking

Several studies, using different types of glass fibers (which varied in fiber length and diameter), were conducted to evaluate whether glass fibers could damage DNA. Most of these studies assessed DNA damage by the single-cell gel/comet assay and most studies were positive (see Table 5-15).

Zhong et al. (1997b) used the alkaline single-cell gel/comet assay to compare DNA damage in Chinese hamster V79 cells with human embryonic lung fibroblasts (Hel 299 cells) exposed to Owens-Corning AAA-10 glass fibers (1.7, 3.4, 6.9, and 27.6 μg/cm²). Significant DNA damage was reported in V79 cells at all four concentrations tested and in human embryonic lung fibroblasts (Hel 299 cells) at the three highest doses. Wang et al. (1999a) reported that both long glass wool fibers (GW1, length = 20 μm) and microfibers (MG1, length = 3 μm) induced DNA damage (as assessed by the comet assay), inhibited DNA repair and caused DNA-DNA intrastrand cross links in human epithelial cells. Cavallo et al. (2004) exposed human mesothelial cells (Me-T-5A) to four concentrations of glass wool (1, 2, 5 and 10 μg/cm² for 2 hours and measured DNA damage.
damage (as assessed by the comet assay) and oxidative DNA damage (assessed by the comet assay with formamidopyrimidine DNA-glycosylase [Fpg]). Glass wool caused non-significant dose-related increases in direct DNA damage and a slight increase in oxidative damage at the highest dose. Kováčiková et al. (2004) isolated and cultured alveolar macrophages and type II cells from F344 rats. After a 20-hour incubation, the cells were exposed to various concentrations of glass fibers, rockwool, wollastonite, and amosite. The comet assay was used to detect DNA damage. DNA strand breaks were enhanced in both cell types by exposure to all fibers in a dose-dependent manner. The highest level of damage was seen in cells exposed to amosite. Type II cells exposed to glass fibers showed the lowest level of damage.

*aWHO fibers are longer than 5 μm and less than 3 μm in diameter with aspect ratio (ratio of fiber length to fiber diameter) > 3, defined as respirable fibers.
Chromosomal or chromatid-related effects

It has been proposed that mineral fibers, including asbestos and synthetic fibers, can enter cells and physically interfere with chromosome segregation during mitosis, possibly resulting in aneuploidy and chromosomal translocation. Numerous studies have been conducted to evaluate nuclear abnormalities (including micronuclei and polynuclei) and chromosomal aberrations (including polyploidy and structural aberrations). There has also been one study evaluating sister-chromatid exchange. Many of these studies evaluated the effect of fiber characteristics (e.g., composition, length, and diameter) on the genotoxic endpoint. The results from these studies are summarized in Table 5-16.

Hart et al. (1994) evaluated the effects of fiber length, fiber diameter, and composition of asbestos and vitreous fibers on cytotoxicity and induction of nuclear abnormalities (micronuclei and polynuclei) in Chinese hamster ovary cells. Cells were exposed to MvL 475 glass fibers of similar lengths but different diameters (ranging from 0.3 to 7 μm) and MvL 901 glass fibers of different lengths (ranging from 3.5 to 31 μm) and similar diameters. Fiber length but not fiber diameter (when calculated as the number of fibers/unit area) affected induction of nuclear abnormalities; longer fibers caused a greater percentage of abnormalities than shorter fibers. Hesterberg et al. (1986) reported that unmilled glass fibers were more effective (almost 7-fold) in inducing micronucleus formation than milled fibers. Milling decreases fiber length, thus supporting the findings of Hart et al. that longer fibers are more potent inducers of micronuclei. Milling of fibers also affected phagocytosis, cytotoxicity, and transformation frequency. However, another study reported two microfibers (Manville 100 microfiber and Owens AAA-10 microfiber), but not Owens-Corning general insulation fibers, induced multinucleated and micronucleated cells in a concentration-dependent manner in Chinese hamster lung fibroblast cells (V79) (Ong et al. 1997). Most of the micronuclei were kinetochore positive, which is an indicator of aneuploidy. The microfibers were short and thin, whereas the general insulation fibers were thicker and longer. Zhong et al. (1997a) also reported that Owens AAA-10 microfibers induced micronuclei in Chinese hamster lung fibroblasts (V79 cells). Significant concentration-related increases in frequencies of micronucleated and multinucleated cells were observed when the cells were exposed to concentrations of 1.7 to 27 μg/cm².
Thin glass wool fibers induced bi- and multinucleated cells in rat liver cells, human primary mesothelial cells (PL-102), and an immortal, non-tumorigenic human mesothelial cell line (MeT-5A). Significant increases in the percentage of binucleated cells were observed at all doses (1, 2, 5 μg/cm²) in the two types of human mesothelial cells but only at the highest dose in rat liver cells. Thin glass fibers appeared to be as effective as asbestos (when doses were expressed as the number of fibers per culture area) in inducing binucleated cells in human mesothelial cells. Milled glass wool caused significant increases in binucleated cells in MeT-5A cells (highest dose only) but not in PL-102 or rat liver cells (Pelin et al. 1995).

Sincock et al. (1982) reported that fine glass fibers (Manville code 100) but not thick glass fibers (Manville code 110) caused chromosomal aberrations (breaks and rearrangements) in Chinese hamster ovary cells (CHO). However, a respirable fraction of the thick glass fibers (but not the total sample) caused a significant increase in chromosomal aberrations (chromatid and isochromatid gaps) in Chinese hamster V79-4 cells in another study (Brown et al. 1979). Koshi et al. (1991) tested three glass fibers (Manville codes 100, 104, and 108A) of different fiber dimensions for chromosomal aberrations in Chinese hamster lung cells. None of the fibers caused significant increases in structural chromosome aberrations, but all three types of fibers caused an increase in polyploidy; however, the thinner fibers (codes 100 and 104) caused increases at lower doses (10 μg/cm²) than the thicker fiber (code 108A). In general, the clastogenic activity of glass fibers was mild compared with that of asbestos. An increase in structural chromosome aberrations was observed in human embryo lung cells treated with a microfiber (MG1) and a glass wool fiber (GW1) (Wang et al. 1999a).

Two insulation glass wool fibers (MMVF10 and MMVF11) did not induce anaphase or telophase aberrations (as assessed by lagging chromatin, bridge, or asymmetric segregation) in rat pleural mesothelial cells when exposed to less than 2.5 × 10⁵ Stanton fibers/cm² [Stanton fibers are defined as fibers with length < 8 μm and diameter ≤ 0.25 μm], which are poorly represented in MMVF10 and MMVF11 fibers (Yegles et al. 1995).
Casey et al. (1983) reported that neither coarse glass nor fine glass fibers caused sister chromatid exchange in CHO-K1 cells, human fibroblasts (primary cells) or human lymphoblastoid cells. However, both fiber types caused mitotic delay (as measured by the number of second metaphase cells) in CHO-K1 cells, and human fibroblasts; the fine glass fibers caused a greater inhibition than the coarse glass fibers.

### Cell transformation and transfection studies

The probable mechanism of asbestos-mediated carcinogenesis involves mutation and/or activation of proto-oncogenes, inhibition of tumor-suppressor genes, and activation of transcription factors controlling the production of cytokines, cell transformation, and cell growth. A number of studies have investigated these endpoints in glass fibers and are reviewed in this section. The data are summarized in Table 5-17.

