FOREWORD

The National Toxicology Program (NTP) is made up of four charter agencies of the U.S. Department of Health and Human Services (DHHS): the National Cancer Institute (NCI), National Institutes of Health; the National Institute of Environmental Health Sciences (NIEHS), National Institutes of Health; the National Center for Toxicological Research (NCTR), Food and Drug Administration; and the National Institute for Occupational Safety and Health (NIOSH), Centers for Disease Control. In July 1981, the Carcinogenesis Bioassay Testing Program, NCI, was transferred to the NIEHS. The NTP coordinates the relevant programs, staff, and resources from these Public Health Service agencies relating to basic and applied research and to biological assay development and validation.

The NTP develops, evaluates, and disseminates scientific information about potentially toxic and hazardous chemicals. This knowledge is used for protecting the health of the American people and for the primary prevention of disease.

The studies described in this Technical Report were performed under the direction of the NIEHS and were conducted in compliance with NTP laboratory health and safety requirements and must meet or exceed all applicable federal, state, and local health and safety regulations. Animal care and use were in accordance with the Public Health Service Policy on Humane Care and Use of Animals. The prechronic and chronic studies were conducted in compliance with Food and Drug Administration (FDA) Good Laboratory Practice Regulations, and all aspects of the chronic studies were subjected to retrospective quality assurance audits before being presented for public review.

These studies are designed and conducted to characterize and evaluate the toxicologic potential, including carcinogenic activity, of selected chemicals in laboratory animals (usually two species, rats and mice). Chemicals selected for NTP toxicology and carcinogenesis studies are chosen primarily on the bases of human exposure, level of production, and chemical structure. Selection *per se* is not an indicator of a chemical's carcinogenic potential.

These NTP Technical Reports are available for sale from the National Technical Information Service, U.S. Department of Commerce, 5285 Port Royal Road, Springfield, VA 22161 (703-487-4650). Single copies of this Technical Report are available without charge while supplies last from the NTP Central Data Management, NIEHS, P.O. Box 12233, MD A0-01, Research Triangle Park, NC 27709 (919-541-1371).

ABSTRACT

C.I. PIGMENT RED 3

CAS No. 2425-85-6

Chemical Formula: C₁₇H₁₃N₃O₃ Molecular Weight: 307.31

Synonyms: 2-Naphthalenol, 1-((4-methyl-2-nitrophenyl)azo)-; Calcotone Toluidine Red YP; Fast Red A; Pigment Scarlet R; Recolite Fast Red RBL; Sengale Light Red B

C.I. Pigment Red 3, a yellowish red solid, is widely used for coloring paints, inks, plastics, and rubber, and in textile printing. It is used in a wide range of consumer items such as wallpaper, typewriter ribbons, carbon paper, and art materials. Toxicology and carcinogenicity studies were conducted by feeding groups of F344/N rats and B6C3F₁ mice of each sex diets containing C.I. Pigment Red 3 (97% pure) for 2 weeks, 13 weeks, and 2 years. Genetic toxicology studies were conducted in *Salmonella typhimurium* and cultured Chinese hamster ovary cells.

2-Week Studies: Groups of five rats and five mice of each sex were given feed containing 0, 6,000, 12,500, 25,000, 50,000, or 100,000 ppm C.I. Pigment Red 3 for 2 weeks. No chemical-related deaths occurred in rats or mice. Final mean body weights of exposed rats and male mice were lower than controls; female mice that received 6,000 and 50,000 ppm had significantly increased final mean body weights compared to that of the controls. The feed consumption of treated rats and mice was slightly greater than that of the controls, suggesting that C.I. Pigment Red 3 had no adverse effects on the feed palatability. Dose-related decreases in erythrocyte counts and hematocrit values and an increase in reticulocyte counts were observed in rats. Changes in these parameters were observed in mice, but there were no clear, dose-related trends.

13-Week Studies: Groups of ten rats and ten mice of each sex were given feed containing 0, 3,000, 6,000, 12,500, 25,000, or 50,000 ppm C.I. Pigment Red 3 for 13 weeks. No chemical-related deaths were observed in rats or mice. The final mean body weights of exposed female rats were significantly lower than that of the controls; the final mean body weights of exposed male rats and exposed mice were similar to controls. There were significant increases in relative liver and kidney weights of exposed male rats. Increases in the relative liver weights in mice did not occur with a dose-related trend and thus they were not considered related to chemical administration. Sites for the toxicity of C.I. Pigment Red 3 were the bone marrow, kidney, liver, and spleen in rats. Lesions observed in rats included bone marrow hyperplasia, congestion and hematopoietic cell proliferation of the spleen, and iron-positive pigmentation of the spleen, kidney, and liver. Sites for the toxicity of C.I. Pigment Red 3 in mice were the liver, kidney, and spleen in males and the liver and spleen in females. Lesions noted among mice in the spleen were hematopoietic cell proliferation and iron-positive pigmentation. In the liver, there was hematopoietic cell proliferation in male and female mice. Cytomegaly occurred in the renal tubule epithelium of the male mouse kidney.

2-Year Studies: Doses selected for the 2-year feed studies were 0, 6,000, 12,500, and 25,000 ppm for rats and 0, 12,500, 25,000, and 50,000 ppm for mice. The dose selection for rats was based on body weight changes observed for females that received 50,000 ppm; the dose selection for mice was based on the lack of body weight depression or death at the doses tested during the 13-week studies. Concentrations higher than 50,000 ppm in the feed were not used because higher levels might have adversely affected the nutritional value of the diet during the 2-year studies.

Body Weight, Feed Consumption, Clinical Findings, and Survival in the 2-Year Studies: Final mean body weights for male rats that received 25,000 ppm, female rats that received 12,500 and 25,000 ppm, and male and female mice that received 50,000 ppm were more than 10% lower than those of the controls. Feed consumption of exposed rats and mice was similar to that of the controls. No clinical findings indicative of toxicity were observed in rats or mice. The survival of low-dose male rats was greater than that of the controls (0 ppm, 28/50; 6,000 ppm, 40/50; 12,500 ppm, 28/50; 25,000 ppm, 20/50). Survival of exposed female rats and exposed male mice was similar to the controls; the survival of high-dose female mice was significantly decreased compared to that of the controls (39/50, 37/50, 31/50, 25/50). The reduced survival in this dose group may have been due to the increased incidence of ovarian abscesses.

Neoplasms and Nonneoplastic Lesions in the 2-Year Studies: Benign adrenal pheochromocytomas were significantly increased in the 12,500 and 25,000 ppm groups of male rats compared to the controls (22/50, 29/50, 35/50, 34/50). However, malignant neoplasms were not increased in incidence (6/50, 7/50, 10/50, 4/50). The incidence of adrenal pheochromocytomas in dosed groups exceeded the range for NTP historical controls for feed studies (22%-48%), and the increased incidence of this neoplasm was attributed to C.I. Pigment Red 3 administration.

Squamous cell papillomas of the skin occurred with a positive trend in male rats (0/50, 4/50, 2/50, 6/50), and the incidence in the high-dose group was

significantly greater than that of the controls. A poorly differentiated squamous cell carcinoma (diagnosed as carcinoma) was observed in a control male. The historical control rate for squamous cell papillomas in NTP feed studies is low (16/800 or 2%, range 0%-4%), and the higher incidence of this tumor in male rats may have been caused by the administration of C.I. Pigment Red 3.

Hepatocellular adenomas occurred with a positive trend in female rats, with a significantly greater incidence in the high-dose group than in the control group (0/50, 0/50, 1/50, 10/50). This neoplasm has occurred in only one historical control group in NTP feed studies (3/800, range 0%-6%), and the increase in hepatocellular adenomas in female rats was attributed to chemical administration.

Chemical-related nonneoplastic lesions observed in the livers of male and female rats included eosinophilic or mixed type foci of cellular alteration. Foci were often accompanied by angiectasis and cystic degeneration in males and by granulomas and cholesterol pigmentation in females. Chronic nephropathy occurred with increased severity in exposed male and female rats. The lesions were more severe in males than in females. Other lesions considered secondary to renal disease included parathyroid gland hyperplasia, fibrous osteodystrophy of the bone, and mineralization of various organs (stomach, intestine, heart, and blood vessels). The increased incidence of hyperplasia of the transitional epithelium of the renal papilla observed in treated rats was considered to be part of the chronic nephropathy.

Zymbal's gland carcinoma incidences were marginally increased in the mid- and high-dose male rats (0/50, 0/50, 2/50, 3/50). The incidence in the high-dose group was outside the NTP historical control range (0%-4%), and the Zymbal's gland carcinomas may have been related to C.I. Pigment Red 3 administration.

Mononuclear cell leukemias, mammary gland fibroadenomas, and preputial gland/clitoral gland adenomas occurred at lower incidences in exposed male and female rats. The decrease in mononuclear cell leukemia was attributed to the direct effect of C.I. Pigment Red 3 or its metabolites on the mechanism responsible for inducing leukemias in aging rats, while the decreased incidence of mammary gland fibroadenomas might be attributed to decreased body weights in female rats. The cause of the decreased incidences of preputial and clitoral gland tumors is unknown.

Tubule adenomas of the renal cortex occurred at a significantly higher incidence in high-dose male mice than in controls (0 ppm, 0/50; 12,500 ppm, 0/50; 25,000 ppm, 0/50; 50,000 ppm, 6/50). Because this tumor occurred only in exposed males and was outside the range for NTP historical controls in feed studies (0%-2%), renal cortical tubule adenomas in male mice were considered to be related to the administration of C.I. Pigment Red 3.

Follicular cell adenoma of the thyroid gland occurred with a positive trend in male mice (0/50,0/49, 1/50, 5/50). The incidence in the high-dose group was significantly greater than that in the controls. This chemical-related effect is supported by the increased incidence of follicular cell hyperplasia. Because the incidence of this tumor exceeded the range of the historical controls from NTP feed studies (0%-4%), the increase of follicular cell adenoma was attributed to chemical administration. Female mice receiving C.I. Pigment Red 3 had a significant increase in follicular cell hyperplasia but showed no increase in tumor incidence at this site.

Focal renal tubule hyperplasia and cystic hyperplasia occurred in exposed male mice but not in the controls. Cytomegaly (karyomegaly) of the renal tubule epithelium was seen in all treated male mice. The severity of the accompanying chronic nephropathy was increased in both male and female mice.

Genetic Toxicology: C.I. Pigment Red 3 was mutagenic in Salmonella typhimurium strains TA100 and TA98 in the presence of exogenous metabolic activation (S9); no increases in gene mutation were observed in strains TA1535 and TA1537, with or without S9. C.I. Pigment Red 3 did not induce sister chromatid exchanges or chromosomal aberrations in Chinese hamster ovary cells in either the presence or the absence of S9.

Conclusions: Under the conditions of these 2-year feed studies, there was some evidence of carcinogenic activity* of C.I. Pigment Red 3 in male F344/N rats as exhibited by increased incidences of benign pheochromocytomas of the adrenal gland. The marginal increase in the incidences of squamous cell papillomas of the skin and Zymbal's gland carcinomas may have been related to C.I. Pigment Red 3 administration. There was some evidence of carcinogenic activity of C.I. Pigment Red 3 in female F344/N rats as indicated by the increased incidence of hepatocellular adenomas. There was some evidence of carcinogenic activity of C.I. Pigment Red 3 in male $B6C3F_1$ mice as exhibited by the increased incidences of tubule adenomas of the renal cortex and follicular cell adenomas of the thyroid gland. There was no evidence of carcinogenic activity of C.I. Pigment Red 3 in female B6C3F, mice that received 12,500, 25,000, or 50,000 ppm.

The incidences of mononuclear cell leukemia and preputial gland tumors in male rats and mononuclear cell leukemia, mammary gland fibroadenoma, and clitoral gland tumors in female rats were lower in the exposed groups. The incidences of liver foci were markedly increased in exposed male and female The severity of chronic nephropathy was rats. increased in male rats and to a lesser extent in female rats given C.I. Pigment Red 3. An increase in the severity of nephropathy was observed in male and female mice; cytomegaly (karyomegaly) of renal tubule epithelium was observed in male mice. Thyroid follicular cell hyperplasia occurred with an increased incidence in male and female mice receiving C.I. Pigment Red 3.

[•] Explanation of Levels of Evidence of Carcinogenic Activity is on page 10. A summary of the Technical Reports Review Subcommittee comments and the public discussion on this Technical Report appears on page 12.

Summary of the 2-Year Carcinogenicity and Genetic Toxicology Studies of C.I. Pigment Red 3 (continued)

EXPLANATION OF LEVELS OF EVIDENCE OF CARCINOGENIC ACTIVITY

The National Toxicology Program describes the results of individual experiments on a chemical agent and notes the strength of the evidence for conclusions regarding each study. Negative results, in which the study animals do not have a greater incidence of neoplasia than control animals, do not necessarily mean that a chemical is not a carcinogen, inasmuch as the experiments are conducted under a limited set of conditions. Positive results demonstrate that a chemical is carcinogenic for laboratory animals under the conditions of the study and indicate that exposure to the chemical has the potential for hazard to humans. Other organizations, such as the International Agency for Research on Cancer, assign a strength of evidence for conclusions based on an examination of all available evidence including: animal studies such as those conducted by the NTP, epidemiologic studies, and estimates of exposure. Thus, the actual determination of risk to humans from chemicals found to be carcinogenic in laboratory animals requires a wider analysis that extends beyond the purview of these studies.

Five categories of evidence of carcinogenic activity are used in the Technical Report series to summarize the strength of the evidence observed in each experiment: two categories for positive results (clear evidence and some evidence); one category for uncertain findings (equivocal evidence); one category for no observable effects (no evidence); and one category for experiments that because of major flaws cannot be evaluated (inadequate study). These categories of interpretative conclusions were first adopted in June 1983 and then revised in March 1986 for use in the Technical Reports series to incorporate more specifically the concept of actual weight of evidence of carcinogenic activity. For each separate experiment (male rats, female rats, male mice, female mice), one of the following quintet is selected to describe the findings. These categories refer to the strength of the experimental evidence and not to potency or mechanism.

- Clear evidence of carcinogenic activity is demonstrated by studies that are interpreted as showing a dose-related (i) increase of malignant neoplasms, (ii) increase of a combination of malignant and benign neoplasms, or (iii) marked increase of benign neoplasms if there is an indication from this or other studies of the ability of such tumors to progress to malignancy.
- Some evidence of carcinogenic activity is demonstrated by studies that are interpreted as showing a chemical-related increased incidence of neoplasms (malignant, benign, or combined) in which the strength of the response is less than that required for clear evidence.
- Equivocal evidence of carcinogenic activity describes studies that are interpreted as showing a marginal increase of neoplasms that may be chemical related.
- No evidence of carcinogenic activity is demonstrated by studies that are interpreted as showing no chemical-related increases in malignant or benign neoplasms.
- Inadequate study of carcinogenic activity is demonstrated by studies that because of major qualitative or quantitative limitations cannot be interpreted as valid for showing either the presence or absence of carcinogenic activity.

When a conclusion statement is selected for a particular experiment, consideration must be given to key factors that would extend the actual boundary of an individual category of evidence. This should allow for incorporation of scientific experience and current understanding of long-term carcinogenesis studies in laboratory animals, especially for those evaluations that may be on the borderline between two adjacent levels. These considerations should include:

- · adequacy of the experimental design and conduct;
- · occurrence of common versus uncommon neoplasia;
- · progression (or lack thereof) from benign to malignant neoplasia as well as from preneoplastic to neoplastic lesions;
- some benign neoplasms have the capacity to regress but others (of the same morphologic type) progress. At present, it is impossible to identify the difference. Therefore, where progression is known to be a possibility, the most prudent course is to assume that benign neoplasms of those types have the potential to become malignant;
- combining benign and malignant tumor incidences known or thought to represent stages of progression in the same organ or tissue;
- latency in tumor induction;
- multiplicity in site-specific neoplasia;
- metastases;
- supporting information from proliferative lesions (hyperplasia) in the same site of neoplasia or in other experiments (same lesion in another sex or species);
- · presence or absence of dose relationships;
- statistical significance of the observed tumor increase;
- · concurrent control tumor incidence as well as the historical control rate and variability for a specific neoplasm;
- · survival-adjusted analyses and false positive or false negative concerns;
- structure-activity correlations; and
- in some cases, genetic toxicology.

NATIONAL TOXICOLOGY PROGRAM BOARD OF SCIENTIFIC COUNSELORS TECHNICAL REPORTS REVIEW SUBCOMMITTEE

The members of the Technical Reports Review Subcommittee who evaluated the draft NTP Technical Report on C.I. Pigment Red 3 on July 9, 1991, are listed below. Subcommittee members serve as independent scientists, not as representatives of any institution, company, or governmental agency. In this capacity, panel members have five major responsibilities in reviewing NTP studies:

- · to ascertain that all relevant literature data have been adequately cited and interpreted,
- to determine if the design and conditions of the NTP studies were appropriate,
- · to ensure that the Technical Report presents the experimental results and conclusions fully and clearly,
- to judge the significance of the experimental results by scientific criteria, and
- · to assess the evaluation of the evidence of carcinogenic activity and other observed toxic responses.

SUMMARY OF TECHNICAL REPORTS REVIEW SUBCOMMITTEE COMMENTS

On July 9, 1991, the draft Technical Report on the toxicology and carcinogenesis studies of C.I. Pigment Red 3 received public review by the National Toxicology Program Board of Scientific Counselors' Technical Reports Review Subcommittee. The review meeting was held at the National Institute of Environmental Health Sciences, Research Triangle Park, NC.

Dr. R.D. Irwin, NIEHS, introduced the toxicology and carcinogenesis studies of C.I. Pigment Red 3 by discussing the uses and rationale for study, describing the experimental design, reporting on survival and body weight effects, and commenting on compound-related neoplastic and nonneoplastic lesions in rats and mice. The proposed conclusions were some evidence of carcinogenic activity of C.I. Pigment Red 3 in male and female rats and in male mice, and no evidence of carcinogenic activity of C.I. Pigment Red 3 in female mice.

Dr. Davis, a principal reviewer, agreed with the proposed conclusions. He asked for clarification of why 50,000 ppm was the upper limit in a feed study, and why, in view of the chemical's uses, the dermal route of exposure was not chosen. Dr. Irwin said there was a long-standing NTP policy that dietary levels exceeding 5% (50,000 ppm) might compromise the nutritional status of the animal. Dr. Davis commented on the inclusion of statements that there were no clinical findings indicative of toxicity and asked how this could be reconciled with reductions in body weight gain of more than 10%. Dr. Irwin agreed that reduced body weight gain could be an indicator of toxicity but was not classified as a clinical finding.

Dr. Klaassen, the second principal reviewer, agreed with the proposed conclusions.

Dr. Bailey, the third principal reviewer, agreed with the conclusions. He also questioned whether dermal exposure might have been appropriate, and thought percutaneous absorption data might have been useful. Dr. Irwin explained that pigments have to be dissolved in an organic solvent for dermal administration and often a residue of the pigment remains on the skin. A variable amount of the residual chemical will be ingested by the animal through natural grooming. Thus, the oral study is likely to be more quantitative and should provide a better measure of carcinogenic potential.

Dr. McKnight suggested that for Zymbal's gland tumors in male rats, a statistically significant trend test and a high-dose group incidence that exceeded that in any historical control group supported these tumors being considered *some evidence of carcinogenic activity*. These tumors were in the conclusion as "may have been related to chemical administration."

Dr. Davis moved that the Technical Report on C.I. Pigment Red 3 be accepted with the revisions discussed and with the conclusions as written for male and female rats and male mice, some evidence of carcinogenic activity, and for female mice, no evidence of carcinogenic activity. Dr. Goodman seconded the motion. Dr. McKnight offered an amendment that Zymbal's gland carcinomas be included as supporting some evidence of carcinogenic activity in male rats. Dr. Zeise seconded the amendment, which was defeated eight votes to two (Drs. McKnight and Zeise). The original motion was then accepted unanimously with ten votes.

INTRODUCTION

C.I. PIGMENT RED 3

CAS No. 2425-85-6

Chemical Formula: C₁₇H₁₃N₃O₃ Molecular Weight: 307.31

Synonyms: 2-Naphthalenol, 1-((4-methyl-2-nitrophenyl)azo)-; Calcotone Toluidine Red YP; Fast Red A; Pigment Scarlet R; Recolite Fast Red RBL; Sengale Light Red B

PHYSICAL AND CHEMICAL PROPERTIES

C.I. Pigment Red 3 is a yellowish red solid with a melting point of 278° C. It is insoluble in water, slightly soluble in ethanol and xylene, and poorly soluble in esters and ketones (*Colour Index*, 1971). Manufacturers couple 2-nitro-4-methylaniline with 2-naphthol to produce this pigment (*Kirk-Othmer*, 1978).

PRODUCTION, USE, AND HUMAN EXPOSURE

United States production of C.I. Pigment Red 3 in 1986 was 440,000 kg (USITC, 1987). The United States imported 3,600 kg of C.I. Pigment Red 3 in 1983 (USITC, 1984). Its low cost, bright scarlet hue, high tinctorial strength, and acid-fast, alkaline-fast, and lightfast properties cause C.I. Pigment Red 3 to be one of the most widely used red pigments (*Colour Index*, 1971). The pigment is used for coloring paints, inks, plastics, rubber, and in textile printing (Gosselin *et al.*, 1976). From a survey conducted from 1981-1983, NIOSH estimated that 51,931 workers, including 11,615 women, have been exposed to C.I. Pigment Red 3 (NIOSH, 1990).

METABOLISM AND DISPOSITION

Disposition studies in which 7- to 8-week-old, male Fischer 344/N rats were given a single dose of C.I. Pigment Red 3 (11.8 mg/kg) by gavage in corn oil demonstrated that 72.4% of the dose was excreted in the feces. Only tissues in contact with C.I. Pigment Red 3 contained detectable amounts of the pigment. The pigment was not detected in samples of blood, plasma, liver, kidney, or lung, even after the administration of doses 10 times as large as the original dose. Recovery in urine was 4% at 24 and 48 hours after dosing (El Dareer et al., 1984). Based on its recovery in urine, it was concluded that C.I. Pigment Red 3 or its microbial breakdown products were absorbed in the intestine and metabolized by the rats. The study did not attempt to identify these metabolites and breakdown products. No other information on the metabolism and disposition of C.I. Pigment Red 3 was found in the literature.

TOXICITY AND CARCINOGENICITY Human

The literature provided no data or epidemiological reports on the toxicity or carcinogenicity of C.I. Pigment Red 3 in humans.

Animal

No reports of toxicity studies on C.I. Pigment Red 3 previous to the 2-week and 13-week studies conducted by the NTP were found in the literature (Morgan et al., 1989). In the NTP studies, F344/N rats and B6C3F, mice fed diets containing 0.3% to 10% of the pigment showed hematologic changes (reduced erythrocyte and hematocrit values, and hemoglobin concentrations) consistent with hemolytic anemia. Methemoglobin concentrations were not determined in these studies. Histopathological evaluation of tissues obtained after 90 days of treatment revealed that the spleen, liver, and kidney of rats and mice, as well as the bone marrow of rats, were the sites of chemical toxicity. The spleen of treated rats showed an increase in hematopoietic cell proliferation, iron-positive pigment, congestion of the red pulp, and inflammation of the splenic Hematopoietic cell proliferation was capsule. observed in the liver and bone marrow of treated In treated mice, there were increases in rats. hematopoietic cell proliferation of the liver and in iron-positive pigment of the spleen. Mild cytomegaly of the renal tubule epithelium was also observed in treated mice.

No animal carcinogenicity study results were found in the literature.

GENETIC TOXICOLOGY

C.I. Pigment Red 3 contains an azo bond, considered to be a structural alert for genotoxic activity by virtue of the potential for azo reduction, releasing aromatic amine products; the aromatic nitro group is also considered to be an alert for potential genotoxicity (Ashby *et al.*, 1989). However, experimental data for this compound are sparse. C.I. Pigment Red 3 was weakly mutagenic in *Salmonella typhimurium* strains TA100 and TA98 in the presence of induced hamster S9 (Mortelmans *et al.*, 1986). An earlier study had reported negative results in a S. typhimurium assay (Miyagoshi et al., 1983), but the lower concentrations used in this test may not have allowed detection of a weak response.

There are no additional published data on the mutagenicity of C.I. Pigment Red 3 or any of its metabolites, but some structural analogs of C.I. Pigment Red 3 have been tested for genotoxicity. 1-[(2-Methylphenyl)azo]-2-naphthalenol was reported to be negative for induction of DNA damage in Bacillus subtilis (Kada et al., 1972) and induction of gene reversion in S. typhimurium (Miyagoshi et al., 1983). C.I. Solvent Yellow 14 was reported to be negative in two S. typhimurium gene mutation tests (Garner and Nutman, 1977; Brown et al., 1978) and weakly positive in two other studies which employed higher doses and different sources of S9 activation enzymes (Cameron et al., 1987; A positive response was Zeiger et al., 1988). reported for C.I. Solvent Yellow 14 in the mouse lymphoma assay for induction of trifluorothymidine resistance in L5178Y cells (Cameron et al., 1987) and the compound gave an equivocal response in the in vivo/in vitro rat hepatocyte assay for induction of unscheduled DNA synthesis (Kornbrust and Barfknecht, 1984). No induction of chromosomal aberrations was observed in Chinese hamster ovary cells exposed to C.I. Solvent Yellow 14, but sister chromatid exchanges were induced in Chinese hamster ovary cells with and without induced S9 (Ivett et al., 1989). Another structural analog, C.I. Solvent Red 1, was negative for induction of gene mutations in several strains of S. typhimurium, negative in a Chinese hamster ovary cell chromosomal aberration test, and positive for induction of sister chromatid exchanges in Chinese hamster ovary cells (Brooks et al., 1989).

STUDY RATIONALE

C.I. Pigment Red 3 was nominated by the National Cancer Institute for testing due to the lack of information on its toxicity and because of its widespread use and high potential for human exposure. In addition, C.I. Pigment Red 3, a nitrophenylazonaphthol, is structurally similar to known phenylazonaphthol carcinogens such as Ponceau 3R, Oil Orange SS, and Citrus Red 2 (IARC, 1975). The oral route was chosen to ensure systemic exposure.

MATERIALS AND METHODS

PROCUREMENT AND CHARACTERIZATION OF C.I. PIGMENT RED 3

C.I. Pigment Red 3 was obtained from American Cyanamid Company (Wayne, NJ; lot G-1292) and Sun Chemical Company (New York, NY; lot S051783). Lot G-1292 was used throughout the 2-week and 13-week studies and in a portion of the 2-year studies. Lot S051783 was used throughout the remainder of the 2-year studies. Identity, purity, and stability analyses were conducted by the analytical chemistry laboratory, Midwest Research Institute (Kansas City, MO), and confirmed by the study laboratory (Appendix H).

Both lots of the study chemical, a red powder, were identified as C.I. Pigment Red 3 by infrared, ultraviolet/visible, and nuclear magnetic resonance spectroscopy. The purity of both lots was found to be greater than 97% by weight loss on drying, elemental analyses, thin-layer chromatography, and high-performance liquid chromatography (HPLC). Stability studies indicated that C.I. Pigment Red 3 was stable as a bulk chemical for 2 weeks at temperatures up to 60° C when stored protected from light. The stability of the bulk chemical was monitored periodically at the study laboratory with ultraviolet spectroscopy and HPLC analysis methods. No change in purity was observed.

PREPARATION AND ANALYSIS OF DOSE FORMULATIONS

The dose formulations were prepared by mixing appropriate amounts of C.I. Pigment Red 3 and feed in a blender (Table H1). Studies to determine homogeneity and stability of the dosed feed preparations were conducted by the analytical chemistry laboratory. Homogeneity was confirmed using an ultraviolet spectroscopic method for sample analysis. The stability of the dose formulations stored for 2 weeks at 45° C and protected from light was confirmed using an HPLC method.

Periodic analyses of the dose formulations of C.I. Pigment Red 3 were conducted at the study laboratory and the analytical chemistry laboratory using ultraviolet spectroscopy. During the 2-week studies, the dose formulations were analyzed at the beginning of the studies (Table H2). During the 13-week studies, the dose formulations were analyzed at the initiation and the midpoint of the studies (Table H3). During the 2-year studies, the dose formulations were analyzed at least once every 8 weeks (Table H4). All dose formulations were within 10% of the target concentrations. Results of periodic referee analyses performed by the analytical chemistry laboratory were in agreement with the results obtained by the study laboratory (Table H5).

2-WEEK STUDIES

Male and female F344/N rats and $B6C3F_1$ mice were obtained from Frederick Cancer Research Center (Frederick, MD). At receipt, the rats had an average age of 29 days, and the mice had an average age of 36 days. The rats and mice were quarantined for 19 days before dosing began.

Groups of five rats and five mice of each sex were fed diets containing 0, 6,000, 12,500, 25,000, 50,000, or 100,000 ppm C.I. Pigment Red 3. The appropriate feed was supplied weekly and was available *ad libitum* for 15 or 16 days for rats and for 15 to 17 days for mice. Animals were housed five to a cage with water available *ad libitum*. Clinical findings were recorded twice daily. The animals were weighed at study initiation, weekly, and at study termination. Details of study design and animal maintenance are summarized in Table 1.

At study termination, blood samples were collected from all animals for hematology and clinical chemistry studies. For rats, blood was obtained from the inferior vena cava; for mice, blood samples were collected by cardiac puncture. The clinical pathology parameters measured are listed in Table 1.

A necropsy was performed on all animals. The brain, heart, right kidney, liver, lung, and thymus of all animals were weighed at necropsy. Tissues for microscopic examination were embedded in paraffin, sectioned to a thickness of 4 to 6 μ m, and stained with hematoxylin and eosin. Histopathology was performed on the 0 and 100,000 ppm dose groups. Table 1 lists those tissues and organs examined microscopically.

13-WEEK STUDIES

13-week studies were conducted to evaluate the cumulative toxic effects of repeated exposure to C.I. Pigment Red 3 and to determine the appropriate doses for the 2-year studies.

Male and female F344/N rats and B6C3F₁ mice were obtained from Frederick Cancer Research Center. At receipt, the average age of the rats was 43 days, and the average age of the mice was 39 days. The animals were quarantined for 19 days prior to study initiation. Five animals of each species and sex were randomly selected and sacrificed for parasite evaluation and gross observation for evidence of disease prior to study initiation. At study termination, serologic analyses were performed on the serum of five control animals of each species and sex in accordance with the protocols of the NTP Sentinel Animal Program (Appendix K).

Groups of 10 rats and 10 mice of each sex were fed diets containing 0, 3,000, 6,000, 12,500, 25,000, or 50,000 ppm C.I. Pigment Red 3. Beginning on day 2, the appropriate feed was available *ad libitum* for 91 to 94 consecutive days to rats and for 92 to 94 consecutive days to mice.

Animals were housed five per cage. Water was available *ad libitum*. Animals were observed twice daily. Animals were weighed at study initiation, weekly, and at termination. Clinical observations were recorded weekly and at study termination.

At study termination, blood samples were collected by cardiac puncture for measurement of hematology and clinical chemistry parameters. Urine samples were collected by tapping into the bladder for urinalysis. Table 1 contains the complete list of the analyses performed on animals in the 13-week studies of C.I. Pigment Red 3.

During necropsy, the organs and tissues of all animals were examined for visible lesions. Organ weights were recorded for the brain, heart, right kidney, liver, lung, and thymus of all animals, and the right testis of all males. Tissues for microscopic examination were embedded in paraffin, sectioned to a thickness of 4 to 6 μ m, and stained with hematoxylin and eosin. A complete histopathologic examination was performed on all animals. Table 1 lists the tissues and organs examined microscopically.

2-YEAR STUDIES

Groups of 60 rats of each sex were fed diets containing 0, 6,000, 12,500, or 25,000 ppm C.I. Pigment Red 3. Groups of 60 mice of each sex were fed diets containing 0, 12,500, 25,000, or 50,000 ppm C.I. Pigment Red 3. The appropriate feed was supplied weekly and available ad libitum for 103 weeks. Up to 10 rats and 10 mice per dose group were designated for interim evaluations (organ weights, hematology, clinical chemistry, and histopathology) after 15 months of chemical administration. An additional five rats and five mice from a separate special study were also evaluated at 15 months. The results from the analyses of these special study animals were incorporated with the results of the 15-month interim evaluations of the 2-year study animals.

Source and Specification of Animals

The F344/N rats and $B6C3F_1$ mice used in these studies were obtained from Frederick Cancer Research Facility. All animals were quarantined for 12 days, then five rats and five mice of each sex were randomly selected and sacrificed for parasite evaluation and gross observation of evidence of disease. The average age of the animals was 42 days when dosing began. Animal health was monitored by serologic analyses during the course of the studies in accordance with the protocols of the NTP Sentinel Animal Program.

Animal Maintenance

Rats were housed five per cage throughout the studies. Mice were housed five per cage for 14 months, then individually until study termination. Cages were rotated vertically (top to bottom) within dose groups, and racks were rotated counter-clockwise every 2 weeks during rack change. Drinking water was available *ad libitum*. Further details of animal maintenance are given in Table 1.