Gene amplification was determined by a Southern blot analysis of K-ras, H-ras, c-myc, and c-fos proto-oncogenes in nine BALB-c-3T3 cell lines transformed by Owens-Corning AAA-10 glass fiber (Whong et al. 1999). Mutational spectra of the p53 tumor-suppressor gene and the K-ras proto-oncogene were also determined. Gene amplification was found in five of nine transformed cell lines for K-ras, five of nine for c-myc, and six of nine for c-fos proto-oncogenes, and all transformed cell lines showed H-ras gene amplification. Point mutations (transitions or transversions) were found in K-ras (exon 2) in two of nine of the transformed cell lines and p53 (exons 2-5) in six of nine. The authors stated that the results show the possibility of genomic instability originating from chromosomal alterations induced by glass fibers, followed by gene amplification and/or gene mutations in proto-oncogenes and/or tumor suppressor genes.

Various types of glass wool fibers, including insulation glass wool and special-purpose glass wool fibers, have been shown to transform mammalian cells; however, transformation efficiency appeared to be affected by fiber length and diameter.

Gao et al. (1995) investigated cell transformation in NIH-c-3T3 cells and cytotoxicity in BALB/c-3T3 cells with three fibers: Owens-Corning insulation glass wool, Owens-Corning AAA-10, and JM100 fibers. All fiber types induced cytotoxicity (measured by relative cloning efficiency) and dose-related increases in cell transformation, and...
anchorage-independent growth of the transformed cells. The authors concluded that cell transformation was inversely related to size, with the shortest fibers (AAA-10) having the highest transforming potency and the longest and thickest fibers (insulation glass wool) having the lowest potency. A similar relationship between fiber size and cytotoxicity (as measured by survival) was observed. In contrast to this, Hesterberg et al. (1986) reported that unmilled glass fibers induced greater toxicity and higher transformation efficiency than milled glass fibers in Syrian hamster embryo cells similar to that observed for micronuclei induction (see above). [However, in the study reported by Gao et al., AAA-10 and JM100 fibers were also smaller in diameter besides being shorter than the insulation glass wool fibers, thus diameter size might also have contributed to differences in cell transformation.] In another study in Syrian hamster embryo cells, thinner glass fibers (Manville code 100) were more potent in inducing cell transformation and cytotoxicity (relative survival) than thicker glass fibers (Manville code 110). Fiber length also affected transformation efficiency; transformation efficiency was reduced 10 fold when the length of the thin fibers was decreased from 9.5 μm to 1.7 μm, and was absent when the length was reduced to 0.95 μm (Hesterberg and Barrett 1984).

Glass fibers did not mediate transfection with plasmids and DNA replication in human MeT-5A mesothelial cells (Gan et al. 1993). Several asbestos fibers were positive in this assay.

5.5.4 Genetic damage: mammalian in vivo systems

Bottin et al. (2003) exposed transgenic male LacI F344 rats (lambda LIZ, BigBlue) by nose only to CM44 glass fibers (mean length = 5.0 μm and mean diameter = 0.37 μm) at a concentration of 6.3 mg/m³ (601 WHO fibers) for 5 days and examined mutations in
lung DNA 1, 3, 14, 28, and 90 days following exposure. No significant differences in mutant frequencies between the exposed and control rats were observed. This fiber was also rapidly cleared from the lungs. Schürkes et al. (2004) investigated the induction of 8-OHdG in female Wistar rats exposed to MMVF11 (see Section 5.5.1), since the production of hydroxyl radicals in cells treated with fibers may result in the formation of pre-mutagenic DNA bases. MMVF11 (14.7, 29.4, 50, and 100 mg MMVF; diameter = 0.08 to 4.20 μm, length = 1.7 to 98.8 μm) was administered to female rats for 10 or 20 weeks. TNF-α released by macrophages from peritoneal lavages and the induction of 8-OHdG were measured. A dose of 14.7 mg resulted in significant increases in macrophages, while 100 mg resulted in decreased relative macrophage numbers. 8-OHdG was increased with increasing doses of MMVF. Percentages of macrophages correlated with the induction of 8-OHdG 10 weeks after treatment.

Topinka et al. (2006b, 2006a) investigated mutagenesis and DNA damage induced by SVFs alone or combined with exposure to benzo[a]pyrene in the lung of male homozygous λ-lacI transgenic F344 rats (Big Blue rats). Rats were administered by intratracheal instillation either single doses of 1 or 2 mg, or four weekly consecutive doses of 2 mg of MMVF10 or rock wool fibers alone, the fibers combined with a 10-mg dose of benzo[a]pyrene, 10 mg of benzo[a]pyrene alone, or vehicle (0.2 mL of physiological saline). The added exposure to benzo[a]pyrene was designed to model the interaction between fibers and tobacco smoke, which the authors suggested might act synergistically to amplify weak mutagenic and carcinogenic effects of fibers. DNA strand breaks (measured by the comet assay) were increased in macrophages and lung epithelial cells in treated rats, but no increase in mutant frequency was observed with MMVF10 fibers alone (Topinka et al. 2006b). The rock wool fibers caused more extensive inflammation than glass wool fibers. There were only minor differences in the extent of inflammation in rats given single or multiple doses. There was some evidence of oxidative damage in rats that had received multiple doses of MMVF10 based on increased levels of malondialdehyde, a marker for oxidative stress, in lung tissue after 16 weeks.

The simultaneous administration of benzo[a]pyrene with rock wool fibers resulted in an increased mutant frequency that was more than three-fold higher than the sum of the
mutant frequencies induced by benzo[a]pyrene and fibers separately and was observed after only 4 weeks compared with 16 weeks for the fibers alone (Topinka et al. 2006a). The authors reported a super-additive mutagenic effect for combined exposure to benzo[a]pyrene and MMVF10 fibers only at the highest dose of fibers tested (4 × 2 mg). Neither rock wool nor MMVF10 fibers co-administered with benzo[a]pyrene caused any significant difference in the levels of benzo[a]pyrene-specific DNA adducts in lung tissue compared with benzo[a]pyrene treatment alone.

5.6 Mechanisms of fiber carcinogenicity

The mechanisms of fiber-induced carcinogenicity are not completely understood, but several hypotheses have been proposed and are discussed below. The pathogenicity of fibers appears to depend on multiple factors, including fiber dimensions, location of deposition, biopersistence, uptake by macrophages or other target cells, migration into the interstitium and pleura, and induction of persistent inflammation and fibrosis. The German Commission for the Investigation of Health Hazards of Chemical Compounds in the Work Area (DFG 2002) concluded that: “in principle, all kinds of elongated dust particles have the potential, like asbestos fibers, to cause tumors if they are sufficiently long, thin and durable in vivo.” However, the definition of pathogenic fiber properties “sufficiently long, thin and durable” is still under discussion. Clearance of the shorter fibers is similar to or faster than clearance of insoluble nuisance dusts (Bernstein 2006, Muhle et al. 1987); however, long fibers are not as easily cleared from the lungs and induce inflammation and fibrosis (Davis and Cowie 1990). Since much of what is known about mechanisms of fiber carcinogenesis comes from studies of asbestos and other SVFs, the following discussion is not limited to glass fibers.

Nguea et al. (2008) proposed that fiber-induced lung carcinogenesis, [which included discussion of fiber interactions with both lung epithelial cells and mesothelial cells,] could be explained by two different mechanisms relating to the physical properties of the fibers in situ and the effects of the fibers on macrophages (Figure 5-5). The potential for harm from inhaled fibers is dependent upon the following physicochemical properties: fiber dimension, biopersistence, surface reactivity, and chemical composition. The fibers can interact directly with target cells (epithelial cells, mesothelial cells, fibroblasts) leading to an inflammatory response and/or genotoxicity. Alveolar macrophages provide
an early immune response through phagocytosis of inhaled foreign bodies and amplification of the inflammatory response through the release of cytokines, reactive oxygen and nitrogen species, interleukins, mitogenic factors, and chemotactic factors. These inflammatory mediators would affect the local cell environment, leading to genotoxicity, proliferation and/or apoptosis. Depending on the properties of the fibers, incomplete phagocytosis (frustrated phagocytosis) can occur, leading to further amplification of the inflammatory response.