Clinical Examinations and Pathology

All animals were observed twice daily. Clinical observations were recorded every 4 weeks. Individual body weights were obtained weekly

through week 13 and monthly thereafter. After 15 months, 10 rats and 10 mice from each dose group were evaluated. Blood samples were collected from the inferior vena cava in rats and by cardiac puncture in mice for measurement of hematology and clinical chemistry parameters. Urine samples were collected in metabolism cages for urinalysis. Organ weights were recorded for the brain, right kidney, liver, and spleen of all animals killed at 15 months. Table 1 contains the complete list of the analyses performed on animals in the 2-year studies of C.I. Pigment Red 3.

A necropsy was performed on all animals. During necropsy, all organs and tissues were examined for visible lesions. Tissues for microscopic examination were fixed in 10% neutral buffered formalin, embedded in paraffin, sectioned to a thickness of 4 to 6 μ m, and stained with hematoxylin and eosin. The 15-month interim evaluations included a complete histopathology on all control and high-dose animals and all animals that died early. For the interim evaluation animals that received lower doses, all gross lesions (excluding red skin and hair), the bone marrow and liver in rats, the kidney in rats and mice, and the spleen in rats and mice were examined. A complete histopathologic examination was performed on all control and high-dose animals that survived to study termination and on all animals that died or were killed moribund after 15 months. For rats that received lower doses, organs examined included all gross lesions (excluding red skin and hair); the bone marrow, liver, lung, lymph nodes (mandibular, mediastinal, and mesenteric), kidney, pancreas, and spleen in male and female rats; the adrenal gland in male rats; and the mammary gland in female rats. Organs examined for mice at lower doses included all gross lesions (excluding red skin and hair); liver, kidney, spleen, and thyroid gland in males and females; and bone marrow and ovary in females.

Microscopic evaluations were completed by the study laboratory pathologist and the pathology data were entered into the Toxicology Data Management System (TDMS). The slides, paraffin blocks, and residual wet tissues were sent to the NTP Archives for inventory, slide/block match, and wet tissue audit for accuracy of labeling and animal identification and for thoroughness of tissue trimming. The slides, individual animal data records, and pathology tables were evaluated by an independent quality assessment laboratory. The individual animal records and tables were compared for accuracy, slides and tissue counts were verified, and histotechnique was evaluated. A quality assessment pathologist reviewed selected tissues for accuracy and consistency of lesion diagnosis.

For rats this review included all diagnoses in the kidney, liver, and pancreas in both sexes, the adrenal medulla in males, and all neoplasms in any tissue. In addition, sections of the spleen and mesenteric lymph node from both sexes were reviewed to confirm the incidence of selected nonneoplastic lesions (including pigmentation, cholesterol in the mesenteric nodes) and the incidence of mononuclear cell leukemia in the spleen. Sections of the femoral and turbinate bones from all animals and the cranial bone from a few females were reviewed to confirm the presence of osteopetrosis. Sections of the bone marrow from all control and high-dose males were reviewed to confirm the incidence of hyperplasia. For mice this review included all diagnoses in the kidney, liver, spleen, and thyroid gland in each sex, the ovary in females, and neoplasms in any tissue.

The quality assessment report and slides were submitted to the Pathology Working Group (PWG) chair, who reviewed tissues for which there was a disagreement in diagnosis between the laboratory and quality assessment pathologists. The PWG chair also reviewed all diagnoses in the kidney, liver, and pancreas in rats of each sex; the adrenal medulla in male rats; the kidney, liver, spleen, and thyroid gland in mice of each sex; and the ovary in female mice. Representative histopathology slides containing examples of lesions related to disagreements between the laboratory and quality assessment pathologists, or lesions of general interest were presented by the chair to the PWG for review. The PWG included the quality assessment pathologist as well as other pathologists experienced in rodent toxicologic pathology, who examined these tissues without knowledge of dose group or previously rendered diagnoses. When the consensus diagnosis of the PWG differed from that of the laboratory pathologist, the final diagnosis was changed to reflect the opinion of the PWG. Details of these review procedures have been described, in part, by Maronpot and Boorman (1982) and Boorman et al. (1985). For subsequent analysis of pathology data, the diagnosed lesions for each tissue type are evaluated separately or combined according to the guidelines of McConnell et al. (1986).

Statistical Methods

Survival Analyses

The probability of survival was estimated by the product-limit procedure of Kaplan and Meier (1958) and is presented in the results section of this report. Animals were censored from the survival analyses at the time they were found dead from other than natural causes; animals dying from natural causes were not censored. Statistical analyses for possible dose-related effects on survival used Cox's (1972) method for testing two groups for equality and Tarone's (1975) life table tests to identify doserelated trends. All reported P values for the survival analysis are two sided.

Calculation of Incidence

The incidence of neoplasms or nonneoplastic lesions is given as the ratio of the number of animals bearing such lesions at a specific anatomic site to the number of animals in which that site was examined. In most instances, the denominators include only those animals for which the site was examined histologically. However, when macroscopic examination was required to detect lesions (e.g., skin or mammary tumors) before tissue sampling for histopathology, or when lesions could have appeared at multiple sites (e.g., mononuclear cell leukemia), the denominators consist of the number of animals on which a necropsy was performed.

Analysis of Tumor Incidence

The majority of tumors in these studies were considered to be incidental to the cause of death or not rapidly lethal. Thus, the primary statistical method used was logistic regression analysis, which assumed that the diagnosed tumors were discovered as the result of death from an unrelated cause and did not affect the risk of death. In this approach, tumor prevalence was modeled as a logistic function of chemical exposure and time. Both linear and quadratic terms in time were incorporated initially, and the quadratic term was eliminated if it did not significantly enhance the fit of the model. The dosed and control groups were compared on the basis of the likelihood score test for the regression coefficient of dose. This method of adjusting for intercurrent mortality is the prevalence analysis of Dinse and Lagakos (1983), further described and illustrated by Dinse and Haseman (1986). When tumors are incidental, this comparison of the timespecific tumor prevalences also provides a

comparison of the time-specific tumor incidences (McKnight and Crowley, 1984).

In addition to logistic regression, alternative methods of statistical analysis were used, and the results of these tests are summarized in the appendixes. These include the life table test (Cox, 1972; Tarone, 1975), appropriate for rapidly lethal tumors, and the Fisher exact test and the Cochran-Armitage trend test (Armitage, 1971; Gart *et al.*, 1979), procedures based on the overall proportion of tumor-bearing animals.

Tests of significance include pairwise comparisons of each dosed group with controls and a test for an overall dose-response trend. Continuity-corrected tests were used in the analysis of tumor incidence, and reported P values are one sided. The procedures described above also were used to evaluate selected nonneoplastic lesions. (For further discussion of these statistical methods, see Haseman, 1984.)

Historical Control Data

Although the concurrent control group is always the first and most appropriate control group used for evaluation, historical control data can be helpful in the overall assessment of tumor incidence. Consequently, control tumor incidences from the NTP historical control database (Haseman *et al.*, 1984, 1985) are included in the NTP reports for tumors appearing to show compound-related effects.

Analysis of Continuous Variables

Two approaches were employed to assess the significance of pairwise comparisons between dosed and control groups in the analysis of continuous variables. Organ and body weight data that had approximately normal distributions were analyzed using the parametric multiple comparison procedures of Williams (1971, 1972) and Dunnett (1955). Organ and body weight and clinical pathology data that had skewed distributions were analyzed using the nonparametric multiple comparison methods of Shirley (1977) and Dunn (1964). Jonckheere's test (Jonckheere, 1954) was used to assess the significance of the dose-response trends and to determine whether a trend-sensitive test (Williams' or Shirley's test) was more appropriate for pairwise comparisons than a test that does not assume a monotonic doseresponse trend (Dunnett's or Dunn's test). Average nephropathy severity values for the 2-year studies

were analyzed for significance using the Mann-Whitney U test (Hollander and Wolfe, 1973).

Quality Assurance Methods

The 13-week and 2-year studies were conducted in compliance with Food and Drug Administration Good Laboratory Practice Regulations (21 CFR, Part 58). In addition, as study records were submitted to the NTP Archives, they were audited by an independent quality assurance contractor. Separate audits covering completeness and accuracy of the pathology data, pathology specimens, final pathology tables, and preliminary review draft of this NTP Technical Report were conducted. Audit procedures are presented in the reports, which are on file at the NIEHS. The audit findings were reviewed and assessed by the NTP staff so that all discrepancies had been resolved or were otherwise addressed during the preparation of this Technical Report.

GENETIC TOXICOLOGY

The genetic toxicity of C.I. Pigment Red 3 was assessed by testing its ability to induce mutations in *Salmonella typhimurium* and sister chromatid exchanges and chromosomal aberrations in Chinese hamster ovary cells. The protocols and results for these studies are given in Appendix E.

Experimental Design and Materials and Methods in the Feed Studies of C.I. Pigment Red 3 (continued)

2-Week Studies	13-Week Studies	2-Year Studies
2-Week Studies Histopathology Histopathologic examinations were performed on all control and 100,000 ppm animals. In addition to tissue masses, gross lesions, and associated lymph nodes, tissues examined included: adrenal gland, bone (femur including marrow), brain, bronchi, clitoral gland (rats), colon, esophagus, gallbladder (mice), heart, kidney, liver, lung, mammary gland, mandibular and mesenteric lymph nodes, nasal cavity, nasal turbinates, ovary, pancreas, parathyroid gland, pituitary gland, preputial gland (rats), prostate gland, salivary gland, small intestine, spleen, stomach, testis, thymus, thyroid gland, trachea, urinary bladder, and uterus.	13-Week Studies Complete histopathologic examinations were performed on all animals. In addition to tissue masses, gross lesions, and associated lymph nodes, the tissues examined included: adrenal gland, bone (femur including marrow), brain, bronchi, clitoral gland (rats), colon, epididymis, esophagus, gallbladder (mice), heart, kidney, liver, lung, mammary gland, mandibular and mesenteric lymph nodes, nasal cavity, nasal turbinates, ovary, pancreas, parathyroid gland, pituitary gland, preputial gland (rats), small intestine, spleen, stomach, testis, thymus, thyroid gland, trachea, urinary bladder, and uterus.	2-Year Studies At the 15-month interim evaluation, complete histopathology was performed on all control and high-dose animals and all animals that died early. For interim evaluation animals receiving lower doses, all gross lesions (excluding rea- skin and hair), bone marrow and liver (rats), kidneys (rats and mice), and spleen (rats and mice) were examined. At terminal sacrifice, a complete histopathology was performed on all control and high-dose animals and animals that died early. For rats receiving lower doses, organs examined included all gross lesions (excluding red skin and hair); bone marrow, liver, lung, lymph nodes (mandibular, mediastinal, and mesenteric), kidney,

23

rats. For mice receiving lower doses, all gross lesions (excluding red skin and hair); liver, kidney, spleen, and thyroid gland in males and females; and bone marrow and ovary in females were examined at terminal sacrifice. In addition to tissue masses, gross lesions, and associated regional lymph nodes, the following organs and/or tissues were included in complete histopathologic examinations: adrenal gland, aorta, bone (femur including marrow), brain, clitoral gland (rats), epididymis, esophagus, gallbladder (mice), heart, kidneys, large intestine (cecum, colon, rectum), liver, lung, mammary gland, mesenteric lymph node, nasal cavity, ovary, pancreas, parathyroid gland, pituitary gland, preputial gland (rats), prostate gland, salivary gland, skin, small intestine (duodenum, jejunum, ileum), spleen, stomach, testis, thymus, thyroid gland, trachea, urinary bladder, and

uterus.

RESULTS

RATS

2-Week Studies

All rats lived to the end of the studies (Table 2). The final mean body weights and body weight gains of male rats that received C.I. Pigment Red 3 were similar to those of the controls. The final mean body weight of female rats that received 100,000 ppm was significantly lower than that of the controls; all exposed female rats had significantly reduced mean body weight gains compared to that of the controls. Average feed consumption by dosed groups was similar to consumption by the control groups.

There were no clinical findings indicative of chemical toxicity. Red-stained extremities, feces, and fur were due to contact with C.I. Pigment Red 3 and were not indicative of toxicity.

All dosed male groups showed significant increases in relative liver weights compared to that of the controls (Table F1). Significantly increased relative heart weights were noted for male rats that received 50,000 and 100,000 ppm. No other significant differences in organ weights were observed in exposed male rats; there were no significant changes in organ weights in exposed female rats.

^c Grams per animal per day, based on average consumption data per group per day for days 1 through 13.

^a Number of animals surviving/number of animals initially in group

Male rats that received doses of 12,500 ppm or greater had significantly decreased erythrocyte counts (Table G1). Males that received 25,000 ppm or greater had significantly increased reticulocyte counts and significantly decreased hemoglobin and hematocrit values. Male rats that received 100,000 ppm showed significantly increased values for total serum bilirubin, alanine aminotransferase (ALT), and cholinesterase. All dosed female rat groups had significantly increased ALT values and significantly decreased hemoglobin values and erythrocyte counts. Female rats that received 25,000 ppm or greater had significantly increased reticulocyte counts and sorbitol dehydrogenase values and significantly decreased hematocrit and cholinesterase levels. Female rats that received 50,000 ppm or greater had significantly increased total serum bilirubin levels. There were no other biologically significant changes in hematology and clinical chemistry parameters for exposed rats.

There were no gross or microscopic lesions attributable to C.I. Pigment Red 3 administration.

13-Week Studies

All rats lived to the end of the studies (Table 3). The final mean body weights of all exposed female groups were significantly less than that of the controls. Mean body weight gains of females that received 6,000 ppm or greater were significantly lower than that of the controls. Average feed consumption by exposed and control groups was similar (Table 4).

There were no clinical findings indicative of chemical toxicity. Red-stained extremities, feces, and fur were due to contact with C.I. Pigment Red 3 and were not indicative of toxicity.

Relative liver weights were significantly increased for all exposed groups compared to those of the controls (Table F2). Relative kidney weights were increased for all male groups except the 6,000 ppm group. Relative lung weights were increased for male groups that received 25,000 or 50,000 ppm and for all exposed female groups. No other biologically significant differences in organ weights were observed in rats.

75 ± 13

Reticulocyte counts and albumin, total serum bilirubin, and cholinesterase values in exposed males and potassium, total serum bilirubin, and sorbitol dehydrogenase values in exposed females were significantly increased, but not in a dose-related manner (Table G2). Hematocrit levels were significantly decreased in all males except for those that received 25,000 ppm; the hematocrit level for this group was significantly increased compared to the Males and females that received controls. 6,000 ppm or greater had significantly decreased erythrocyte counts. Female rats that received

6,000 ppm or greater had significantly increased reticulocyte counts and albumin levels. Total serum protein was significantly increased for all males except for those that received 6,000 ppm. Significant decreases in hemoglobin concentration in males and urea nitrogen and lactate dehydrogenase in females that received 25,000 or 50,000 ppm were detected. High-dose males had a significantly increased platelet count and serum phosphorus value and significantly decreased alanine aminotransferase and aspartate aminotransferase values. High-dose females had significantly increased creatinine and

67 ± 12

75 ± 15

phosphorus values and a significantly decreased hematocrit value. No other clinically significant changes in hematology, clinical chemistry, and urinalysis parameters were noted for exposed rats.

The most significant histopathologic alterations in exposed rats occurred in the bone marrow, liver, spleen, and kidney (Tables 5 and 6). These lesions were of greater severity and/or occurred with an increased frequency in the higher dose groups. Most of the changes were considered secondary to the anemia. These secondary changes included hematopoietic cell proliferation within the bone marrow, spleen, and liver, and the presence of pigment within the kidney, liver, and spleen which was interpreted as hemosiderin. The slightly increased incidence of renal protein casts in male rats suggests a possible exacerbation of the progression of chronic glomerulonephropathy commonly seen in aging F344/N rats, particularly males.

Dose Selection Rationale: Exposure concentrations for rats in the 2-year studies were based on the body weight changes observed in rats that received 50,000 ppm in the 13-week studies. The final mean body weight of female rats that received 50,000 ppm was 10% less than that of the controls; therefore, the next highest dose, 25,000 ppm, was chosen as the highest dose for use in the 2-year study of female rats. Based on the 2-week and 13-week studies, males may have tolerated 50,000 ppm, but for consistency, 25,000 ppm was also used as the highest dose for male rats.

2-Year Studies

15-Month Interim Evaluations

Ten male and ten female rats from each study group were evaluated after 15 months. Five rats of each sex receiving the same doses as rats in the 2-year studies were taken from a special study of C.I. Pigment Red 3* and evaluated at 15 months as well. The results of the analyses from animals taken from the special study were incorporated with those from rats used for the interim evaluations of the 2-year studies.

Rats were stained with red dye, due to contact with the chemical rather than to chemical toxicity. The absolute and relative weights of the liver and spleen were significantly increased in a dose-related manner as a result of increased hematopoietic activity and congestion in the spleen (Table F3). There were marginal dose-dependent decreases in hematocrit, hemoglobin, and erythrocyte counts and increases in total serum bilirubin concentrations (Table G3).

The administration of C.I. Pigment Red 3 was associated with histologic changes in bone marrow, kidney, liver, and spleen (Table 7). Liver changes in male rats consisted of cystic degeneration (spongiosis hepatis) which was often associated with foci of Foci of cellular change were cellular change. increased in a dose-related manner and were morphologically similar to the eosinophilic and mixed cell foci described in the results of the 2-year study. Three of these foci were relatively advanced in development. There was a marginal increase in the incidence and severity of bile duct epithelial hyperplasia. The degree of hematopoietic activity present in the bone marrow and spleen was greater in dosed groups than in the controls. Focal splenic subcapsular fibrosis occurred in six exposed males (Table 7). These lesions were small fibrotic areas with increased deposition of pigment (hemosiderin). The severity of chronic nephropathy was slightly increased in exposed rats; the increase in severity was more obvious in females than in males. There were no significant differences in the incidences of neoplasms at any site among groups (Table 8).

A special study was conducted to investigate whether the apparent increase in urinary bilirubin concentrations observed in the 13-week studies (Appendix G) was due to contamination with C.I. Pigment Red 3. The results of the special study showed that the increased concentrations were due to C.I. Pigment Red 3.

TABLE 8 Incidence of Neoplasms in Rats at the 15-Month Interim Evaluations in the 2-Year Feed Studies of C.I. Pigment Red 3

^a Not examined microscopically
 Only those animals noted to have gross lesions were examined microscopically.

Body Weight, Feed Consumption, and Clinical Findings

Mean body weights of low- and mid-dose male rats were within 10% of the control weights throughout the study (Table 9 and Figure 1). From week 82 to the end of the studies, the mean body weights of the high-dose males were over 10% lower than those of controls. The mean body weights of exposed females were more than 10% lower than those of the controls from week 82 for the low-dose group, week 66 for the mid-dose group, and week 42 for high-dose group (Table 10). The average daily feed consumption of exposed rats was similar to that of the controls (Tables I1 and I2). There were no clinical findings indicative of chemical toxicity. Redstained extremities, feces, and fur were not indicative of toxicity, but were due to contact with C.I. Pigment Red 3.

^a Interim evaluation occurred during this week.

Survival

Survival of the mid- and high-dose male rats was similar to that of the controls; survival of the low-dose male rats was slightly greater than that of the controls (Table 11 and Figure 2). In dosed female rats, there were no significant differences in survival.

Pathology and Statistical Analyses of Results

This section describes the statistically significant or biologically noteworthy changes in the incidences of neoplastic or nonneoplastic lesions of the liver, adrenal medulla, skin, Zymbal's gland, clitoral and preputial glands, kidney, and mammary gland, as well as incidences of mononuclear cell leukemia in rats.

Summaries of the incidences of neoplastic and nonneoplastic lesions, individual animal tumor diagnoses, statistical analyses of primary tumors that occurred at an incidence of at least 5% in at least one study group, and historical incidences for the neoplasms mentioned in this section are presented in Appendixes A and B.

Liver: There was a marked increase in the occurrence of hepatocellular adenomas in high-dose female rats (Table 12); hepatocellular carcinomas were not observed in any dose group. These adenomas were well-demarcated, nodular proliferations which often occupied several lobules and caused compression of the surrounding parenchyma (Plate 1). There was loss of normal lobular architecture, and hepatic cords abruptly intersected those of the surrounding parenchymal tissue (Plate 2). Generally, neoplastic cells were larger and contained abundant eosinophilic or vacuolated cytoplasm as well as large round nuclei. In NTP feed study historical control groups, hepatocellular adenomas were observed in only 3/800 females (0.4%, range 0%-6%; Table B4a), and those 3 females were all in the control group of the same study.

Females also had an increased incidence of eosinophilic and mixed cell foci. Many of the foci were large and occupied several hepatic lobules but exhibited limited or no compression of the adjacent parenchymal tissue. The eosinophilic foci contained large hepatocytes resembling those described for hepatocellular adenoma. Mixed cell foci usually had a predominance of cells similar to those in the eosinophilic foci, but also included admixtures of cells that exhibited clear, vacuolated, or amphophilic cytoplasm. A dose-related increased incidence of small granulomas was seen in female groups, and the granulomas were most commonly associated with the foci of cellular alteration. These granulomas consisted of focal aggregates (50 to 250 μ m in diameter) of macrophages and lesser numbers of lymphocytes. Often, minuscule clear clefts (diagnosed as pigmentation, cholesterol) were observed within the granulomas. Cholesterol clefts were also present in mesenteric lymph nodes in all study groups of each sex, but the severity was marginally increased in dosed groups. Spontaneously occurring hepatic granulomas are common in rats, but are more common in females and may occur in foci of cellular alteration (Eustis et al., 1990). There was also a small increase in biliary tract proliferation in the high-dose females.

Increased incidences of eosinophilic and mixed cell foci were observed in dosed males; generally these foci were smaller than those observed in females and there was little evidence of compression of the adjacent parenchyma. Exposed males had increased incidences of cystic degeneration (spongiosis hepatis) and angiectasis (peliosis hepatis). These conditions were often associated with foci of hepatocellular alteration or hepatocellular adenoma. Cystic degeneration was characterized by variably sized cystic spaces containing proteinaceous fluid and scattered viable and degenerated erythrocytes. Spaces were not lined, or were only partially lined, by flattened cells. Microscopic examination revealed that angiectasis of the liver consisted of dilated vascular spaces filled with erythrocytes. Cystic degeneration occurs spontaneously at low incidences in aging rats, but may be quite common in younger rats following exposure to a hepatocarcinogen. Angiectasis is more common in males and can be induced by certain chemicals, particularly nitrosamines; the spontaneous occurrence of angiectasis is also common in F344/N rats (Eustis et al., 1990).

Adrenal Medulla: The incidence of benign adrenal pheochromocytomas medulla (unilateral and bilateral) in dosed male rats occurred with a positive trend, and the incidences in the mid- and high-dose groups were significantly greater than that of the control group by pairwise comparisons (Table 13). The incidence of malignant pheochromocytoma in dosed groups was similar to that of the controls. The combined incidence of benign and malignant pheochromocytoma occurred with a positive trend and the incidence in the mid- and high-dose groups was significantly greater than in the control. The incidence in all dose groups exceeded the NTP historical control rate (benign 284/788, 36%, range 14%-47%; benign and malignant combined 306/788, 39%, range 22%-48%; Table A4a). The pheochromocytomas were often large, discrete masses occupying most of the medulla with the neoplastic cells arranged in packets or trabeculae. The incidence of adrenal medulla hyperplasia in high-dose males was similar to controls. However, in the present study, hyperplasias were only diagnosed when no pheochromocytomas were present in the same gland. Thus, it is probable that had both been diagnosed when present, the incidence of hyperplasias would have been higher. Also, when large adenomas occupied most of the medulla, hyperplasias would not be observed.

PLATE 1

TABLE 13

Adrenal Medulla Lesions in Male Rats in the 2-Year Feed Study of C.I. Pigment Red 3

¹Number of lesion-bearing animals/number of animals with tissues examined microscopically

^b Kaplan-Meier estimated tumor incidence at the end of the study after adjustment for intercurrent mortality

^c Observed incidence at terminal kill

^a Beneath the control incidence are the P values associated with the trend test. Beneath the dosed group incidence are the P values corresponding to pairwise comparisons between the controls and that dosed group. The logistic regression tests regard lesions in animals dying prior to terminal kill as nonfatal. A negative trend or lower incidence in a dose group is indicated by N.

Historical incidence for 2-year NTP feed studies with untreated control groups (mean ± standard deviation): 306/788 (38.8% ± 8.4%); range 22%-48%

Skin: The incidence of squamous cell papillomas of the skin was increased in dosed males (0/50, 4/50, 2/50, 6/50). However, one control male had an anaplastic squamous cell carcinoma (diagnosed as carcinoma) and when combined with the papillomas (1/50, 4/50, 2/50, 6/50), only the trend test remained marginally significant. The historical control incidence of skin squamous cell papillomas in male rats in NTP studies is 16/800 (2.0%, range of 0%-4%); the historical control incidence of squamous cell papillomas and carcinomas combined in male rats in NTP studies is 20/800 (2.5%, range of 0%-4%; Table A4b). These neoplasms were located on the head, ears, feet, and tail. Microscopically, the papillomas were characterized by arborized, fingerlike projections supported by a fibrovascular stromal

core and covered by thickened keratinized squamous epithelium. The squamous cell carcinoma was located on the lip and was poorly differentiated with invasion of surrounding tissue by anaplastic epithelial cells. The marginal increase in squamous cell papillomas in this study may have been associated with chemical administration.

Zymbal's Gland: There was a marginal increase in the occurrence of Zymbal's gland carcinomas in male rats (0/50, 0/50, 2/50, 3/50; Table A3). The incidence in the high-dose group was greater than in the NTP historical control groups (6/800, 1%, range 0%-4%; Table A4c). Zymbal's gland neoplasms infrequently occur spontaneously but are induced by a variety of carcinogens, particularly the aromatic amines (Copeland-Haines and Eustis, 1990). The marginal increase in carcinomas in this study may have been associated with chemical administration.

Clitoral Gland/Preputial Gland: The incidences of clitoral gland and preputial gland neoplasms were lower in exposed animals than in controls (Table 14). The NTP feed study historical control incidence is 64/800 (8%, range 2%-18%) for clitoral gland adenomas and 74/800 (9%, range 4%-22%) for

preputial gland adenomas; for combined adenomas and carcinomas the historical incidences are 88/800 (11%, range 4%-20%) for clitoral gland and 112/800 (14% range 4%-28%) for preputial gland. Clitoral gland carcinomas were not observed in females; a single preputial gland carcinoma occurred in the male control group. This effect is supported by a marginal decrease in hyperplasias of these glands as well. Additionally, fewer clitoral gland duct cysts were observed in dosed females than in controls.

^a In the 6,000 and 12,500 ppm groups only preputial or clitoral glands observed to be abnormal at necropsy were examined microscopically; thus those groups were excluded from statistical analysis.

^b Number of lesion-bearing animals/number of animals with tissues examined microscopically

Kidney: The severity of nephropathy was greater in dosed rats than in controls (Table 15). Severity grades were based upon the percentage of the renal parenchyma exhibiting the tissue changes. Nephropathy in dosed rats was typical of the spontaneously occurring lesions observed in aged F344/N rats. Nephropathy was characterized by varying degrees of tubule dilation and distortion with occasional cyst formation; proteinaceous tubule casts, atrophy, regeneration, and hypertrophy of tubule epithelium; thickening of tubule and glomerular basement membranes; interstitial fibrosis; scattered foci of suppurative inflammation (primarily within degenerating tubules); and various mononuclear inflammatory cells within the interstitium. Regenerating tubule epithelial cells had basophilic nuclei and scant cytoplasm and usually formed a single cell laver.

There was also an increased incidence of renal tubule hyperplasia in the high-dose male rats as well as a dose-related increased incidence of renal papillary transitional epithelium hyperplasia and renal cortical cysts (Table 16). The renal tubule hyperplasia was characterized by one or more slightly dilated tubules with the lumens partially or completely filled with tubule epithelial cells. The cells were typically small with a scant amount of cytoplasm. Hyperplasia of the renal papillary transitional epithelium was minimal to mild and consisted of focal papillary projections of the transitional epithelium lining the renal papilla.

A dose-related increase in the severity of nephropathy was observed in female rats (Table 15). However, as opposed to the males, the only associated secondary lesion was a dose-related increased incidence of renal papillary transitional epithelial hyperplasia (1/50, 5/50, 4/50, 12/49; Table B5).

a Number of lesion-bearing animals/number of animals necropsied or number of animals with tissues examined microscopically

^b Tissues examined microscopically only when observed to be abnormal.

Mammary Gland: The incidence of mammary gland fibroadenomas was marginally decreased in the high-dose females (23/50, 16/50, 20/49, 12/50; Table B2). Fibroadenomas are the most common neoplasm of the mammary gland in female rats, occurring in 314/800 (39%, range 8%-58%) NTP feed study control animals. The lower incidence of fibroadenomas in high-dose females may be due to chemical administration or to the decreased body weights in this group.

Mononuclear Cell Leukemia: Exposure to C.I. Pigment Red 3 resulted in decreased incidences of mononuclear cell leukemia in male (22/50, 6/50, 2/50, 1/50; Table A3) and female rats (10/50, 1/50, 0/50, 2/50; Table B3). Historically, the administration of aniline and aniline-related compounds has caused significant reductions in the incidence of leukemias in F344/N rats (NCI, 1977, 1978, 1979a,b,c; NTP, 1982a,b, 1989).

Other Lesions: Male rats also had treatment-related increased incidences of parathyroid gland hyperplasia, fibrous osteodystrophy, and glandular stomach mineralization; these lesions are thought to be secondary to nephropathy (Table 16).

There was histologic evidence of treatment-related increased incidences of focal and multifocal pancreatic acinus atrophy in both males (24/50, 32/50, 39/49, 41/50; Table A5) and females (22/50, 33/50, 40/50, 36/49; Table B5). Microscopic examination revealed a loss of acinar tissue from a lobule or lobule portion. Atrophy resulted in condensation of the stromal tissue around the remaining pancreatic ducts and islets with a few lymphocytes scattered within the stroma.

The association of pancreatic acinus atrophy with chemical administration is uncertain. While the incidence was increased in dosed groups, the severity of these lesions was minimal and was similar among all groups. Pancreatic acinus atrophy is the most common spontaneous degenerative lesion of the exocrine pancreas in aging F344/N rats and occurs at a high and variable rate. The cause of naturally occurring pancreatic atrophy in the rat is unknown. It may be induced by pancreatic duct ligation, dietary copper or magnesium deficiency, and cytotoxic chemicals (Eustis *et al.*, 1990).

MICE

2-Week Studies

All mice lived to the end of the studies (Table 17). Male mice that received 100,000 ppm had 9% lower final mean body weight than the controls. All exposed females except those that received 25,000 ppm had significantly increased body weight gains relative to that of the controls. Average feed consumption by exposed groups was similar to that of the controls.

There were no clinical findings indicative of chemical toxicity. Red-stained extremities, feces, and fur were due to contact with C.I. Pigment Red 3 and were not indicative of toxicity.

Absolute and relative liver weights were significantly increased in females that received 50,000 or 100,000 ppm (Table F4). Relative brain weights were decreased for females that received 12,500 ppm or greater. No other biologically significant differences in organ weights were observed in mice.

Hemoglobin values and erythrocyte counts were significantly decreased for all mice that received 12,500, 25,000, or 50,000 ppm (Table G4). Male mice that received 100,000 ppm had significantly increased reticulocyte, leukocyte and segmented neutrophil counts and albumin/globulin ratios. Female mice that received 25,000 ppm or greater had significantly increased leukocyte counts; female mice that received 50,000 or 100,000 ppm had significantly increased lymphocyte counts. There were no other biologically significant changes in hematology and clinical chemistry parameters for exposed mice.

There were no gross or microscopic lesions attributable to C.I. Pigment Red 3 administration.

13-Week Studies

One male mouse that received 12,500 ppm died during week 4, and one control male mouse died during week 13 (Table 18). The final mean body weights and body weight changes of exposed mice were similar to those of the controls. Average feed consumption by exposed groups was similar to those of control groups (Table 19).

There were no clinical findings indicative of chemical toxicity. Red-stained extremities, feces, and fur were due to contact with C.I. Pigment Red 3 and were not indicative of toxicity.

Male mice that received 25,000 or 50,000 ppm had significantly increased relative liver weights (Table F5). No other biologically significant changes in organ weights were observed in mice.

There were no biologically significant changes in hematology, clinical chemistry, or urinalysis parameters for exposed mice (Table G5).

a Grams of feed consumed per kilogram body weight per day

The most significant histopathologic alterations occurred in the kidney, liver, and spleen of dosed males and in the liver and spleen of dosed females (Table 20). Increased incidences of hematopoietic cell proliferation in the spleen and liver and splenic pigment (hemosiderin) are probably associated with mild anemia. Renal tubule epithelial cytomegaly, although a minimal to mild change, was thought to be a toxic effect of C.I. Pigment Red 3 administration. This lesion is described in more detail in the results of the 2-year studies.