The potential mechanisms of fiber carcinogenesis have also been reviewed by others (Fubini and Fenoglio 2007, Hesterberg and Hart 2001, IARC 2002, Kane et al. 1996b, Nguea et al. 2008). The available reviews identify the following mechanisms as having important roles in the development of fiber-induced diseases: production and release of ROS and DNA damage, genotoxicity, chronic inflammation with release of cytokines and growth factors, cytotoxicity and increased cell proliferation, and co-carcinogenicity. In addition, Christensen et al. (2008, 2009) recently investigated the role of gene silencing through DNA hypermethylation in asbestos carcinogenesis.
5.6.1 Release of reactive oxygen species

Both natural fibers and SVFs have generated ROS and reactive nitrogen species (RNS) in cell-free or in-vitro model systems (Nguea et al. 2008). Proposed mechanisms include iron-catalysed generation of the hydroxyl radical in the presence of molecular oxygen, superoxide anion, or hydrogen peroxide or release of ROS/RNS (hydrogen peroxide, superoxide anion, nitric oxide, hydroxyl radical, peroxynitrite, or nitronium ions) from macrophages during incomplete phagocytosis (frustrated phagocytosis) of long fibers (Kane 1996a). Biopersistent fibers deposited in the lung cause chronic inflammatory reactions leading to generation of free radicals that mediate DNA damage and mutations in oncogenes, growth regulatory genes, and tumor-suppressor genes. Thus, inflammatory reactions induced by persistent fibers in the lung are thought to be important genotoxic mediators that accelerate tumor development and progression (Nguea et al. 2008, Okada 2007) (see Section 5.6.3 for DNA damage).
Alveolar macrophages are the first line of defense in the alveolar environment and play a central role in recruiting and activating other inflammatory cells (Nguea et al. 2008).

Rihn et al. (2000) demonstrated that inhaled crocidolite induced the release of ROS and RNS resulting in oxidation and nitrosylation of protein and DNA, and lipoperoxidative damage of type II pneumocytes, fibroblasts, and mesothelial cells. Thus, cell injuries caused by release of these reactive species contribute to the pathogenesis of fiber-related lung disease and indicate that oxidative stress is a basic mechanism of the carcinogenic effect (Nguea et al. 2008). Zeidler-Erdely et al. (2006) showed that increasing the dose of JM100 glass fibers resulted in an increase in reactive species production by human alveolar macrophages. However, there was no effect of fiber length over the range of 8 to 20 μm. Ohyama et al. (2000, 2001) investigated the chemiluminescent response (an indicator of reactive oxygen species production) from human monocyte-derived macrophages exposed to glass wool, rock wool, refractory ceramic fibers, and others. These authors reported that there was a strong correlation between geometric-mean length and the ability to induce chemiluminescence for various fiber samples longer than 6 μm in length. There was no correlation with geometric-mean width; however, between two refractory fiber samples with similar lengths, the narrower width sample induced more chemiluminescence.

5.6.2 Chronic inflammation

A potential indirect mechanism of fiber carcinogenesis involves the release of cytokines and growth factors from inflammatory cells in the lungs (Kane 1996a). Macrophages are activated in response to particulates deposited in the lung resulting in increased release of ROS, chemical mediators, and cytokines. Cytokines sustain and amplify the inflammatory reaction. Thus, persistent fibers in the lung, interstitium, or subpleural connective tissue may cause a sustained chronic inflammatory reaction. A chronic imbalance between cytokines and growth factors may contribute to tissue injury and proliferation of epithelial and mesenchymal cells. Injury to the alveolar epithelial lining and basement membranes could enhance translocation of fibers and inflammatory mediators to the interstitium of the lung.

Poland et al. (2008) reported that concerns over the potential pathogenicity of carbon nanotubes had been raised because their needle-like fiber shape was similar to asbestos.
Therefore, the pathogenicity of multiwalled carbon nanotubes was compared with long-fiber and short-fiber amosite asbestos (used as positive and negative controls, respectively). Four samples of carbon nanotubes were prepared. Two of the samples contained a substantial proportion of straight fibers that were longer than 20 µm while the other two samples consisted of nanotubes that were arranged in low-aspect–ratio tangled aggregates. Each material was injected i.p. into mice (50 µg), and the peritoneal cavity was washed out either 24 hours or 7 days post exposure with physiological saline. The authors reported that carbon nanotubes produced an asbestos-like, length-dependent, pathogenic response, which included inflammation and formation of granulomas. Polymorphonuclear leukocytes, protein exudation, and granulomas were observed only in samples that contained long fibers.

Cytokines and growth factors

Results for production of TNF-α in response to exposure to glass fibers are variable. Fujino et al. (1995) tested the toxicity of several SVFs and natural fibers by measuring TNF-α production and release of lactate dehydrogenase (LDH) and β-glucuronidase (BGU) from rat alveolar macrophages in vitro. Cell cultures were incubated for 24 hours with the various fibers (100 µg/mL). There was a significant increase in TNF-α, LDH, and BGU in cell cultures exposed to glass fibers (specified as SiO2·Na2O with a median length of 12.8 µm and diameter of 0.54 µm). The results were similar to the responses reported for chrysotile, crocidolite, and amosite. Murata-Kamiya et al. (1997) reported the TNF-α production was slightly increased (not significant compared with controls) in a murine macrophage cell line (J774 cells) exposed to 100 µg/mL of glass fibers for 18 hours. Cell cultures exposed to chrysotile asbestos showed a significant increase in TNF-α production. The glass fibers used in this study had the same geometric mean length and diameter as those tested by Fujino et al. (1995). Cullen et al. (1997) tested the
effects of MMVF10, MMVF11, 100/475, 104E, amosite, crocidolite, and other SVFs on
TNF-α production in rat alveolar macrophages. MMVF10 and MMVF11 did not
stimulate TNF-α production, whereas the effects of 100/475 and 104E glass were
intermediate. [No statistics were reported, but values were less than twice the control
values.] Values for amosite and crocidolite asbestos were about 2.5 to 3.2 times greater
than controls. Fisher et al. (2000) investigated TNF-α production in four different cell
types: primary rat alveolar macrophages, human peripheral blood monocytes, Thp-1 cells
(derived from the peripheral blood of a 1-year-old boy with acute monocytic leukemia),
and J774.2 cells (recloned from J774.1 cells that were recovered from a Balb C mouse).
Fibers tested included amosite (35.3% > 20 μm), 100/475 glass (19.3% > 20 μm), and
MMVF10 (67.2% > 20 μm). Cells were incubated with the various fiber types for 16
hours. None of the fiber types resulted in a significant increase in TNF-α production for
any of the cell types. The authors concluded that TNF-α release did not equate to fiber
pathogenicity in this study.

The glass fiber-induced expression of TNF-α likely involves several different
transcription factors, including NF-κB, which is involved in the activation of a variety of
proinflammatory genes (Schins and Donaldson 2000). Mechanisms involved in NF-κB
activation by fibers include ROS, arachidonic acid metabolism, physicochemical
properties of the fibers (e.g., fiber dimensions, transition metals), lipid peroxidation, and
frustrated phagocytosis. Gilmour et al. (1997) reported that MMVF10 upregulated the
nuclear translocation of AP-1 transcription factor in rat alveolar macrophages by about
12% compared with untreated controls but did not affect NF-κB. In the same study, AP-1
was upregulated by 37.4% and NF-κB by about 20% by amosite. Brown et al. (1999)
investigated the effects of fiber exposure on NF-κB nuclear translocation in A549 human
alveolar epithelial cells. Asbestos fibers caused a dose-dependent increase in NF-κB
nuclear translocation, but MMVF10 and code 100/475 fibers did not. When the fiber dose
was doubled from $8.24 \times 10^6$ to $16.48 \times 10^6$, MMVF10 caused a significant increase in
the nuclear translocation of NF-κB. Doubling the dose of 100/475 fibers had no effect.

In other studies, a substantial increase in TNF-α production and the DNA-binding
activity of NF-κB in RAW 264.7 mouse monocytes (Ye et al. 1999) and NR8383 rat
alveolar macrophages (Ye et al. 2001) was observed when exposed to code 100 fibers. These studies compared the effects of long fibers (17 μm) and short fibers (7 μm) after exposure for 3, 6, or 16 hours. TNF-α production was not induced after a 3-hour exposure, but a significant induction was observed after 6 or 16 hours. The TNF-α gene promoter was activated after exposure to both short and long fibers; however, the long fibers showed a 100% increase in stimulatory activity compared with short fibers. The increase in DNA binding activity of NF-κB indicated that this transcription factor was responsible for activation of the gene promoter. On a fiber-per-fiber basis, long glass fibers were two to four times more potent than short fibers in inducing NF-κB, the gene promoter activity, and production of TNF-α.

Ye et al. (2001) also demonstrated that glass fibers induced phosphorylation of MAP kinases, p38, and ERK in primary rat alveolar macrophages exposed to code 100 fibers and that this phosphorylation was associated with TNF-α gene expression. When transcription factor inhibitors were included in the assays, release of TNF-α was almost completely inhibited by SN50 (an inhibitor of NF-κB), 70% by SB203580 (an inhibitor of p38), and 50% by PD98059 (which prevents phosphorylation of ERK by MEK). Xie et al. (2000) conducted a study to determine if TNF-α affected binding (defined as resistance to removal by a simple washing technique) of fibers to epithelial cells. Rat tracheal explants were exposed to TNF-α, or to culture medium alone, followed by a suspension of amosite or MMVF10. Exposure to TNF-α increased epithelial fiber binding, but higher TNF-α doses were needed to show an effect with MMVF10. This effect was abolished by an anti-TNF-α antibody and an NF-κB inhibitor indicating that fiber binding was controlled by a NF-κB–dependent mechanism.

Interleukin-1 beta (IL-1β) is a cytokine released from activated macrophages and, like TNF-α, is a mediator of inflammation, cell proliferation/differentiation, and apoptosis. It is involved in recruitment of inflammatory cells and has been shown, along with TNF-α, to regulate mesothelial cell proliferation (Wang et al. 2004).

Dostert et al. (2008) has studied the proinflammatory response of macrophages to asbestos and silica particles. Using a macrophage-like cell line, THP1, mature IL-1β was
released after 6-hour exposure to asbestos or silica particles, but not to cigarette smoke or
diesel exhaust particles. Further experiments demonstrated that ROS generated upon
actin-mediated phagocytosis activated the Nalp3 inflammasome within the macrophage.
Caspase-1 within this multiprotein complex then cleaved pro-IL-1ß releasing mature IL-
1ß. Inhibitors of NADPH oxidase decreased IL-1ß production, providing evidence in
support of activation of ROS through generation of NADPH oxidase. Using a mouse
model, the role of Nalp3 inflammasome in asbestos-induced inflammation was further
investigated. Nalp3−/− and Nalp3+/+ mice were exposed for 9 days to chrysotile asbestos,
and markers of inflammation were analyzed. Lymphocyte, eosinophil, and neutrophil
infiltrations were decreased in the lungs of Nalp3−/− mice, as were the levels of IL-1ß and
KC [keratinocyte chemoattractant], a neutrophil chemokine. These data support the role
of the Nalp3 inflammasome in particulate-induced pulmonary inflammation.

Inflammation and fibrosis
Chronic inflammation also is known to be an important factor for fibrosis. In rodent
inhalation studies of fibers and other particulates, lung cancer is almost always preceded
by chronic inflammation and fibrosis (IARC 2002). Although high levels of pulmonary
fibrosis have been found in studies showing significant lung tumor incidences, a direct
cause and effect relationship has not been established (Kane 1996a). Nevertheless, IARC
(2002) concluded that the proposed mechanistic links between chronic inflammation,
fibrosis, and cancer are biologically plausible.

5.6.3 Genotoxic effects
Genotoxic effects include oxidized bases, DNA breaks, aneuploidy, and mutations and
may result from three possible mechanisms: (1) direct interaction of fibers with the
spindle apparatus, (2) release of fiber components that directly damage DNA, and (3)
indirect damage resulting from chemical species released during chronic inflammation.
As discussed previously (see Section 5.5.3, “Chromosomal or chromatid-related
effects”), phagocytized fibers might interfere with chromosome segregation during
mitosis. Some studies using light microscopy on fixed cells have suggested that long
fibers can interfere with the mitotic spindle, causing lagging chromosomes and
subsequent aneuploidy (Kane 1996a). Aneuploidy, polyploidy, and binucleated cells have
been observed in a wide variety of rodent and human cell types in vitro; however, it has
not yet been established *in vivo* whether fibers are internalized by the target cells that are responsible for bronchogenic carcinoma or malignant mesothelioma.

Physical interference with chromosomal segregation is not the only way fibers might disrupt mitosis (Kane 1996a). Disruption of the cytoskeletal organization of the cell could enhance the interaction of fibers with the mitotic spindle, and interference with the cleavage furrow might result in binucleated daughter cells.

Johnson and Jaramillo (1997) examined expression of p53, Cip1, and Gadd153 proteins following treatment of A549 cells with crocidolite and JM100 fibers. These proteins are associated with DNA damage and cell-cycle arrest. A dose-dependent toxicity was observed with both fiber types, but the cytotoxic effects were more marked with JM100 when compared with crocidolite on an equal mass/unit area basis. There was a dose-dependent increase in expression of all three proteins in cells exposed to crocidolite, but not to JM100 fibers. Pache *et al.* (1998) exposed a human mesothelial cell line (MET5A) or A549 cells to various concentrations of crocidolite and MMVF10 and measured the intensity and distribution of epidermal growth factor receptor (EGF-R) protein. Crocidolite asbestos, but not MMVF10, caused an increase in the number of EGF-R–positive MET5A cells. No increase in EGF-R–positive A549 cells was observed with either fiber type.

Most of the studies of DNA damage were conducted with target cell populations *in vitro*. Important factors include the fiber source and preparation, cell type, species, and assay conditions. Several natural and synthetic fibers (i.e., SVFs) have caused DNA damage in rodent and human cells. Studies with asbestos indicate that mesothelial cells might be more sensitive to DNA damage than epithelial cells or fibroblasts (Kane 1996a). Nguea *et al.* (2008) reviewed SVF-induced genotoxicity and reported that asbestos fibers (including amosite, chrysotile, and crocidolite) appeared to be more genotoxic that glass fibers based on higher levels of DNA base oxidation (i.e., 8-OHdG). *In vivo* studies using Big Blue transgenic rats indicated that glass fibers of low biopersistence were not mutagenic for lung DNA (see Section 5.5.4); however, asbestos fibers caused an increase in mutant frequency (Bottin *et al.* 2003, Rihn *et al.* 2000). Although a number of studies (see Section 5.5.3) have shown that glass fibers can cause DNA damage, micronuclei,
and chromosomal aberrations \textit{in vitro}, relatively few \textit{in vivo} studies have been conducted. The exact genotoxic mechanisms initiated and sustained by SVF are not well understood and further study is needed to distinguish between direct and indirect DNA damage (Greim 2004).