Dose Selection Rationale: Exposure concentrations for mice in the 2-year studies were based on the lack of chemical-related deaths or decreases in body weights in the 13-week studies. Doses higher than 50,000 ppm might have diluted the nutrients in feed excessively, thereby altering its nutritional value.

2-Year Studies 15-Month Interim Evaluations

Ten male and ten female mice from each study group were evaluated after 15 months. Five mice of each sex receiving the same doses as mice in the 2-year studies were taken from a special study of C.I. Pigment Red 3* and evaluated at 15 months as well. The results of the analyses from **animals** taken from the special study were incorporated with those from animals used for the interim evaluations of the 2-year studies.

All of the animals were stained with red dye, but there were no clinical findings indicative of chemical toxicity. Absolute and relative liver weights were significantly increased in exposed male and female mice (Table F6). The high-dose female group had a significantly decreased hematocrit value and hemoglobin concentration; serum total bilirubin was significantly increased in the high-dose male and female groups (Table G6).

Significant histologic findings at 15 months were increased incidences of nephropathy in high-dose males, dose-related cytomegaly of individual renal tubule epithelial cells in males, golden brown granular pigment (hemosiderin) in the spleens of high-dose males and females (Tables 21 and 22). The nephropathy in males was characterized by regenerative tubules and eosinophilic tubular casts. Cytomegaly was characterized by multifocal renal tubule epithelial cells that had enlarged nuclei and, frequently, increased amounts of cytoplasm. Incidences of neoplasms were similar among groups (Table 23).

Body Weight, Feed Consumption, and Clinical Findings

Mean body weights of mice that received 12,500 or 25,000 ppm were generally within 10% of those of the controls throughout the studies (Tables 24 and 25 and Figure 3). Mean body weights of high-dose mice were decreased by more than 10% from those of the controls from week 62 for males

and from week 38 for females. Average feed consumption was similar among all groups (Tables I3 and I4). No clinical findings indicative of chemical toxicity were observed. Red-stained extremities, feces, and fur were due to contact with the administered chemical and were not indicative of toxicity.

^a Interim evaluation occurred during this week.

FIGURE 3 Growth Curves for Male and Female Mice Administered C.I. Pigment Red 3 in Feed for 2 Years

Survival

Survival of exposed male mice was similar to that of the controls (Table 26 and Figure 4). The survival of the high-dose females was significantly decreased due to moribund sacrifices. The moribund state of these mice may have been associated with ovarian abscesses.

Pathology and Statistical Analyses of Results This section describes the statistically significant or biologically noteworthy changes in mice in the incidences of neoplastic or nonneoplastic lesions of the kidney, ovary, thyroid gland, liver, and skin.

Summaries of the incidences of neoplasms and nonneoplastic lesions, individual animal tumor diagnoses, statistical analyses of primary tumors that occurred with an incidence of at least 5% in at least one animal group, and historical incidences for the neoplasms mentioned in this section are presented in Appendixes C and D.

¹ One control female was killed moribund prior to the interim evaluation.

^e The entry in the control column is the trend test (Tarone, 1975) result. Subsequent entries are the results of pairwise tests (Cox, 1972).

Kidney: Six tubule adenomas of the renal cortex occurred among the high-dose males; none were seen in other groups (Table 27). Renal tubule adenomas have occurred in 2/865 (0.2%, range 0%-2%) male mice in NTP feed study historical controls (Table C4a). A treatment-related increase in the incidence of potentially preneoplastic renal tubule hyperplasia was also seen and was not considered to be associated with the mild nephropathy which occurred in these animals. Renal tubule cystic hyperplasias were found in four other high-dose males, but were considered to be associated with the mild nephropathy rather than preneoplastic lesions. The adenomas (Plate 3) ranged in size from 0.4-10 mm and consisted of a uniform population of large, pale, eosinophilic cells arranged in variably sized tubular or lobular structures separated by a fine fibrovascular stroma. Tubule hyperplasia typically consisted of portions of tubules lined by multiple layers of slightly enlarged epithelial cells occluding the lumen. In contrast, cystic hyperplasia consisted of a dilated tubule lined by one layer of slightly enlarged epithelial cells and an enlarged tubule lumen. There was a mild increase in the severity of nephropathy in dosed males and females (Table 28); however, the severity was significantly less than in the rats. Also, unlike the rat studies, no associated increase in the incidences of secondary lesions was seen except a marginal dose-related increase in the incidence of renal cortical cysts, which was presumed to be related to increased nephropathy severity.

Cytomegaly of the tubule epithelium consisted primarily of random enlargement of nuclei (karyomegaly) and was noted in all dosed male groups but was quite subtle in all except the high-dose group. Any association between this lesion and the development of adenomas is uncertain.

There was a marginal positive trend Ovary: (P=0.032) in the incidence of ovarian granulosa cell adenomas (0/50, 0/49, 1/50, 2/50; Table D1). These tumors are relatively uncommon (Table D4a) but were not considered related to chemical administration because the incidences were low, and incidences of 1/50 have been seen in control groups from NTP feed studies. However, interpretation of this marginal increase is made difficult by ovarian abscesses which, in several high-dose mice, were severe enough to have potentially interfered with the diagnosis of a tumor. In high-dose females, 24 of 100 ovaries were severely affected; both ovaries were affected in six of the high-dose females. Only 7 of 100 ovaries were severely affected in the mid-dose females.

The incidence of ovarian abscesses increased with dose (2/50, 2/49, 12/50, 19/50; Table D5). These abscesses were large and frequently completely replaced the ovarian tissue (Plate 4). The abscesses were often encapsulated by a variably thick fibrous band and were filled with neutrophils, erythrocytes, cell debris, and fibrin. The adjacent mesentery and occasionally the kidney capsule were involved. Other dose-related lesions included myeloid cell hyperplasia of the bone marrow, neutrophils in hepatic sinusoids, hematopoietic cell proliferation in the spleen and liver, suppurative inflammation in the abdominal cavity, and lymphoid hyperplasia of the iliac, mediastinal, and renal lymph nodes. Involvement of these tissues was probably related to the ovarian inflammatory process and reflects the increased demand for the production of neutrophils as well as an immunologic response by the area lymph nodes.

^a Number of animals with severity grade/number of animals examined. Average severity grade is expressed as the mean \pm standard deviation. 0 = none, 1 = minimal, 2 = mild, 3 = moderate, 4 = marked.

Thyroid Gland: There was a treatment-related increased incidence of thyroid gland follicular cell adenomas in males, as well as of follicular cell hyperplasia and follicular cysts (Table 29). The incidence of adenomas in the high-dose males exceeds the incidence of 14/856 (2%, range 0%-4%) in historical controls from NTP feed studies Typically adenomas were partially (Table C4b). encapsulated, well-demarcated masses which compressed surrounding parenchyma and were composed of cells forming follicles and papillary projections. Cells were well-differentiated, but varied in size. Hyperplasia consisted of focal areas with increased numbers of cuboidal to columnar follicular epithelial cells generally in a single layer.

Often the cells formed rows or ribbons; papillary projections were often present and were lined by these cells. Some follicular hyperplasias were cystic; in these cases, follicles were dilated and lined by cuboidal epithelium and exhibited small papillary projections. Follicular cysts were characterized by one or more enlarged (>300 μ m) follicles filled with colloid and lined by a single layer of flattened to cuboidal epithelium. In females, incidences of thyroid follicular cell hyperplasia and follicular cysts were also increased. However, the incidence of follicular cell adenomas in females was not increased and was not considered related to chemical administration.

Results

Liver: There was a marginal but statistically significant increase in the incidence of hepatocellular adenomas in the male mice (8/50, 12/48, 11/50, 16/49; Table C3); the combined incidence of hepatocellular adenomas and carcinomas (12/50, 16/48, 16/50, 19/49) was even less significant. All incidences of hepatocellular adenoma or carcinoma (combined) in male mice are well within the range of NTP historical controls for feed studies (10%-58%) and were not considered to be chemical related. The incidence of basophilic foci was also marginally increased in high-dose males (3/50, 2/48, 3/50, 8/49; Table C5). The adenomas in mice were similar to those described in rats. Compression of the surrounding parenchyma by adenomas was distinct as opposed to minimal or no compression by the foci. Hepatocellular carcinomas were large, often occupying most of the section or lobe, and component cells were often pleomorphic. No significant increase in the incidence of liver neoplasms was observed in female mice.

Male and female mice exhibited dose-related increased incidences of cytologic alteration, Kupffer cell pigmentation, and granulomatous inflammation (Tables C5 and D5). Cytologic alteration involved the centrilobular hepatocytes, and this general diagnosis included one or more of the following: cytomegaly, nuclear basophilia, increased cytoplasmic eosinophilia, and, occasionally, cytoplasmic vacuolation or cellular necrosis. Kupffer cells contained a green-brown pigment which was most easily recognized in the high-dose males and was variably present in other male and female groups. Generally, granulomatous inflammation was diagnosed to address an aggregate of mononuclear cells (2 to 4 cells or more) associated with the previously described green-brown pigment.

Skin: There was a marginal statistically significant decreased incidence of combined subcutaneous tissue fibroma or fibrosarcoma in male mice (15/50, 7/50,

10/50, 6/50; Table C3). The NTP feed study historical control rate for combined subcutaneous fibroma, neurofibroma, neurofibrosarcoma, fibrosarcoma, or sarcoma in male mice is 127/872 (15%, range 0%-41%). This combination is used for comparison because without further diagnostic procedures, such as electron microscopy or immunohistochemistry, the ability to distinguish the various subcutaneous malignant spindle cell tumors can be low. Though within the historical control range, the 30% incidence in the concurrent control group, as opposed to the incidences in the treatment groups, exceeds the average rate of 15%. Also, mice in these 2-year studies were initially housed in groups, and there is a suspected association between fight wounds and the development of subcutaneous sarcomas in male This negative trend was not considered mice. related to chemical administration.

GENETIC TOXICITY

C.I. Pigment Red 3 (33 to 3,333 μ g/plate) was tested for induction of gene mutations in *Salmonella typhimurium* strains TA100, TA1535, TA1537, and TA98 using a preincubation protocol with and without Aroclor 1254-induced male Sprague-Dawley rat or Syrian hamster liver S9 (Table E1) (Mortelmans *et al.*, 1986). Positive responses were obtained with strains TA100 and TA98 in the presence of hamster S9 and an equivocal response was obtained with TA100 in the presence of rat S9; no mutagenic activity was detected in any of the four tester strains in the absence of S9.

In cytogenetic tests with Chinese hamster ovary cells, C.I. Pigment Red 3 was negative for induction of sister chromatid exchanges (Table E2) and chromosomal aberrations (Table E3) in the presence and the absence of Aroclor 1254-induced male Sprague-Dawley rat liver S9. Doses tested were 10 to 50 μ g/mL in the sister chromatid exchange test without S9 and up to 160 μ g/mL in all other trials.

DISCUSSION AND CONCLUSIONS

C.I. Pigment Red 3, a yellowish red solid, is used for coloring paints, inks, plastics, rubber, and in textile printing. This chemical was nominated by the National Cancer Institute (NCI) for testing because of the lack of information on its carcinogenicity and toxicity and its structural similarity to several known phenylazonaphthol carcinogens such as Ponceau 3R, Oil Orange SS, and Citrus Red 2. The large volume of C.I. Pigment Red 3 produced annually (440,000 kg in 1986) suggests a great potential for human exposure. Carcinogenicity and toxicity studies were conducted by feeding diets containing C.I. Pigment Red 3 to groups of F344/N rats and B6C3F₁ mice for 2 weeks, 13 weeks, and 2 years. The dosed feed route of administration was selected to ensure systemic exposure. Genetic toxicology studies were conducted in Salmonella typhimurium and Chinese hamster ovary cells.

Morgan et al. (1989) described the results of the NTP 2-week and 13-week feed studies of The major toxic effects C.I. Pigment Red 3. observed in the 2-week studies included dose-related decreases in erythrocyte counts and hematocrit values and an increase in reticulocyte counts in rats. Changes in these hematology parameters occurred in mice, but not with a clearly dose-related trend. No chemical-related deaths occurred in rats or mice. Final mean body weights were significantly lower than controls in female rats and male mice that received 100,000 ppm and significantly increased in female mice that received 6,000 ppm and 50,000 ppm. The feed consumption of exposed rats and mice was similar to that of the controls, suggesting that C.I. Pigment Red 3 doses had no adverse effects on the feed palatability.

In the 13-week studies, male rats fed diets containing C.I. Pigment Red 3 showed a significant increase in the relative weight of the liver (all doses) and kidney (12,500 ppm and higher). There were significant decreases in the final mean body weights of all exposed female rats. No chemical-related changes in body or relative organ weights were observed in mice. The major sites of toxicity of C.I. Pigment Red 3 in the 13-week studies were the bone marrow, kidney, liver, and spleen in rats; the kidney, liver, and spleen in male mice; and the liver and spleen in female mice.

Chemical-related decreases in erythrocyte counts, hematocrit values, hemoglobin concentrations, and mean cell volumes and an increase in reticulocyte counts occurred in rats in the 13-week studies. Serum and urine bilirubin levels were also elevated in exposed rats. Although there were increases in urine bilirubin levels, no significant chemical-related changes of hematology parameters were observed in exposed mice in the 13-week studies.

In rats, histopathologic lesions attributed to C.I. Pigment Red 3 included bone marrow hyperplasia, congestion and hematopoietic cell proliferation in the spleen, and pigmentation (interpreted as hemosiderin) of the kidney, liver, and spleen. Protein casts occurred in kidneys of exposed male rats. Chemical-related histopathologic lesions seen in male and female mice included hematopoietic cell proliferation and pigmentation in the spleen and hematopoietic cell proliferation in the liver. Renal tubule epithelial cytomegaly was noted in male mice.

The appearance of these toxic effects in dosed rats and mice suggests that C.I. Pigment Red 3 or its metabolites were absorbed. Because C.I. Pigment Red 3 is insoluble in water and other solvents, it is unlikely that absorption of the chemical occurred in the gastrointestinal tract. In a preliminary disposition study in rats, it was concluded that a limited amount of C.I. Pigment Red 3 may be degraded by intestinal microflora since not all of the administered dose was recovered (El Dareer et al., 1984). Based on these observations, the active agent may have been one of the more readily absorbable potential aromatic amine metabolites of this pigment. Azo reduction of C.I. Pigment Red 3 by 4-methylintestinal microflora would vield 2-nitroaniline and 2-hydroxy- α -naphthylamine. The hematologic changes caused by C.I. Pigment Red 3 could be due to one or both of these metabolites. Structurally related aromatic amines have been reported to produce similar hematologic effects (Beard and Noe, 1981). Absorption and further metabolism of these aromatic amines may produce the *n*-hydroxy metabolites which are considered to

be responsible for the hematologic changes (Weisburger, 1983). The histopathologic lesions (hemosiderin deposition in the spleen and hematopoietic cell proliferation in the bone marrow and liver) as well as the hematologic changes observed are all indicative of hemolytic anemia. Amino and nitro aromatic compounds produce this type of anemia and also produce methemoglobinemia (Beard and Noe, 1981; Beutler, 1985). Blood methemoglobin levels were determined in rats and mice only at the 15-month interim evaluations and values were only marginally increased in dosed The hemolytic anemia in rats fed animals. C.I. Pigment Red 3 was characterized by microcytosis, indicated by the decrease in the mean cell volume.

There were chemical-related hematologic changes in rats at the end of the 2-week studies as well as at the end of the 13-week studies. There were dose-related hematologic changes in mice at the end of the 2-week studies but not at the end of the 13-week studies. This suggests that hemolytic anemia produced by C.I. Pigment Red 3 in mice is transient and indicates a species difference in susceptibility to hemolytic anemia. This species difference could be related to the differences between rat and mouse erythrocyte life span and in the rate of metabolism and clearance of C.I. Pigment Red 3 and its aromatic amine metabolites from the blood. Erythrocyte life span has been estimated at 50 to 65 days for rats and 20 to 30 days for mice (Prankerd, 1961). The shorter life span of mice erythrocytes may allow these animals to replace damaged erythrocytes faster than rats. Differences in the clearance rates of aromatic amines have been demonstrated in several species. Clearance of p-chloroaniline from blood in A/J mice was 10 times faster than in dogs or F344/N rats (Perry et al., 1981). Similarly, aromatic amine metabolites of C.I. Pigment Red 3 may be more rapidly cleared from mouse blood, which would result in a short-lived hematologic effect in this species.

Doses of C.I. Pigment Red 3 selected for the 2-year feed studies were 0, 6,000, 12,500, and 25,000 ppm for rats and 0, 12,500, 25,000, and 50,000 ppm for mice. The dose selection was based on the body weight change observed in female rats that received 50,000 ppm and the absence of body weight depression or mortality in mice in the 13-week studies.