Schürkes \textit{et al.} (2004) investigated the role of inflammation-driven genotoxicity in fiber-induced carcinogenesis (MMVF11 glass fibers and crocidolite) (see Section 5.5.1) and reported a correlation between parameters of inflammation and the induction of 8-OHdG.

\textbf{5.6.4 Epigenetic effects}

Malignant pleural mesothelioma is highly associated with asbestos exposure, which occurs in 70% to 80% of cases of this type of mesothelioma (Christensen \textit{et al.} 2008, Christensen \textit{et al.} 2009). Christensen \textit{et al.} (2008) noted that asbestos is a nonmutagenic carcinogen, and they focused their investigations on the epigenetic mechanism of gene silencing through hypermethylation of cytosines in CpG islands in tumor-suppressor genes. Using a biochemical pathway-based approach, they examined promoter hypermethylation of an array of genes involved in cell-cycle control. One or more of these genes was methylated in 60% of a set of 70 cases of pleural mesothelioma. In a larger study of 158 pleural mesotheliomas and 18 non-tumorigenic parietal pleura samples, the methylation patterns of 1,505 CpG loci associated with 803 cancer-related genes were determined (Christensen \textit{et al.} 2009). The number of asbestos bodies, which reflects the exposure to asbestos, was significantly ($P < 0.03$) associated with the pattern of methylation, and there was a clear distinction between the methylation patterns for malignant versus normal pleura ($P < 0.0001$). The lung burden of asbestos bodies also was found to be significantly ($P < 0.02$) associated with methylation of any of the six cell-cycle genes in the earlier paper by Christensen \textit{et al.} (2008). A significant ($P < 0.05$) trend between increasing asbestos body count and increasing number of methylated cell-cycle pathway genes remained after controlling for age, gender, and tumor histology, consistent with the hypothesis that asbestos body burden contributes to epigenetic dysregulation of cell-cycle genes. Gender was associated with asbestos body count, with significantly ($P < 0.001$, more than 5-fold) higher asbestos body count in males compared with females. The authors of these papers suggested that methylation could represent a novel tumorigenic mechanism of action for asbestos as an epigenetic cause for malignant
mesothelioma. That is, mesotheliomas are driven by both genetic and epigenetic alterations (Tsou et al. 2007).

5.6.5 Cytotoxicity and proliferation of target cells

High concentrations of asbestos fibers are toxic to target cell populations in vitro; however, under certain conditions, asbestos fibers induce cell proliferation (Kane 1996a). Kane (1996a) identified four potential mechanisms of growth stimulation based on studies with asbestos fibers. Each mechanism requires direct interaction with target cells and includes the following: (1) compensatory cell proliferation in response to toxicity, (2) stimulation of intracellular signal transduction pathways, (3) direct mitogenesis, and (4) induction of growth factor and growth factor receptor expression.

Cell proliferation

Cell proliferation is triggered as part of the healing response to tissue injury. Intraperitoneal injection of asbestos has caused injury to the mesothelial lining of the parietal pleura (diaphragm) in mice, and localized damage to the alveolar epithelium following inhalation or intratracheal administration is believed to facilitate translocation of fibers into the interstitium of the lungs (Kane 1996a). Hart et al. (1994) evaluated MvL 901 glass fibers and Blake et al. (1998) evaluated code 100 glass fibers. Both studies showed length-related toxicity. Fibers of lengths 17 to 33 μm showed marked increases in toxicity, while fibers less than 7 μm in length showed significantly less, or no toxicity. Fiber thickness also had a modest effect on toxicity in one study. It was concluded that long fibers were toxic per se, in addition to their ability to accumulate in the lung due to slower clearance rates. It was suggested that the increased toxicity of long fibers was due to frustrated phagocytosis leading to leakage of oxidants and enzymes.

Signal transduction pathways

Intracellular signal transduction pathways are commonly triggered in response to tumor promoters and asbestos fibers (Kane 1996a). Experimental evidence demonstrates that asbestos fibers can act as a tumor promoter, activate protein kinase C, cause increased expression of ornithine decarboxylase, and cause hydrolysis of inositol phospholipids.
Mitogenic effects

Evidence for the mitogenic effects of fibers is based on in vitro studies that show induction of the proto-oncogenes \( c-fos \) and \( c-jun \) following exposure to asbestos (Gao et al. 1997, Janssen et al. 1994). Prolonged expression of proto-oncogenes may result in growth stimulation of target cells.

The induction of proto-oncogenes (Gao et al. 1997, Janssen et al. 1994), expression of DNA-damage–inducible genes (Johnson and Jaramillo 1997), and epidermal growth factor-receptor (Pache et al. 1998) by glass wool has also been investigated. Janssen et al. (1994) examined the effects of crocidolite, chrysotile, MMVF10, and other fibers and particulates on mRNA levels of \( c-fos \), \( c-jun \), and ornithine decarboxylase in hamster tracheal epithelial (HTE) cells and rat pleural mesothelial (RPM) cells. These cells were selected because they are the progenitor cells of bronchogenic carcinoma and mesothelioma, respectively. MMVF10 was less cytotoxic than asbestos, and RPM cells were more susceptible to cytotoxicity than HTE cells. There was an increase in \( c-jun \) mRNA levels in HTE cells after exposure to asbestos or MMVF10; however, increases were less after exposure to MMVF10 compared with asbestos. No alterations in \( c-fos \) mRNA levels were observed in HTE cells. Ornithine decarboxylase mRNA levels also were increased in HTE cells after exposure to asbestos or MMVF10. Crocidolite asbestos caused increases in \( c-fos \), \( c-jun \), and ornithine decarboxylase in RPM cells, but MMVF10 did not when added at nontoxic concentrations (< 10 \( \mu \)g/cm\(^2\)). At a higher concentration of MMVF10 (25 \( \mu \)g/cm\(^2\)), \( c-fos \) and \( c-jun \) mRNA levels were increased. Gao et al. (1997) investigated the relationship between silica and glass fiber-induced cell transformation and oncoprotein expression (protein products from seven proto-oncogenes), and p53 in BALB/c-3T3 cells. All transformants induced by glass fibers were positive for \( c-jun \) protein expression. The other proto-oncogene proteins or tumor suppressor genes (c-K-ras, c-H-ras, c-myc, c-sis, c-erb B1, c-myb, and p53) were either not detectable or were not significantly different between transformed and non-transformed cells.

Growth factors

Increased expression of platelet-derived growth factor (PDGF-AA) and its receptor was demonstrated in vitro in rat lung fibroblasts exposed to asbestos fibers (Lasky et al. 1995). Increased expression of growth factors and their receptors may trigger cell
proliferation by activating an autocrine growth-stimulatory pathway. However, the
mechanism responsible for turning on transcription factors that regulate specific genes
has not been identified. One possibility is oxidant stress from generation of ROS and
activation of NF-κB.

Cytotoxicity
Nguea et al. (2005) reported that cell viability was inversely related to fiber concentration
regardless of the type and size of fibers. These authors concluded that cell overloading
may be responsible for the cytotoxicity of fibers, because cytotoxicity was observed only
when the ratio of fibers to cells was high. Castranova et al. (1996) reported that long and
thick fibers designed for building insulation had only a weak effect on cell viability of rat
alveolar macrophages and did not affect macrophage function.