In the 2-year rat studies, males in the 6,000 ppm dose group had significantly higher survival than the control group (0 ppm, 28/50; 6,000 ppm, 40/50; 12,500 ppm, 28/50; 25,000 ppm, 20/50). There was no significant difference between the survival rates of female rats fed C.I. Pigment Red 3 and that of the controls (32/50, 41/50, 39/50, 40/50). The lower survival of male control rats may have been due to the high incidence of leukemia. The decreased survival of male rats that received 12,500, or 25,000 ppm was probably due to the increased severity of chronic nephropathy. However, a sufficient number of animals survived long enough to be at risk for developing tumors. Additionally, the body weights of dosed rats were lower than those of the controls, which suggests that the doses used were sufficient for testing the potential carcinogenic activity of C.I. Pigment Red 3. The depression in body weight suggests that the pigment may have been absorbed from the gastrointestinal tract.

In the 2-year studies, the survival rates of dosed mice were similar to those of the controls, except for an increased number of females killed moribund that received 50,000 ppm. The increased incidence of ovarian abscesses in this group may have contributed to the moribund state. Although the final survival rate in the 50,000 ppm female group was reduced, 78% of the animals were alive at week 90, and the study was considered adequate for determining the potential carcinogenicity of C.I. Pigment Red 3. Decreases in mean body weights occurred in male mice that received 50,000 ppm and female mice that received 25,000 or 50,000 ppm. The decreased body weights in the 50,000 ppm dose groups suggest that C.I. Pigment Red 3 or its metabolites were absorbed from the gastrointestinal tract.

A significant positive trend was observed in the incidence of benign pheochromocytoma of the adrenal medulla of male rats (22/50, 29/50, 35/50, 34/50). Pairwise comparisons between the control and dosed groups showed that the incidences in the 12,500 and 25,000 ppm dose groups were significantly greater than that in the control group. Because the incidences of benign pheochromocytoma of the adrenal medulla in dosed male groups were also greater than the historical control rate of 284/788 (36%, range 14%-47%), this increase was considered to be due to chemical administration.

Discussion and Conclusions

Similarly, the incidence of squamous cell papilloma of the skin occurred with a positive trend and the incidence in the 25,000 ppm dose group was significantly greater than that in the control group (0/50, 4/50, 2/50, 6/50). Further, the incidence of squamous cell papillomas in each exposed group was also above the historical control rate of 16/800 (2%, range 0%-4%); the increased incidence of this neoplasm may have been caused by the administration of C.I. Pigment Red 3. Evidence of a carcinogenic effect is weakened by the uncertain biological behavior of these benign squamous cell papillomas and by the occurrence of a squamous cell carcinoma on the lip of a control male rat.

The majority of chemicals tested by the NTP which have caused neoplasms in the skin of F344/N rats have been the benzidine derivatives which were administered orally and caused an increased incidence of basal and squamous cell neoplasms mostly in males (Elwell et al., 1990). Other chemicals applied to skin may result in hyperplasia of the epithelium of the epidermis and adnexa. In these instances it may be appropriate to combine most or all epithelial tumors of the skin. However, in this C.I. Pigment Red 3 study it appears inappropriate to combine all epithelial neoplasms of the skin as most of the squamous cell papillomas were located on the face, ears, feet, and tail, and occurred with an increased incidence, while the other skin epithelial tumors occurred in various locations and with an incidence rate similar to that of their respective historical control groups. Data are insufficient to determine if there was an association between chemical contact with the skin and development of squamous cell papillomas. However, these less haired extremities do allow the greatest contact of dye with the skin.

Of the structurally related compounds studied via the dosed feed route by NCI and NTP, aniline hydrochloride was the only compound that caused an increase in the incidence of adrenal gland pheochromocytoma (NCI, 1978), and none of the compounds caused an increase in the incidence of squamous cell papilloma. *p*-Chloroaniline hydrochloride, administered by gavage, caused an increased incidence in pheochromocytoma in F344/N male rats (NTP, 1989).

The incidence of hepatocellular adenoma occurred with a positive trend in female rats given C.I. Pigment Red 3 (0/50, 0/50, 1/50, 10/50).

Because the incidence of this neoplasm in the 25,000 ppm group was significantly greater than that in the control group and because hepatocellular adenomas are uncommon in historical controls (3/800, 0.4%, range 0%-6%; Table B4a), the increased incidence was considered to be associated with chemical administration. Increases in hepatocellular (neoplastic nodules) adenomas have been reported in the 2-year feed studies of two water insoluble pigments, C.I. Solvent Yellow 14 and D & C Red No. 9 (NTP, 1982a,b).

The marked increased incidence in hepatocellular adenomas in high-dose female rats was accompanied by an increased incidence in eosinophilic and mixed cell foci. Foci of hepatocellular alteration, hepatocellular adenoma, and hepatocellular carcinoma are thought to represent a spectrum of lesions that constitute the natural history of neoplasia. There are several morphological classifications of foci. One cannot determine with certainty which foci of cellular alteration may progress to neoplasia; however, morphological criteria used for diagnosis of an adenoma are indicative of development of autonomy of growth. Adenomas are typically larger, and, foci, cause distinct compression of unlike surrounding parenchyma with abrupt intersection of hepatic cords with the adjacent parenchyma. Generally the growth pattern of adenomas is altered and cellular atypia is greater than in foci.

In these studies, the morphology of cells within the eosinophilic and mixed cell foci was similar to cells of the adenomas, which may suggest the potential for progression of these foci to adenomas. The number of adenomas in the high-dose females was significantly increased, but in weighing the biological significance of this effect, one must consider that many of these adenomas were not advanced in their development, and there were no diagnoses of hepatocellular carcinoma. Eosinophilic and basophilic foci accompanied by angiectasis and cystic degeneration were seen in female F344/N rats given the hepatocarcinogens C.I. Solvent Yellow 14 and D & C Red No. 9. Both of these pigments, as well as C.I. Pigment Red 3, are azonaphthol compound.

The decreased incidence of clitoral gland and preputial gland neoplasms is difficult to interpret, but appears related to the administration of C.I. Pigment Red 3. Zymbal's glands, clitoral glands, and preputial glands are of similar origin (modified sebaceous glands), and in NTP studies, chemicals which cause neoplasms in one of these glands often cause neoplasms in the others as well as in the skin. However, there are exceptions, and in the present studies, the incidence of Zymbal's gland neoplasms was slightly increased in the high-dose male rats. The clitoral or preputial glands of rodents produce pheromones or pheromone-like substances which seem to affect some aspects of sexual behavior. The decrease or absence of trophic pituitary hormones or androgens result in decreased function and atrophy of these glands. However, there was no evidence that these hormones may have been significantly decreased or absent in the dosed animals.

A significant negative trend in the incidence of mammary gland fibroadenoma was observed in female rats. Aniline hydrochloride, a structurally related compound, was reported to cause a similar negative trend (NCI, 1978). The decreased incidence of mammary tumors could be related to body weight depression in dosed females. The incidence of mammary tumors in NTP studies has been found to be positively associated with body weight. No association has been found between mammary tumor incidence and survival (Rao *et al.*, 1990).

As with other structurally related compounds, C.I. Pigment Red 3 caused a significant decrease in the incidence of mononuclear cell leukemia in male and female rats. A review of NCI and NTP studies revealed that leukemia was negatively associated with survival (Rao et al., 1990). Because the incidence of mononuclear cell leukemia in F344/N rats was found to be inversely associated with survival, the reduced survival of the 25,000 ppm dose groups in the present studies cannot be attributed to mononuclear cell leukemia. The hematopoietic system and the spleen are the major sites for the toxicity of C.I. Pigment Red 3, as well as for structurally related compounds; the decreased mononuclear cell leukemia incidence may be due to the direct effect of the pigment on the mechanism responsible for the induction of mononuclear cell leukemia in aging rats. Splenectomy has been reported to greatly decrease the incidence of mononuclear cell leukemia in F344/N rats, suggesting that this neoplasm originates in the spleen (Moloney and King, 1973).

Chronic nephropathy, a disease seen in aging F344/N rats, was more severe in male and female

rats given C.I. Pigment Red 3 than in the control rats. The increased severity of nephropathy appears to be associated with the administration of C.I. Pigment Red 3. In male rats there was an increase in the incidence and/or severity of a number of renal and nonrenal lesions that are commonly observed in male rats with nephropathy. and, thus are generally considered secondary to the nephropathy: renal papillary transitional epithelial hyperplasia, renal cortical cysts, parathyroid gland hyperplasia, glandular stomach mineralization, and fibrous osteodystrophy. The incidence and/or severity of these lesions increases in concert with increasing severity of the nephropathy. As the severity of nephropathy increases, the number of normal nephrons remaining decreases until the kidney loses its ability to function normally. One major adverse effect is loss of calcium, which leads to the inability of the animal to properly maintain calcium/phosphorus homeostasis. Renal secondary hyperparathyroidism often develops to increase calcium levels; this causes calcium to be removed from bones with subsequent development of fibrous osteodystrophy. The exact cause of mineralization of various tissues secondary to renal disease is uncertain, but it is thought to be associated with uremia.

Hyperplasia of the renal papillary transitional epithelium was minimal to mild. The mechanism for renal papillary transitional epithelium hyperplasia is not determined but hyperplasia is commonly increased in severity and incidence with increased severity of nephropathy.

The incidence of renal tubule hyperplasia was increased in the high-dose male rats. With progression of nephropathy, regeneration of tubule epithelium increases. Frequently, hyperplastic lesions which are potentially preneoplastic occur, and in these studies, they occurred in animals with moderate to marked nephropathy. However, a direct effect of C.I. Pigment Red 3 cannot be eliminated.

A dose-related increase in the severity of nephropathy was also observed in the females; however, as opposed to the males, the only associated secondary lesion was a dose-related increase in renal papillary transitional epithelium hyperplasia. This is not unexpected as most of the associated secondary lesions are observed only in animals in which the nephropathy is severe enough to markedly alter kidney morphology or interfere with certain functions (thresholds may vary for specific effects). Renal nephropathy in aged female rats is generally not as severe as in males, and while there was a chemical exacerbation of the nephropathy in the females in the present study, the severity of the nephropathy in the females was much less than in the males.

Pancreatic acinar cell atrophy was observed with increased incidence in dosed rats. Because this lesion is quite common in aging rats and because the severity of these lesions was similar among all dosed groups, the increased incidence of this lesion was not considered to be related to chemical administration.

Although the spleen was a site for the toxicity of C.I. Pigment Red 3 in the 13-week studies in rats, no chemical-related effects were seen in this organ for rats given similar doses in the 2-year studies. This lack of effect suggests a possible adaptive response to the treatment.

In mice, renal cortical tubule adenoma occurred in six males that received 50,000 ppm, and none occurred in the other dosed groups or controls. Because this tumor occurred only in high-dose male mice, and because the incidence exceeds the historical rate for this tumor (2/865, 0.2%, range 0%-2%), the increased incidence of renal cortical tubule adenoma was considered to be related to chemical administration. Adenoma of the renal cortex was not seen in females. Chronic nephropathy occurred with increased severity in dosed males and females. Karyomegaly observed in dosed male mice was attributed to chemical administration; the lesion was subtle in all but the 50,000 ppm group.

Thyroid gland follicular cell adenomas were observed at a significantly increased incidence in male mice that received 50,000 ppm (0 ppm, 0/50; 12,500 ppm, 0/49; 25,000 ppm, 1/50; 50,000 ppm, 5/50). There was also a significant, dose-related follicular cell hyperplastic response. Progression from follicular cell hyperplasia to adenoma and carcinoma is common among laboratory rodents; however, removal of thyroid stimulating hormone will cause reversal of some of the proliferative lesions. Also, morphologic criteria are not always predictive of biological behavior. Generally, follicular cell adenomas have greater overall complexity and cellular atypia than focal hyperplasias. The marked hyperplastic response coupled with the low historical rate for adenomas (14/856, 2%, range 0%-4%) indicated that the increased incidence of thyroid follicular cell adenoma observed in the 50,000 ppm males was caused by C.I. Pigment Red 3 administration. However, in evaluation of the overall biological significance of this carcinogenic effect, one must consider that the adenomas were not advanced in development. Also, carcinomas were not observed in any group, and an increase in follicular cell hyperplasia was observed in females with no corresponding carcinogenic response.

The increased incidence in hepatocellular neoplasms in the high-dose male mice (12/50, 16/48, 16/50, 19/49; Table C3) was marginal but statistically significant. The discussion of the morphological and biological progression of hepatocellular proliferative lesions in rats also applies to mice. The marginal increase in hepatocellular neoplasms was not considered to be associated with C.I. Pigment Red 3 administration for the following reasons: a) the occurrence of these neoplasms in male mice was highly variable; b) the incidence in the concurrent control group (24%) is slightly below that of the historical controls (29%) in NTP feed studies while the incidences in the low-and mid-dose groups were similar to the historical controls; also, the incidence in the high-dose group (38%) is only slightly above the historical rate and well within the range (10%-58%) in historical control groups; and c) only the incidence of adenomas increased; there was no increase in the incidence of carcinomas.

Ovarian infection has been observed in other NTP studies (Rao *et al*, 1987). In these studies, most mice died or were killed in moribund condition, indicating that this is a life shortening disease of aged B6C3F₁ mice. The incidence of lesions ranged from less than 1% to 70% in different studies. Of those animals from which the ovarian abscesses were cultured, many were positive for *Klebsiella spp*. Cultures were not done in these C.I. Pigment Red 3 studies. These organisms are usually considered to be opportunistic pathogens for laboratory mice. The abscesses may be the result of altered microbial status or other physiological changes (maybe immunological) secondary to the chemical, rather than a direct effect.

C.I. Pigment Red 3, with its aromatic nitro group and diazo bond, is structurally alerting for DNA reactivity (Tennant and Ashby, 1991) and is mutagenic in Salmonella typhimurium in the presence of S9 activation enzymes (Mortelmans et al., 1986). The positive results in S. typhimurium are highly predictive of carcinogenicity (89% of chemicals mutagenic to S. typhimurium are carcinogenic in rodents) based on the detailed analysis of the NTP genetic toxicity testing database conducted by Tennant et al. (1987), and are in accord with the results of this bioassay, where tumor induction was noted in 3 of 4 treatment groups. C.I. Pigment Red 3 can, therefore, be considered a genotoxic carcinogen, as was predicted by Tennant et al. (1990) prior to the completion of the bioassay.

Conclusions: Under the conditions of these 2-year feed studies, there was some evidence of carcinogenic activity* of C.I. Pigment Red 3 in male F344/N rats as exhibited by increased incidences of benign pheochromocytomas of the adrenal gland. The marginal increase in the incidences of squamous cell papillomas of the skin and Zymbal's gland carcinomas may have been related to C.I. Pigment Red 3 administration. There was some evidence of carcinogenic activity of C.I. Pigment Red 3 in female F344/N rats as indicated by the increased incidence of hepatocellular adenomas. There was some evidence of carcinogenic activity of C.I. Pigment Red 3 in male B6C3F₁ mice as exhibited by the increased incidences of tubule adenomas of the renal cortex and follicular cell adenomas of the thyroid gland. There was no evidence of carcinogenic activity of C.I. Pigment Red 3 in female B6C3F₁ mice that received 12,500, 25,000, or 50,000 ppm.

The incidences of mononuclear cell leukemia and preputial gland tumors in male rats and mononuclear cell leukemia, mammary gland fibroadenoma, and clitoral gland tumors in female rats were lower in the exposed groups. The incidences of liver foci were markedly increased in exposed male and female The severity of chronic nephropathy was rats. increased in male rats and to a lesser extent in female rats given C.I. Pigment Red 3. An increase in the severity of nephropathy was observed in male and female mice; cytomegaly (karyomegaly) of renal tubule epithelium was observed in male mice. Thyroid follicular cell hyperplasia occurred with an increased incidence in male and female mice receiving C.I. Pigment Red 3.

^{*} Explanation of Levels of Evidence of Carcinogenic Activity is on page 10. A summary of Technical Reports Review Subcommittee comments and the public discussion on this Technical Report appears on page 12.

^a Incidences are expressed as the ratio of animals with lesions to the number of animals examined microscopically at the site.

 b Interestives are expressed as the ratio of animals with resions to the number of animals examined interesception at the Each dosed group contains one animal that died or was sacrificed moribund prior to the interim scheduled sacrifice
 c Number of animals with any tissue examined microscopically
 d Primary tumors: all tumors except metastatic tumors
 e Secondary tumors: metastatic tumors or tumors invasive to an adjacent organ b

(T)Terminal sacrifice

Number of tumor-bearing animals/number of animals examined. Denominator is number of animals examined microscopically for adrenal gland, bone marrow, brain, clitoral gland, epididymis, gallbladder (mouse), heart, kidney, larynx, liver, lung, nose, ovary, pancreas, parathyroid gland, pituitary gland, preputial gland, prostate gland, salivary gland, spleen, testes, thyroid gland, and urinary bladder; for other tissues, denominator is number of animals necropsied.

^b Kaplan-Meier estimated tumor incidence at the end of the study after adjustment for intercurrent mortality

^c Observed incidence at terminal kill

^d Beneath the control incidence are the P values associated with the trend test. Beneath the dosed group incidence are the P values corresponding to pairwise comparisons between the controls and that dosed group. The life table analysis regards tumors in animals dying prior to terminal kill as being (directly or indirectly) the cause of death. The logistic regression tests regard these lesions as nonfatal. The Cochran-Armitage and Fisher exact tests compare directly the overall incidence rates. For all tests, a negative trend or a lower incidence in a dose group is indicated by N.

^e Not applicable; no tumors in animal group

f Tissue was examined microscopically only when it was observed to be abnormal at necropsy; thus, no statistical analyses are provided.

a Incidences are expressed as the ratio of animals with lesions to the number of animals examined microscopically at the site.

b

с d

Number of animals with any tissue examined microscopically Primary tumors: all tumors except metastatic tumors Secondary tumors: metastatic tumors or tumors invasive to an adjacent organ

TABLE B3 Statistical Analysis of Primary Neoplasms in Female Rats in the 2-Year Feed Study of C.I. Pigment Red 3 (continued)

(T)Terminal sacrifice

^c Observed incidence at terminal kill

d Beneath the control incidence are the P values associated with the trend test. Beneath the dosed group incidence are the P values corresponding to pairwise comparisons between the controls and that dosed group. The life table analysis regards tumors in animals dying prior to terminal kill as being (directly or indirectly) the cause of death. The logistic regression tests regard these lesions as nonfatal. The Cochran-Armitage and Fisher exact tests compare directly the overall incidence rates. For all tests, a negative trend or a lower incidence in a dose group is indicated by N.

e Tissue was examined microscopically only when it was observed to be abnormal at necropsy; thus, no statistical analyses are provided. Not applicable; no tumors in animal group

f

Number of tumor-bearing animals/number of animals examined. Denominator is number of animals examined microscopically for adrenal gland, bone marrow, brain, clitoral gland, epididymis, gallbladder (mouse), heart, kidney, larynx, liver, lung, nose, ovary, pancreas, parathyroid gland, pituitary gland, preputial gland, prostate gland, salivary gland, spleen, testes, thyroid gland, and urinary bladder; for other tissues, denominator is number of animals necropsied.

Ь Kaplan-Meier estimated tumor incidence at the end of the study after adjustment for intercurrent mortality

Total secondary neoplasms	2	3	3	

a Incidences are expressed as the ratio of animals with lesions to the number of animals examined microscopically at the site.

b One male receiving 25,000 ppm and two males receiving 50,000 ppm died prior to the interim evaluation.

¢ Number of animals with any tissue examined microscopically đ

Primary tumors: all tumors except metastatic tumors

e Secondary tumors: metastatic tumors or tumors invasive to an adjacent organ

First incidence (days)	450	512	521	294
Life table tests	P=0.041	P=0.193	P=0.076	P=0.042
Logistic regression tests	P=0.004	P=0.216	P=0.057	P=0.009
Cochran-Armitage test	P=0.016			
Fisher exact test		P=0.421	P=0.078	P=0.033

(T)Terminal sacrifice

Number of tumor-bearing animals/number of animals examined. Denominator is number of animals examined microscopically for adrenal gland, bone marrow, brain, clitoral gland, epididymis, gallbladder (mouse), heart, kidney, larynx, liver, lung, nose, ovary, pancreas, parathyroid gland, pituitary gland, preputial gland, prostate gland, salivary gland, spleen, testes, thyroid gland, and urinary bladder; for other tissues, denominator is number of animals necropsied.

^b Kaplan-Meier estimated tumor incidence at the end of the study after adjustment for intercurrent mortality

^c Observed incidence at terminal kill

^d Beneath the control incidence are the P values associated with the trend test. Beneath the dosed group incidence are the P values corresponding to pairwise comparisons between the controls and that dosed group. The life table analysis regards tumors in animals dying prior to terminal kill as being (directly or indirectly) the cause of death. The logistic regression tests regard these lesions as nonfatal. The Cochran-Armitage and Fisher exact tests compare directly the overall incidence rates. For all tests, a negative trend or a lower incidence in a dose group is indicated by N.

^e Not applicable; no tumors in animal group

f Tissue was examined microscopically only when it was observed to be abnormal at necropsy; thus, no statistical analyses are provided.

Summary of the Incidence of Neoplasms in Female Mice in the 2-Year Feed Study of C.I. Pigment Red 3 (continued)

	0 ppm	12,500 ppm	25,000 ppm	50,000 ppm
Respiratory System				
Lung	(50)	(13)	(21)	(50)
Alveolar/bronchiolar adenoma	3 (6%)			3 (6%)
Alveolar/bronchiolar carcinoma	1 (2%)		1 (5%)	
Fibrosarcoma, metastatic, skin				1 (2%)
Hepatocellular carcinoma,				
metastatic, liver	1 (2%)			
Hepatocellular carcinoma, metastatic,		1 (97%)		
multiple, greater than five, liver Histiocytic sarcoma		1 (8%) 1 (8%)		
Osteosarcoma, metastatic, multiple,		1 (870)		
greater than five, bone	1 (2%)		1 (5%)	
greater than five, cone				
Special Senses System				
Harderian gland	(3) 3 (100%)	(2)	(1)	(1)
Adenoma	3 (100%)	1 (50%)	1 (100%)	1 (100%)
Carcinoma		1 (50%)		
Urinary System				
Kidney	(50)	(49)	(49)	(50)
Histiocytic sarcoma		ì (2%)		ì (2%)
Mast cell tumor malignant				1 (2%)
Osteosarcoma, metastatic,				
multiple, two, bone	1 (2%)			
Urinary bladder	(50)	(12)	(18)	(50)
Systemic Lesions				
Multiple organs ^c	(50)	(50)	(50)	(50)
Histiocytic sarcoma	()	2 (4%)	2 (4%)	3 (6%)
Lymphoma malignant histiocytic				1 (2%)
Lymphoma malignant mixed	14 (28%)	9 (18%)	8 (16%)	6 (12%)
Lymphoma malignant	· · ·			
undifferentiated cell	1 (2%)			
Tumor Summary				
Total animals with primary neoplasms ^d	36	29	23	33
Total primary neoplasms	58	29 44	23	43
Total animals with benign neoplasms	21	15	6	43 23
Total benign neoplasms	30	13	6	25
Total animals with malignant neoplasms	21	20	19	15
Total malignant neoplasms	28	27	21	13
Total animals with secondary neoplasms ^e	3	1	2	2

а Incidences are expressed as the ratio of animals with lesions to the number of animals examined microscopically at the site.

b One control female was sacrificed moribund prior to the interim evaluation. с

Number of animals with any tissue examined microscopically

d Primary tumors: all tumors except metastatic tumors

е Secondary tumors: metastatic tumors or tumors invasive to an adjacent organ

(T)Terminal sacrifice

³ Number of tumor-bearing animals/number of animals examined. Denominator is number of animals examined microscopically for adrenal gland, bone marrow, brain, clitoral gland, epididymis, gallbladder (mouse), heart, kidney, larynx, liver, lung, nose, ovary, pancreas, parathyroid gland, pituitary gland, preputial gland, prostate gland, salivary gland, spleen, testes, thyroid gland, and urinary bladder, for other tissues, denominator is number of animals necropsied.

Kaplan-Meier estimated tumor incidence at the end of the study after adjustment for intercurrent mortality

^c Observed incidence at terminal kill

^d Beneath the control incidence are the P values associated with the trend test. Beneath the dosed group incidence are the P values corresponding to pairwise comparisons between the controls and that dosed group. The life table analysis regards tumors in animals dying prior to terminal kill as being (directly or indirectly) the cause of death. The logistic regression tests regard these lesions as nonfatal. The Cochran-Armitage and Fisher exact tests compare directly the overall incidence rates. For all tests, a negative trend or a lower incidence in a dose group is indicated by N.

^e Tissue was examined microscopically only when it was observed to be abnormal at necropsy; thus, no statistical analyses are provided.

f Not applicable; no tumors in animal group

Summary of the Incidence of Nonneoplastic Lesions in Female Mice in the 2-Year Feed Study of C.I. Pigment Red 3 (continued)

a Incidences are expressed as the ratio of animals with lesions to the number of animals examined microscopically at the site.
 b One control female was killed moribund prior to the interim evaluation.

GENETIC TOXICOLOGY

SALMONELLA PROTOCOL

Testing was performed as reported by Mortelmans *et al.* (1986). C.I. Pigment Red 3 was sent to the laboratory as a coded aliquot from Radian Corporation (Austin, TX). It was incubated with the *Salmonella typhimurium* tester strains (TA100, TA1535, TA1537, and TA98) either in buffer or S9 mix (metabolic activation enzymes and cofactors from Aroclor 1254-induced male Sprague-Dawley rat or Syrian hamster liver) for 20 minutes at 37° C prior to the addition of soft agar supplemented with *l*-histidine and *d*-biotin, and subsequent plating on minimal glucose agar plates. Incubation continued for an additional 48 hours.

Each trial consisted of triplicate plates of concurrent positive and negative controls and of at least five doses of C.I. Pigment Red 3. High dose was limited by solubility and did not exceed 3,333 μ g/plate. All trials were repeated.

In this assay, a positive response is defined as a reproducible, dose-related increase in histidineindependent (revertant) colonies in any one strain/activation combination. An equivocal response is defined as an increase in revertants which was not dose-related, not reproducible, or of insufficient magnitude to support a determination of mutagenicity. A negative response was obtained when no increase in revertant colonies was observed following chemical treatment.

CHINESE HAMSTER OVARY CELL CYTOGENETICS ASSAYS

Testing was performed as reported by Galloway *et al.* (1985, 1987) and is presented briefly below. C.I. Pigment Red 3 was sent to the laboratory as a coded aliquot from Radian Corporation (Austin, TX). It was tested in cultured Chinese hamster ovary (CHO) cells for induction of sister chromatid exchanges (SCE) and chromosomal aberrations (Abs) both in the presence and absence of Aroclor 1254-induced male Sprague-Dawley rat liver S9 and cofactor mix. Cultures were handled under gold lights to prevent photolysis of bromodeoxyuridine-substituted DNA. Each trial consisted of concurrent solvent and positive controls and of at least three doses of C.I. Pigment Red 3; the high dose was limited by toxicity or solubility, but did not exceed 160 μ g/mL.

In the SCE test without S9, CHO cells were incubated for 26 hours with the C.I. Pigment Red 3 in McCoy's 5A medium supplemented with 10% fetal bovine serum, *l*-glutamine (2mM), and antibiotics. Bromodeoxyuridine (BrdU) was added 2 hours after culture initiation. After 26 hours, the medium containing C.I. Pigment Red 3 was removed and replaced with fresh medium plus BrdU and Colcemid, and incubation was continued for 2 hours. Cells were then harvested by mitotic shake-off, fixed, and stained with Hoechst 33258 and Giemsa. In the SCE test with S9, cells were incubated with C.I. Pigment Red 3, serum-free medium, and S9 for 2 hours. The medium was then removed and replaced with medium containing BrdU and no C.I. Pigment Red 3 and incubation proceeded for an additional 26 hours, with Colcemid present for the final 2 to 3 hours. Harvesting and staining was the same as for cells treated without S9.

In the chromosomal aberration test without S9, cells were incubated in McCoy's 5A medium with C.I. Pigment Red 3 for 10 hours; Colcemid was added and incubation continued for 2 to 3 hours. The cells were then harvested by mitotic shake-off, fixed, and stained with Giemsa. For the Abs test with S9, cells were treated with C.I. Pigment Red 3 and S9 for 2 hours, after which the treatment medium was removed and the cells incubated for 11 hours in fresh medium, with Colcemid present for the final 2 to 3 hours. Cells were harvested in the same manner as for the treatment without S9.

Genetic Toxicology

Cells were selected for scoring on the basis of good morphology and completeness of karyotype $(21 \pm 2 \text{ chromosomes})$. All slides were scored blind and those from a single test were read by the same person. For the SCE test, 50 second-division metaphase cells were scored for frequency of SCE per cell from each dose level; generally, 200 first-division metaphase cells were scored at each dose level for the Abs test. Classes of aberrations included simple (breaks and terminal deletion), complex (rearrangements and translocations), and other (pulverized cells, despiralized chromosomes, and cells containing 10 or more aberrations).

Statistical analyses were conducted on both the slopes of the dose-response curves and the individual dose points. An SCE frequency 20% above the concurrent solvent control value was chosen as a statistically conservative positive response. The probability of this level of difference occurring by chance at one dose point is less than 0.01; the probability for such a chance occurrence at two dose points is less than 0.001. Chromosomal aberration data is presented as percentage of cells with aberrations. As with SCE, both the dose-response curve and individual dose points were statistically analyzed. For a single trial, a statistically significant (P \leq 0.05) difference for one dose point and a significant trend (P \leq 0.015) was considered weak evidence for a positive response (+w); significant differences for two or more doses indicated the trial was positive (+) (Galloway *et al.*, 1987).

RESULTS

C.I. Pigment Red 3 (33 to 3,333 μ g/plate) was tested for induction of gene mutations in Salmonella typhimurium strains TA100, TA1535, TA1537, and TA98 using a preincubation protocol with and without Aroclor 1254-induced male Sprague-Dawley rat or Syrian hamster liver S9 (Table E1) (Mortelmans *et al.*, 1986). Positive responses were obtained with strains TA100 and TA98 in the presence of hamster S9 and an equivocal response was obtained with TA100 in the presence of rat S9; no mutagenic activity was detected in any of the four tester strains in the absence of S9.

In cytogenetic tests with Chinese hamster ovary cells, C.I. Pigment Red 3 was negative for induction of sister chromatid exchanges (Table E2) and chromosomal aberrations (Table E3) in the presence and the absence of Aroclor 1254-induced male Sprague-Dawley rat liver S9. Doses tested were 10 to 50 μ g/mL in the SCE test without S9 and up to 160 μ g/mL in all other trials.

TABLE E1 Mutagenicity of C.I. Pigment Red 3 in Salmonella typhimurium^a

^a Study performed at EG&G Mason Research Institute. The detailed protocol and these data are presented in Mortelmans *et al.* (1986). Cells and C.I. Pigment Red 3 or solvent (dimethylsulfoxide) were incubated in the absence of exogenous metabolic activation (-S9) or with Aroclor 1254-induced S9 from male Syrian hamster liver or male Sprague-Dawley rat liver. High dose was limited by solubility, but did not exceed 10 mg/plate; 0 μg/plate dose is the solvent control.

^D Revertants are presented as mean \pm standard error from three plates.

^c Precipitate on plate

^d 2-aminoanthracene was used on all strains in the presence of S9. In the absence of metabolic activation, 4-nitro-o-phenylenediamine was tested on TA98, sodium azide was tested on TA100 and TA1535, and 9-aminoacridine was tested on TA1537.

^a Study performed at Environmental Health Research and Testing, Inc. SCE = sister chromatid exchange; BrdU = bromodeoxyuridine. A detailed description of the SCE protocol is presented by Galloway *et al.* (1985, 1987). Briefly, Chinese hamster ovary cells were incubated with C.I. Pigment Red 3 or solvent (dimethylsulfoxide) as described in ^c and ^e below, and cultured for sufficient time to reach second metaphase division. Cells were then collected by mitotic shake-off, fixed, air-dried, and stained.

^b SCE's/chromosome of culture exposed to C.I. Pigment Red 3 relative to those of culture exposed to solvent.

^c In the absence of S9, cells were incubated with or solvent for 2 hours at 37° C. Then BrdU was added and incubation was continued for 24 hours. Cells were washed, fresh medium containing BrdU and Colcemid was added, and incubation was continued for 2 hours.

d Significance of relative SCEs/chromosome tested by the linear regression trend test vs. log of the dose

In the presence of S9, cells were incubated with C.I. Pigment Red 3 or solvent for 2 hours at 37° C. The cells were then washed, and medium containing BrdU was added. Cells were incubated for a further 26 hours, with Colcemid present for the final 2 to 3 hours. S9 was from the livers of Aroclor 1254-induced male Sprague-Dawley rats.