Extracellular release of cytoplasmic LDH and BGU can result from cytotoxicity (Nguea
et al. 2008). Release of LDH indicates loss of membrane integrity, and BGU is a
lysosomal enzyme biomarker of phagocyte damage or activation. Castranova et al.
(1996) reported that glass microfibers induced a dose-dependent release of both LDH and
BGU from rat alveolar macrophages. Blake et al. (1998) reported that cytotoxicity in rat
alveolar macrophages was directly related to glass fiber length over 17 μm; however,
chemical composition also had some influence.

5.6.6 Co-carcinogenesis
Lung cancer risk is enhanced in asbestos workers who smoke (Hesterberg and Hart
2001). Although a small excess of lung cancer occurs in non-smokers exposed to
asbestos, most cases of lung cancer occur in people exposed to asbestos who are smokers
(Kane et al. 1996b). It is not known if the mechanisms leading to lung cancer are the
same for smokers and non-smokers exposed to asbestos. However, there is experimental
evidence that asbestos fibers enhance the delivery of the carcinogens in cigarette smoke
and increase their metabolic activation (Kane 1996a). Furthermore, cigarette smoking
reduces ciliary action in the tracheobronchial region and enhances fiber penetration into
the bronchial epithelium. Topinka et al. (2006a) administered benzo[a]pyrene
simultaneously with rock wool fibers to model the interaction between fibers and tobacco
smoke (see Section 5.5.4). Intratracheal instillation of benzo[a]pyrene and fibers
combined in Big Blue rats resulted in mutant frequencies that were higher and occurred earlier than those with benzo[a]pyrene or fibers alone.

Exposure to SVFs generally consists of a mixture of non-fibrous and fibrous particulates. Several of the mechanisms described in this section (e.g., cell proliferation and chronic inflammation) are responses to particulate exposure in general and not just to fibers.

Little is known about the interactions of fibers with non-fibrous particles, particularly the less toxic particulates. However, increased incidences of lung tumors and mesotheliomas have been reported in rats exposed by inhalation to a mixture of chrysotile asbestos and non-fibrous dust (Kane 1996a).

Another possible, yet controversial, co-carcinogenic interaction is with SV40 virus. SV40-like DNA sequences have been identified in human mesothelioma tissue samples but not in adjacent lung tissue (Carbone et al. 1994, Rivera et al. 2008). The origin of the viral DNA and its relationship to malignant mesothelioma is unknown. The viral oncoprotein can bind to p53 and inhibit its activity (IARC 1999). Rivera et al. (2008) reported that co-carcinogenesis between SV40 and asbestos in causing malignant mesothelioma has been demonstrated in three separate laboratories using different experimental approaches; however, epidemiological evidence is lacking due “to unattainable identification of infected from noninfected cohorts.”

5.7 Summary

5.7.1 Deposition, clearance, and retention

Fibers that are carried in the inhaled air to the tracheobronchial region are considered inhalable while those that reach the alveolar region are considered respirable. Fibers that are inhalable but non-respirable can deposit in the extrathoracic and tracheobronchial regions and can cause adverse effects. Deposition refers to the actual dose deposited in the lung and is influenced by the anatomy and physiology of the airway, respiratory rate, and physical properties of the fiber. Deposition occurs by impaction, sedimentation, interception, and diffusion. Peak deposition occurs in rodents and humans for fibers with aerodynamic diameters of 1 to 2 μm.

Clearance and retention of fibers are affected by chemical composition, size distribution, number of fibers deposited, and time since last exposure. Clearance mechanisms also
depend on the region of deposition. Short fibers are readily phagocytized by alveolar
macrophages and transported from the lower lung to the upper airways and cleared
through the mucociliary escalator, or they can be cleared via lymphatics. Long fibers are
not effectively cleared by phagocytosis, and can effectively kill the phagocyte, but
depending on the fiber type, may be subject to dissolution and transverse breakage.

Particle overload (which has been observed in rats) occurs when the deposition rate of
poorly-soluble, less toxic particles exceeds the normal clearance rate, and can result in
adverse effects.

5.7.2 Dissolution, biodurability, and biopersistence of glass fibers

Dissolution occurs when water molecules attack the surface of the fiber and remove
material. Biodurability describes the rate of removal through dissolution or
disintegration; biopersistence includes biodurability plus physiological clearance and
refers to the capacity of a fiber to persist and to conserve its chemical and physical
features over time in the lung. Biodurability is expected to be similar in rats and humans,
but biopersistence may be substantially different due to differences in the physiological
clearance mechanisms. In general, biodurability of various fibers in the lung has been
ranked as follows: glass fibers < refractory ceramic fibers < chrysotile asbestos <
an amphibole asbestos. Highly durable fibers, such as asbestos, are resistant to dissolution
and transverse breakage. Although experimental dissolution rates for glass fibers show
variability (up to a 30-fold range), they generally show some correlation with clearance
rates of long fibers in short-term biopersistence studies. Certain components of SVFs are
subject to leaching resulting in changes in composition over time. The literature indicates
that the special-purpose fibers cited in this document tend to have greater biopersistence
than the insulation glass wools. The fibers become weaker from fractures, peeling, and
pitting and may break.

5.7.3 Toxic effects

Several studies have evaluated mortality from non-malignant respiratory disease or
morbidity related to the respiratory system among workers exposed to glass wool. A
significantly elevated SMR for non-malignant respiratory disease was found in the earlier
updates, but not the most recent update of the large U.S. cohort study. Mixed findings
have also been observed for adverse respiratory symptoms, pulmonary function, and lung
abnormalities (detected on chest radiographs); workers in some studies were also exposed
to asbestos.

Various types of glass wool fibers (MMVF10, MMVF11, 104E glass fibers, JM100/475
microfibers) caused adverse lung effects (such as inflammation and fibrosis) in rats
exposed by inhalation (Bellmann et al. 2003, Bermudez et al. 2003, Cullen et al. 1997,
Hesterberg et al. 1993, 2002). In hamsters, inhalation of MMVF10 fibers caused
inflammatory effects, but not fibrosis (Bermudez et al. 2003, Hesterberg et al. 1993). In
cytotoxicity studies, longer fibers induced greater toxicity in rat alveolar macrophages
(Blake et al. 1998, Hart et al. 1994).

5.7.4 Genetic and related effects
Glass fibers were shown to induce production of reactive oxygen species in cell-free
systems and cultured cells, to damage DNA, and to cause chromosomal aberrations,
nuclear abnormalities, mutations, gene amplification in proto-oncogenes, and cell
transformation in mammalian cells. However, glass wool fibers did not cause mutations
in bacteria or cause sister chromatid exchange in mammalian cells, but only two types of
fibers were tested in each of these assays. Glass wool fibers also induced DNA strand
breaks (measured by the comet assay) in macrophages and lung epithelial cells, and
oxidative stress in rats, but did not induce mutations in vivo. An increase in mutant
frequencies was reported for benzo[a]pyrene and rock wool fibers instilled
simultaneously in Big Blue rats.