TABLE E3

Induction of Chromosomal Aberrations in Chinese Hamster Ovary Cells by C.I. Pigment Red 3^a

a Study performed at Environmental Health Research and Testing, Inc. Abs = aberrations. A detailed presentation of the technique for detecting chromosomal aberrations is found in Galloway et al. (1985, 1987). Briefly, Chinese hamster ovary cells were incubated with C.I. Pigment Red 3 or solvent (dimethylsulfoxide) as indicated in ^b and ^c. Cells were arrested in first metaphase by addition of Colcemid and harvested by mitotic shake-off, fixed, and stained in 6% Giemsa.

b In the absence of S9, cells were incubated with C.I. Pigment Red 3 or solvent for 10 hours at 37° C. Cells were then washed and fresh medium containing Colcemid was added for an additional 2 to 3 hours followed by harvest.

¢ In the presence of S9, cells were incubated with C.I. Pigment Red 3 or solvent for 2 hours at 37° C. Cells were then washed, medium was added, and incubation was continued for 11 hours. Colcemid was added for the last 2 to 3 hours of incubation before harvest. S9 was from the livers of Aroclor 1254-induced male Sprague-Dawley rats.

d Significance of percent cells with aberrations tested by the linear regression trend test vs. log of the dose

CHEMICAL CHARACTERIZATION AND DOSE FORMULATION STUDIES

PROCUREMENT AND CHARACTERIZATION OF C.I. PIGMENT RED 3

C.I. Pigment Red 3 was obtained from American Cyanamid Company (Wayne, NJ; lot G-1292), and Sun Chemical Company (New York, NY; lot S051783). Lot G-1292 was used throughout the 2-week and 13-week studies and during a portion of the 2-year studies, and lot S051783 was used throughout the remainder of the 2-year studies. Reports from the analytical chemistry laboratory, Midwest Research Institute (Kansas City, MO), on analyses performed in support of the C.I. Pigment Red 3 studies are on file at the National Institute of Environmental Health Sciences.

Both lots of the study chemical, a red powder, were identified as C.I. Pigment Red 3 by infrared, ultraviolet/visible, and nuclear magnetic resonance spectroscopy. All spectra (Figures H1 and H2) were consistent with those expected for the structure and with the literature description for the spectra of C.I. Pigment Red 3 (Sadtler Standard Spectra).

Initially, lot G-1292 was divided into two subbatches. The relative purity of the subbatches was determined by high-performance liquid chromatography (HPLC) with a μ Bondapak CN column with a solvent system of hexane:methylene chloride (90:10) at a flow rate of 1 mL/minute. Nitrobenzene was added as an internal standard. Ultraviolet detection was at 254 nm. The major peak area of one subbatch was 99.0 \pm 0.5% of that of the second subbatch. Three subbatches of lot S051783 were analyzed using the same HPLC system, but with a solvent system of hexane:methylene chloride (85:15) The three subbatches were found to be identical within the limits of experimental error.

The purity of both lots was found to be greater than 97% by elemental analyses, weight loss on drying, thin-layer chromatography (TLC), and HPLC. TLC was performed on silica gel plates with two solvent systems: 1) methylene chloride and 2) chloroform:xylene:methanol (75:25:1). After drying, plates were examined under shortwave (254 nm) and longwave (366 nm) ultraviolet light and visible light. HPLC was performed with the same system described above, but with solvent ratios of 95:5 for lot G-1292 and 92:8 for lot S051783.

For lot G-1292, elemental analyses for carbon, hydrogen, and nitrogen were in agreement with the theoretical values for C.I. Pigment Red 3. Weight loss on drying indicated less than 0.05% water. TLC indicated a major spot and a slight trace impurity by one solvent system and a single homogeneous spot by a second solvent system. HPLC indicated a major peak and three impurities with a combined area of approximately 2% relative to the major peak. The largest impurity had a peak area of 1.8% of the major peak. More polar mobile phases revealed three additional impurities with combined areas of less than 1% of that of the major peak.

For lot S051783, elemental analyses for carbon and hydrogen were in agreement with the theoretical values for C.I. Pigment Red 3; the analysis for nitrogen was low. Weight loss on drying indicated $0.12 \pm 0.01\%$ water. TLC by both solvent systems indicated only a major spot. HPLC indicated a major peak and four impurities with a total area of approximately 2% relative to the major peak. The largest impurity had a peak area of 1.1% of the major peak. HPLC major peak comparison of the two lots indicated similar purity.

Chemical Characterization and Dose Formulations

Stability studies on lot G-1292 were performed by the analytical chemistry laboratory using HPLC with the system described above but with a solvent ratio of 90:10 and with nitrobenzene added as an internal standard. These studies indicated that C.I. Pigment Red 3 was stable as a bulk chemical for 2 weeks at temperatures up to 60° C when protected from light. The stability of the bulk chemical was monitored periodically at the study laboratory with ultraviolet spectroscopy and HPLC analysis methods similar to those described above. No change in purity was observed.

PREPARATION AND ANALYSIS OF DOSE FORMULATIONS

The dose formulations were prepared by mixing amounts of C.I. Pigment Red 3 and feed in a blender (Patterson-Kelly Twin Shell with intensifier bar) and mixing for 15 minutes (Table H1). Studies were conducted by the analytical chemistry laboratory to determine homogeneity and stability of the dosed feed preparations. For homogeneity analyses, the formulations were extracted and diluted with methylene chloride, and the absorbance of the samples was measured versus methylene chloride by spectroscopy at 510 nm. For the stability studies, feed samples were extracted with methylene chloride, centrifuged, and further diluted with methylene chloride. The samples were then injected into a HPLC system equipped with a μ Bondapak CN column. The mobile phase was a mixture of hexane:methylene chloride at a ratio of 40:60 and a flow rate of 2 mL/minute. Visible detection was at 436 nm. Homogeneity was confirmed; stability of the formulations was established for 2 weeks when stored in the dark at temperatures up to 45° C.

Periodic analyses of the dose formulations of C.I. Pigment Red 3 were conducted at the study laboratory and the analytical chemistry laboratory with visible spectroscopy at 510 nm. During the 2-week studies, the dose formulations were analyzed at the beginning of the studies (Table H2). During the 13-week studies, the dose formulations were analyzed at the initiation and the midpoint of the studies (Table H3). During the 2-year studies, the dose formulations were analyzed at least once every 8 weeks and 99% (181/183) were within 10% of the target concentrations (Table H4). Results of the periodic referee analysis performed by the analytical chemistry laboratory indicated good agreement with the results obtained by the study laboratory (Table H5).

ngredients ^b	Percent by Weight	
Ground #2 yellow shelled corn	21.0	
Ground whole wheat	35.5	
Soybean meal (49% protein)	5.00	
Fish meal (60% protein)	9.00	
Wheat middlings	10.00	
Alfalfa meal (dehydrated, 17% protein)	2.0	
Corn gluten meal (60% protein)	2.0	
Soy oil	1.5	
Dried brewer's yeast	1.00	
Dicalcium phosphate	1.5	
Ground limestone	0.5	
Salt	0.5	
Premixes (vitamin and mineral)	0.5	

TABLE J1 Ingredients of NIH-07 Rat and Mouse Ration^a

a b

NCI, 1976; NIH, 1978 Ingredients ground to pass through a U.S. Standard Screen No. 16 before being mixed

TABLE J2		
Vitamins and	Minerals in NIH-07 Rat and Mouse Ration ^a	

	Amount	Source
Vitamins		
Α	20,000,000 IU	Stabilized vitamin A palmitate or acetate
D ₃	3,800,000 IU	D-activated animal sterol
K ₃	2.0 g	Menadione
d - α -Tocopherol acetate	15,000 IU	
Choline	700 g	Choline chloride
Folic acid	1.0 g	
Niacin	20.0 g	
d-Pantothenic acid	25.0 g	d-Calcium pantothenate
Riboflavin	5.0 g	
Thiamine	65.0 g	Thiamine mononitrate
B ₁₂	14,000 μg	
Pyridoxine	2.0 g	Pyridoxine hydrochloride
Biotin	120.0 mg	d-Biotin
Minerals		
Iron	60.0 g	Iron sulfate
Manganese	100.0 g	Manganous oxide
Zinc	10.0 g	Zinc oxide
Copper	4.0 g	Copper sulfate
Iodine	1.5 g	Calcium iodate
Cobalt	0.4 g	Cobalt carbonate
Magnesium	400 g	

^a Per ton (2,000 lb) of finished product

.

TABLE J3

Nutrient Composition of NIH-07 Rat and Mouse Ration

Nutrients	Mean ± Standard Deviation	Range	Number of Samples
Protein (% by weight)	22.33 ± 0.83	21.0 - 24.3	25
Crude Fat (% by weight)	5.34 ± 0.67	4.2 - 6.4	25
Crude Fiber (% by weight)	3.59 ± 0.32	2.9 - 4.5	25
Ash (% by weight)	6.64 ± 0.28	5.9 - 7.3	25
Amino Acids (% of total diet)			
Arginine	1.308 ± 0.606	1.210 - 1.390	8
Cystine	0.306 ± 0.084	0.181 - 0.400	8
Glycine	1.150 ± 0.047	1.060 - 1.210	8
Histidine	0.576 ± 0.024	0.531 - 0.607	8
Isoleucine	0.917 ± 0.029	0.881 - 0.944	8
Leucine	1.946 ± 0.055	1.850 - 2.040	8
Lysine	1.270 ± 0.058	1.200 - 1.370	8
Methionine	0.448 ± 0.128	0.306 - 0.699	8
Phenylalanine	0.987 ± 0.140	0.665 - 1.110	8
Threonine	0.877 ± 0.042	0.824 - 0.940	8
Tryptophane	0.236 ± 0.176	0.107 - 0.671	8
Tyrosine	0.676 ± 0.105	0.564 - 0.794	8
Valine	1.103 ± 0.040	1.050 - 1.170	8
Essential Fatty Acids (% of total die	t)		
Linoleic	2.393 ± 0.258	1.830 - 2.570	7
Linolenic	0.280 ± 0.040	0.210 - 0.320	7
Vitamins			
Vitamin A (IU/kg)	$11,308 \pm 4,691$	4,200 - 22,000	25
Vitamin D (IU/kg)	$4,450 \pm 1,382$	3,000 - 6,300	4
α-Tocopherol (ppm)	37.95 ± 9.41	22.50 - 48.90	8
Thiamine (ppm)	20.08 ± 5.07	12.0 - 37.0	25
Riboflavin (ppm)	7.92 ± 0.87	6.10 - 9.00	8
Niacin (ppm)	103.38 ± 26.59	65.0 - 150.0	8
Pantothenic acid (ppm)	29.54 ± 3.60	23.0 - 34.0	8
Pyridoxine (ppm)	9.55 ± 3.48	5.60 - 14.0	8
Folic Acid (ppm)	2.25 ± 0.73	1.80 - 3.70	8
Biotin (ppm)	0.254 ± 0.042	0.19 - 0.32	8
Vitamin B ₁₂ (ppb)	38.45 ± 22.01	10.6 - 65.0	8
Choline (ppm)	$3,089 \pm 328.69$	2,400 - 3,430	8
Minerals			
Calcium (%) ^a	1.20 ± 0.15	0.87 - 1.43	24
Phosphorus (%)	0.95 ± 0.06	0.84 - 1.10	25
Potassium (%)	0.883 ± 0.078	0.772 - 0.971	6
Chloride (%)	0.526 ± 0.092	0.380 - 0.635	8

TABLE J4 Contaminant Levels in NIH-07 Rat and Mouse Ration

^a For values less than the limit of detection, the detection limit is given for the mean. Four batches (02/22/84, 03/14/84, 05/09/84, and 06/13/84) contained 0.20 ppm; all others contained <0.10 ppm.

d CFU = colony-forming unit

MPN = most probable number
 f
 All values were corrected for per

All values were corrected for percent recovery.

^g BHC is hexachlorocyclohexane or benzene hexachloride.

h Fourteen lots contained more than 0.05 ppm.

SENTINEL ANIMAL PROGRAM

Methods

Rodents used in the Carcinogenesis Program of the National Toxicology Program are produced in optimally clean facilities to eliminate potential pathogens that may affect study results. The Sentinel Animal Program is part of the periodic monitoring of animal health that occurs during the toxicologic evaluation of chemical compounds. The sentinel animals come from the same production source and weanling groups as animals used for the studies of chemical compounds, and these animals and the study animals are subject to identical environmental conditions.

Rats

During the 13-week studies, five F344/N rats of each sex were maintained with the study animals to serve as sentinel animals. At termination of the 13-week studies, blood samples were taken from the sentinel rats. The blood was allowed to clot, and the serum was separated. The serum was cooled and sent to Microbiological Associates, Inc. (Bethesda, MD) for determination of antibody titers. The following tests were performed:

Method of Analysis	<u>Time of Analysis</u>
Hemagglutination Inhibition	
PVM (pneumonis virus of mice)	Study termination
Sendai	Study termination
KRV (Kilham rat virus)	Study termination
H-1 (Toolan's H-1 virus)	Study termination
Complement Fixation	
RCV (rat corona virus)	Study termination

During the 2-year studies, 15 F344/N rats of each sex were maintained with the study animals to serve as sentinel animals. Blood was drawn from five rats of each sex at 6, 12, and 18 months following study initiation. Five randomly selected control animals of each sex were bled at study termination (24 months). Blood collected from each animal was allowed to clot and the serum was separated. The serum was cooled on ice and shipped to Microbial Associates, Inc. (Bethesda, MD) for determination of antibody titers. The following tests were performed:

Method of Analysis Hemagglutination Inhibition	Time of Analysis
PVM Sendai	6 and 12 months 6, 12, and 18 months
KRV H-1	6, 12, 18, and 24 months 6, 12, 18, and 24 months
ELISA	
PVM	18 and 24 months
Sendai	18 and 24 months
RCV/SDA (rat corona virus/sialodacryoadenitis virus)	6, 12, 18, and 24 months
Mycoplasma pulmonis	6, 12, 18, and 24 months
Mycoplasma arthritidis	24 months

Mice

During the 13-week studies, five $B6C3F_1$ mice per sex were maintained with the study animals to serve as sentinel animals. At termination of the 13-week studies, blood samples were obtained from the sentinel mice. Blood collected from each animal was allowed to clot, and the serum was separated. The serum was cooled on ice and shipped to Microbiological Associates, Inc. (Bethesda, MD) for determination of antibody titers. The following tests were performed:

Method of Analysis	Time of Analysis
Hemagglutination Inhibition	
PVM	Study termination
Reovirus 3	Study termination
GDVII (mouse encephalomyelitis virus)	Study termination
Polyoma virus	Study termination
Sendai	Study termination
MVM (minute virus of mice)	Study termination
Ectromelia virus (mouse pox)	Study termination
Complement Fixation	
Mouse adenoma virus	Study termination
LCM (lymphocytic choriomeningitis virus)	Study termination

ELISA

MHV (mouse hepatitis virus)

Study termination

During the 2-year studies, 15 $B6C3F_1$ mice per sex were maintained with the study animals to serve as sentinel animals. Blood was drawn from five mice of each sex at 6, 12, and 18 months following study initiation. Five randomly selected control animals of each sex were bled at study termination (24 months). Blood collected from each animal was allowed to clot, and the serum was separated. The serum was cooled on ice and shipped to Microbiological Associates, Inc. (Bethesda, MD) for determination of antibody titers. The following tests were performed:

Method of Analysis	Time of Analysis
Hemagglutination Inhibition	
PVM	6 and 12 months
Reovirus 3	6 and 12 months
GDVII	6 months
Polyoma virus	6, 12, 18, and 24 months
Sendai	6 and 12 months
MVM	6, 12, 18, and 24 months
Ectromelia virus	6 and 12 months
K (papovavirus)	24 months
Complement Fixation	

Mouse adenoma virus LCM

6 and 12 months 6, 12, 18, and 24 months

Method of Analysis (continued)	Time of Analysis			
ELISA				
PVM	18 and 24 months			
Reovirus 3	18 and 24 months			
GDVII	18 and 24 months			
MHV	6, 12, 18, and 24 months			
Mouse adenoma virus	18 and 24 months			
Ectromelia virus	18 and 24 months			
Sendai	18 and 24 months			
Mycoplasma pulmonis	6, 12, 18, and 24 months			
Mycoplasma arthritidis	18 and 24 months			
Immunofluorescence Assay				
EDIM (epizootic diarrhea of infant mice)	18 and 24 months			

TABLE K1

Murine Virus Antibody Determinations for Rats and Mice in the 13-Week and 2-Year Feed Studies of C.I. Pigment Red 3

	Interval	Incidence of Antibody in Sentinel Animals	Positive Serologic Reaction for
3-Week Studies	101	1000	
Rats	13 weeks	10/10	Sendai