Further, fiber persistence may also lead to inflammation-driven (indirect) genotoxicity, as
reactive inflammatory cells release reactive oxygen species, growth factors, and
cytokines. Fiber characteristics did not appear to be important in the production of
reactive oxygen species, and studies assessing oxidative damage by different endpoints
were positive for both special-purpose fibers and insulation glass wool fibers. Similarly,
fibers of different lengths and diameters were able to cause DNA damage in mammalian
cells. However, effects on chromosomes and nuclear abnormalities might be related to
fiber characteristics; longer fibers appeared to be more potent in causing these genotoxic
effects. Some studies suggested that thinner fibers were also more effective. Results from
cell transformation studies also suggested that longer and thinner fibers produced higher
transformation efficiency.

5.7.5 *Mechanisms of fiber carcinogenicity*

Several investigators have evaluated fiber characteristics (dimensions and durability or
biopersistence) and tumorigenicity in studies in experimental animals. These studies (by
i.p. injection and intrathoracic implantation) show that fiber dimensions and durability
were important determinants of tumorigenicity. In intrathoracic implantation studies,
pleural sarcomas were correlated with fiber dimensions; long, thin fibers were associated
with the highest tumor incidence. Fibers with a high dissolution rate tended to have a low
potency in the i.p. assay. A relationship between biopersistence in the lung and pathology
was also observed in inhalation studies in rats. Clearance half-times of long fibers (> 20
μm) were approximately 400 to 800 days for two types of asbestos, 80 days for E glass,
50 days for JM100/475 glass, 15 days for MMVF10, and 9 days for MMVF11.

The major proposed mechanisms of fiber-induced carcinogenicity are related to the
physical and chemical properties (such as size or dimensions, durability, surface
reactivity, and chemical composition) of the fibers and to the inflammatory response that
results from the inhalation of fibers. Fiber size affects deposition and clearance, and
biodurability and biopersistence are related to biological effects. Fibers can directly
interact with target cells (epithelial cells, mesothelial cells, fibroblasts) leading to an
inflammatory response and/or genotoxicity. Fibers may induce genotoxic effects by
interacting with the spindle apparatus of chromosomes, directly damaging DNA, or
indirectly damaging DNA through chronic inflammation. Fibers may also induce
epigenetic changes. Alveolar macrophages are activated in response to particulates or
fibers deposited in the lung, resulting in increased release of reactive oxygen species,
chemical mediators, and cytokines (such as TNF-α) and activation of signalling
pathways. A sustained inflammatory reaction may result from incomplete phagocytosis
and prolonged interaction of persistent fibers with the cell surface. Chronic imbalance
between cytokines and growth factors may contribute to tissue injury, proliferation,
and/or apoptosis, which may lead to fibrosis and tumors.

Glossary of Terms

**Acute:** The clinical term is used for a disease having a short and relatively severe course. In rodent testing, usually pertains to administration of an agent in a single dose.

**Adduct:** A complex that forms when a chemical binds to a biological molecule such as DNA or a protein.

**Adenocarcinomas:** A cancerous tissue of epithelial origin.

**Adenoma:** An ordinarily benign neoplasm of epithelial tissue in which the neoplastic cells form glands or gland-like structures in the stroma.

**Aerodynamic diameter:** A physical property of a particle or fiber in a viscous fluid such as air. In general, particles have irregular shapes with actual geometric diameters that are difficult to measure. The equivalent aerodynamic diameter is defined as the diameter of a spherical particle of unit density which has the same terminal settling velocity in still air as the particle or fiber in question.

**Allele:** Any one of a series of two or more different genes that occupy the same position (locus) on a chromosome.

**Alveolar/bronchiolar:** Pertaining to the alveoli or bronchi of the lungs.

**Ambient air:** Outdoor air to which the general public is exposed.

**Aneuploidy:** One or a few chromosomes above or below the normal chromosome number.

**Apoptosis:** Cell deletion by fragmentation into membrane-bound particles which are phagocytosed by other cells.

**Aromatic hydrocarbon:** An organic chemical compound formed primarily from carbon and hydrogen atoms with a structure based on benzene rings and resembling benzene in chemical behavior; substituents on the rings(s) may contain atoms other than carbon or hydrogen.

**Aspect ratio:** The ratio of a fiber’s length to its diameter.

**Assay:** A procedure whereby a property or concentration of an analyte is measured.

**Batt:** Precut panels of insulation available in a variety of widths, lengths, and R-values.

**Benign tumor:** An abnormal mass of tissue that does not spread and that is not life-threatening.

**Bioaccumulation:** The process by which a material in an organism's environment progressively concentrates within the organism.
**Biodegradation:** Biotransformation; the conversion within an organism of molecules from one form to another. A change often associated with change in pharmacologic activity.

**Biodurability:** The rate of removal of a fiber from the lungs by dissolution or disintegration.

**Biopersistence:** The ability of a fiber to remain in the lung. Biopersistence is a function of the fiber solubility and the biological ability of the lung to clear the fiber.

**Bronchiolization:** A process of migrating bronchiolar cells progressively colonizing alveolar spaces.

**Bronchioloalveolar:** Derived from epithelium of terminal bronchioles.

**Bronchoalveolar lavage:** A technique used to obtain a sample of the cells, fluids, and other materials present in the very small airways and alveoli of the lung by instilling saline into the airway via a bronchoscope.

**Carcinoma:** A malignant neoplasm of the epithelium.

**Chromosomal aberrations:** Any abnormality of a chromosome's number or structure.

**Chronic:** Continuing for a long period time. In rodent testing, pertains to dosing schedules of greater than 3 months.

**Clastogen:** Any substance which causes chromosomal breaks.

**Clearance rate:** The rate at which deposited particles are removed by various processes from the respiratory tract. Both the fiber’s physical and chemical characteristics affect the clearance rate.

**Confounding:** A relationship between the effects of two or more causal factors observed in a set of data such that it is not logically possible to separate the contribution of any single causal factor to the observed effects.

**Continuous glass filament:** An extruded filament usually having a relatively large diameter (greater than 6 μm) and a very narrow range of diameter distribution.

**Dehydrogenation:** The removal of one or more hydrogen ions or protons from a molecule.

**Density:** The density for solids and liquids is expressed in grams per cubic centimeter (g/cm³) and is generally assumed to refer to temperatures near room temperature unless otherwise stated. Values for gases are generally the calculated ideal gas densities in grams per liter at 25°C and 101.325 kPa.
**Diffusion:** One of four mechanisms of fiber deposition in the respiratory tract (see also impaction, sedimentation, and interception). Deposition by diffusion is especially important for smaller particles. As particles decrease in size, thermodynamic properties prevail over aerodynamic properties, and for particles < 0.5 μm, deposition and is governed mainly by the diffusional movement induced by Brownian motion of gas molecules.

**Diffusion coefficient:** The rate at which a substance moves from an area of high concentration to an area of low concentration.

**Dissolution:** The act or process of dissolving.

**Durability:** The ability to exist for a long time without significant deterioration.

**Endogenous:** Originating within an organism.

**Epidemiology:** A science concerned with the occurrence and distribution of disease in populations.

**Epithelial:** Relating to or consisting of epithelium.

**Ferruginous body:** A mineral particle to which pulmonary macrophages have added an iron protein coat. Ferruginous bodies are used as an indicator of exposure to specific dusts or fibers.

**Fiber:** A particle with a length to width ratio of at least 3:1

**Flux:** Another term used for a modifier in the glass wool manufacturing process. Typically, oxides such as magnesium oxide (magnesia, MgO), lithium oxide (Lithia, Li2O), barium oxide (baria, BaO), calcium oxide (calcia, CaO), sodium oxide (soda, Na2O) and potassium oxide (K2O) are used as fluxes.

**Fibroblasts:** Connective tissue cells.

**Genotoxicity:** The amount of damage caused to a DNA molecule.

**Glass fiber:** General term that may be used to refer to reinforcing glass filament, glass wool, or superfine glass fiber.

**Glass wool:** A fibrous product formed by blowing or spinning molten glass. The resultant fibers are collected as a tangled mat of fibrous product.

**Hematopoietic:** Pertaining to the formation of blood or blood cells.

**Half-life:** The time required for a substance to be reduced to one-half its present value through degradation or through elimination from an organism.

**Hodgkin’s disease:** A form of malignant lymphoma characterized by painless progressive enlargement of the lymph nodes, spleen, and general lymphoid tissue.
**Homozygotes**: An organism that has the same alleles at a particular gene locus on homologous chromosomes.

**Hydrolysis**: The chemical breakdown of a compound due to reaction with water.

**Hydroxyl radicals**: A particularly reactive, damaging type of free radical that is formed when superoxide radicals react with hydrogen peroxide.

**ICD**: The International Classification of Diseases. Published by World Health Organization, ICD codes are specific three-character codes used to describe a patient’s health care condition.

**Impaction**: One of four mechanisms of fiber deposition in the respiratory tract (see also sedimentation, diffusion, and interception). Deposition by impaction occurs when the airflow encounters rapid changes in direction and the momentum of the fiber carries it along in a straight line to deposit on the airway wall. The larger the aerodynamic diameter, the greater the deposition efficiency due to impaction. This mechanism is most effective for aerodynamic diameters 0.5–1.0 µm.

**In vitro**: Biological process taking place in a test tube, culture dish, or elsewhere outside a living organism.

**In vivo**: Biological processes taking place in a living organism.

**Interception**: One of four mechanisms of fiber deposition in the respiratory tract (see also impaction, diffusion, and sedimentation). Deposition by interception occurs when an airborne fibre in the airway gets close enough to the airway wall to allow one end to touch the wall. For an elongated object such as a fibre, this occurs more readily than for a spherical particle, and thus, interception is a particularly important mechanism for fibre deposition, especially for longer fibers.

**Intraperitoneal [i.p.] injection**: Injection within the peritoneal cavity, i.e., the area that contains the abdominal organs.

**Intrapleural injection**: Injection within the serous membrane (pleura) investing the lungs.

**Intrathoracic injection**: Injection with the thoracic cavity, i.e., the area that contains the heart and lungs.

**Intratracheal instillation**: Instillation within the trachea.

**k_{dis}**: The dissolution rate (k) of a fiber is typically determined by elemental analysis of the flow-through solution to measure the mass of material leached from the fibers over a given time (ng/cm² per hour).

**Leukemia**: A cancer of the blood-forming tissues that is characterized by a marked increase in the number of abnormal white blood cells (leukocytes).
**Lymphatic:** A small sac or node in which lymph is stored; or pertaining to the lymph, lymph nodes, or vascular channels that transport lymph to the lymph nodes.

**Lymphohaematopoietic:** Of, relating to, or involved in the production of lymphocytes and cells of blood, bone marrow, spleen, lymph nodes, and thymus.

**Lymphoma:** A neoplasm of the lymphatic tissue.

**Lymphosarcoma:** Any of various malignant neoplastic disorders of lymphoid tissue; excluding Hodgkin's disease.

**Macrophage:** A large cell that is present in blood, lymph, and connective tissues, removing waste products, harmful microorganisms, and foreign material from the bloodstream.

**Malignant:** Tending to become progressively worse; life-threatening.

**Mesothelioma:** Cancer of the mesothelium a lining covering most internal organs.

**Metabolism:** The whole range of biochemical processes that occur within living organisms, consisting both of anabolism and catabolism (the buildup and breakdown of substances, respectively).

**Metabolite:** A substance produced by metabolism.

**Micronuclei:** Nuclei separate from, and additional to, the main nucleus of a cell, produced during the telophase of mitosis or meiosis by lagging chromosomes or chromosome fragments derived from spontaneous or experimentally induced chromosomal structural changes.

**Mineral wool:** May refer to either slag wool or rock wool depending on the raw material from which it is produced.

**Multiple myeloma:** A malignant neoplasm derived from plasma cells and found at several locations in the body.

**Necropsy:** The examination of the dead body of an animal by dissection so as to detail the effects of the disease.

**Necrosis:** The pathologic death of one or more cells, or of a portion of tissue or organ, resulting from irreversible damage.

**Neoplasm:** An abnormal mass of cells.

**Non-Hodgkin’s lymphoma:** A heterogeneous group of malignant lymphomas; the only common feature being an absence of the giant Reed-Sternberg cells characteristic of Hodgkin's disease.
Odds ratio: The odds ratio is a way of comparing whether the probability of a certain event is the same for two groups. It is often used as a statistical measure of the likelihood of developing a disease if a certain factor – such as exposure to an agent.

Parenchyma: The distinguishing or specific cells of a gland or organ, contained in and supported by the connective tissue, framework, or stroma.

Pledge: A small plug.

Resin: Any of numerous physically similar polymerized synthetics or chemically modified natural resins.

Respirability: The relative amount of airborne particles or fibers reaching the alveolar region of the lung.

Respirable fiber: These fibers can reach the deepest part of the lung. For humans, respirable fibers are defined as particles with a diameter less than 3 μm and length greater than 5 μm and with an aspect ratio of greater than 3:1. These fibers can reach the deepest part of the lung.

Respirable fraction: That portion of dust or fibers that can reach the lower, or gas exchange, part of the respiratory system.

Sarcoma: Cancer of connective tissue; can also refer to tumors in soft tissue.

Sedimentation: One of four mechanisms of fiber deposition in the respiratory tract (see also impaction, diffusion, and interception). Sedimentation refers to the settling of fibers due to gravitational forces, which eventually results in the fibers touching the airway wall and depositing on the epithelium. This mechanism operates mainly on fibers with aerodynamic diameters of 0.5–1.0 μm.

Sister chromatid exchange (SCE): The exchange during mitosis of homologous genetic material between sister chromatids; increased as a result of inordinate chromosomal fragility due to genetic or environmental factors.

Slag wool: a fibrous product manufactured by blowing or spinning of a molten mass of metallurgical furnace slag.

Standardized Incidence Ratio (SIR): The ratio of observed to expected new incidences of a specific health outcome (e.g., cancer). The figure for expected incidence reflects the number of incidences for the larger population from which the study sample has been taken e.g., national level incidences.

Standardized Mortality Ratio (SMR): The ratio of observed to expected deaths to a specific health outcome (e.g., cancer). The figure for expected deaths reflects the number of deaths for the larger population from which the study sample has been taken e.g., national level of mortality attributed to a particular health outcome.
**Stanton fibers:** Fibers with length > 8 μm and diameter ≤ 0.25 μm.

**Subacute:** Between acute and chronic; denoting the course of a disease of moderate duration or severity. In rodent testing, usually pertains to a dosing schedule of less than one month.

**Subchronic:** In rodent testing, generally refers to a dosing schedule lasting from one to three months.

**Subcutaneous injection:** Injection beneath the skin.

**Threshold limit value (TLV):** The maximum permissible concentration of a material, generally expressed in parts per million in air for some defined period of time.

**Time-weighted average (TWA):** The average exposure concentration of a chemical measured over a period of time (not an instantaneous concentration).

**Volatile:** Quality of a solid or liquid allowing it to pass into the vapor state.

**Xenobiotic:** A pharmacologically, endocrinologically, or toxicologically active substance not endogenously produced and therefore foreign to an organism.

**Z-score:** The sum of the percent composition of alkali and alkaline earth oxides (Na₂O + K₂O + CaO + MgO + BaO).
